The consensus standards discussed above provide procedures and protocols to address air pollutant issues and to assure an energy-efficient and healthy IAQ environment for building occupants. It is to point out that before standardized procedures are to be developed, a good understanding about exposure and risk assessments of indoor air pollutants are needed. Nevertheless, with the advances in technology in building energy efficiency, rapid market changes of consumer products and building materials, and consumers’ demand driven by health effects, new standards will be developed to further facilitate addressing the risk of indoor air pollution from emerging contaminants and improve IAQ.

Tens of thousands of chemicals are in use daily and hundreds more are introduced into the market every year. In the USA, EPA regulates new or already existing

chemicals under the Toxic Substances Control Act (TSCA) and its amendment, the Frank R. Lautenberg Chemical Safety for the Twenty-First Century Act. Ten chemicals have undergone risk evaluation since they were identified and initiated

in December 2016. Twenty more chemicals were further identified as priority chemicals in December 2019 (Table 3) (US EPA 2020d). These chemicals are predominantly VOCs or SVOCs with different chemical-physical properties and widely used in consumer products, furniture, and building materials in the indoor environment. The risk evaluation process includes hazard and exposure assessment for risk characterization and determination of chemicals. There is an essential need to develop consensus test protocols to inform and refine estimates of indoor exposures, especially standards for characterizing indoor SVOC sources, fate and transport of emissions, and exposure to people through inhalation, ingestion, and dermal contact. The majority of the existing test standards focus on VOC emissions as opposed to SVOCs but there are few standards for indoor exposure testing and assessment for both VOCs and SVOCs. One of the reasons for the lack of SVOC protocols is that SVOC testing is very experimentally challenging due to their low volatilities. There is an increasing interest and demand for the development of consensus standards for the measurement of SVOCs, such as flame retardants, phthalates, per- and poly-fluoroalkyl substances (PFAS), and polychlorinated biphenyls (PCBs), in support of indoor exposure assessment.

Although IAQ is often assessed by standards involving chemical testing, microbial populations (molds, bacteria, and viruses) in the indoor environment can also cause serious health problems for building occupants. Moisture-related microbial contaminants of indoor air have brought lots of attention during IAQ evaluation practice. Standards for characterizing moisture-related pollutants, including microbial and chemical emissions, and for assessing microbial contaminated building environments and exposures of occupants are greatly needed (Stetzenbach et al. 2004).

Existing test standards for IAQ assessments are limited to target pollutants with specifically optimized off-line analytical procedures, which determine trace concentrations in complex environmental and biological matrices using conventional methods. There are new technical sampling and analytical methodologies that have notably progressed in recent years. The nontargeted analysis (NTA) method is a new technology that screens a large number of environmental pollutants using databases and libraries, which allows rapid characterization of many chemicals simultaneously (Sobus et al. 2018). With the increase of chemical usage in the indoor environment and demand for rapid exposure assessment, nontargeted screening of indoor environmental pollutants provides the possibility to collect analytical information efficiently. This analytical approach can be adapted to the assessment of IAQ.

Another technology that is currently evolving is real-time air sensors (Kumar et al. 2016; Zhang and Srinivasan 2020). There are many different air sensors developed in a wide variety of capacities for detecting gases and particles, such as PM2.5, carbon monoxide (CO), carbon dioxide (CO₂), and some VOCs, in the air. They can be used in indoor air monitoring and provide instantaneous measurement data for IAQ assessment and management, especially under emergency circumstances, such as indoor pollutant monitoring during wildfire events. Standards for using air sensors to detect indoor air pollutants and for evaluating the performance of

	Octamethylcyclotetra- siloxane (D4)	556-67-2

this blooming technology, especially low-cost air sensors emerging in the market, could help the IAQ community identify best practices and obtain comparable data for detecting indoor air pollutants.

Currently, as COVID-19 continues to spread across the USA and around the world, there are numerous efforts to better manage IAQ. Urgent questions remain

regarding how to prevent the spread of airborne diseases in indoor environments (Morawska et al. 2020). There is a consensus among the majority of engineers, building professionals, and researchers around the globe that changes in ventilation and filtration provided by HVAC systems can reduce the airborne concentration of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) (Schoen 2020). As such, there is a growing demand for mechanical improvements, utilizing ASHRAE Standard 62.1 and 62.2, to address the effectiveness of engineering control methods such as ventilation and air cleaning in buildings to reduce exposure risk. Surface cleaning and disinfecting, handwashing, and air cleaner usage (e.g., ultraviolet (UV) disinfection systems) are other straightforward steps that people can take to reduce the potential exposure to the virus (Raeiszadeh and Adeli 2020). Not surprisingly, widespread use of these cleaning agents and disinfection products has raised questions about generating potential air pollutants leading to a broad range of exposure scenarios that could adversely affect people's health and can sometimes be associated with respiratory symptoms, asthma, and other sick building syndrome symptoms (Atolani et al. 2020). To address these concerns, test standards for antimicrobial chemicals used in consumer products and building materials are expected to be fast developing.

Indoor air modeling for source characterization and exposure assessment is also an important tool for IAQ management. Consensus models will allow the prediction of the pollutants' concentrations and the evaluation of their behaviors in indoor settings (Eichler et al. 2020). However, the existing standards on this topic are scarce. To effectively conduct indoor air modeling, there are two components that are equally important: (i) physically based models of emissions and their dynamics based on scale and nature of chemicals indoors and (ii) the parameters used as inputs of models, which can be determined by experimental approaches or estimated by empirical methods. Standardizing these methods and protocols could benefit building communities and IAQ managers in predicting and reducing exposures.

In short, consensus IAQ standards development should consider the rapid changing market of consumer products, emerging materials, advanced analytical tools, environmental emergency, and pandemic outbreaks. With this under consideration, future standardization efforts should focus on:

- Determining SVOCs (e.g., flame retardants, phthalates, PFAS, and PCBs) sources, fate and transport in the indoor environment.
- Exposure tests for regulatory use. These standards could include test methods or guidance for indoor existing and new chemicals, including antimicrobial chemicals, emitting from materials and products, migrating to indoor exposure media, such as dust and airborne particle formation, and transferring from sources to dust, and dermal and oral exposure routes.
- New and advanced indoor air sampling and analytical methods.
- Characterizing moisture-related pollutants, including microbial and chemical emissions.
- Indoor air modeling, including indoor sources and exposures.
- ASHRAE 62.1 and 62.2 updates to highlight the control methodology of ventilation for effectively reducing the aerosol generation and infectious transmission.

Conclusions

In summary, consensus standards play an essential role in environmental risk assessment and management. The standards discussed in this chapter comprise harmonized procedures and protocols to address indoor air pollutants and IAQ issues from different perspectives. ASTM standards and other test standards, including sampling and analysis, emission and product testing, IAQ evaluation, and exposure assessment, can help to identify contaminant sources in the indoor environment and inform the need for risk evaluation and source control strategies. ASHRAE Standards 62.1 and 62.2 provide effective measures for mitigating the air pollutants in practice through ventilation. These two standards are widely used in combination by professionals, industry, public, and governmental regulators to assure that minimum ventilation rates are achieved to provide IAQ that is acceptable for building occupants in order to minimize adverse health effects. There have been years of determined efforts developing comprehensive up-to-date standards to comply with government regulations and keep up with product development and manufacturing in the twenty-first century. Future IAQ standards development should reflect the dynamic changes and needs on the market from the environmental viewpoint.

Abstract

At no time in the history over the past century have so many media and consumer concerns been centered on the health of our breathing space as we have seen in 2020 and 2021. COVID-19 has a profound effect on helping us to recognize the importance of the air we breathe. As a very effective household appliance to improve indoor air quality, air cleaners have been used a lot in recent years for cleaning indoor particulate, gaseous, and microbial pollutants. Different levels of relevant standards also got widespread attention from regulatory agencies, testing laboratories, enterprises, and consumers. However, as is known to all, international standards are more effective in gauging all the good features and serving consumers worldwide.

This chapter aims to introduce the international standards of air cleaners and the corresponding IEC (International Electrotechnical Committee) and ISO (International Organization for Standardization) development organizations,

D. Ma (✉) · S. Li

China Household Electric Appliance Research Institute (CHEARI), Beijing, China
e-mail: madj@cheari.com; liss@cheari.com

including their basic information, structure, technical committees and the way of participation. Both the two standardization organizations have technical committees responsible for standardization of air treatment appliances or equipment. In total, there are about 25 published standards and 16 standards under development for air cleaners and air cleaning equipment till the end of 2020. Furthermore, this chapter gives a detailed introduction of IEC 63086 series, especially the published IEC 63086-1: 2020 and the two underdeveloped standards on microbe reduction and fresh-air air cleaners.

In conclusion, the international standard organizations have realized the importance of air cleaner standards and their role in improving indoor air quality, and encouraged the technical committees to carry out a lot of preliminary research and standard development work, to lead the development of industries and protect people's health and lives all over the world.

Keywords

Air cleaners · International standards · IEC · ISO

Introduction

Statistics show that humans spend at least 70% of their time indoors, while the urban population spends more than 90% of their time indoors, especially infants and young children, the elderly, the weak, and the disabled (Morris 2020). However, the concentrations of indoor air pollutants are generally several times that of outdoor pollutants, and in some cases tens or even hundreds of times that of outdoor pollutants (Yinping 2013). The pollutions may come from the human body's metabolism, kitchen fume, electrical appliances, smoking, decoration, microorganisms, etc., which may cause respiratory diseases and damage the human hematopoietic system or central nervous system (Morris 2020).

In 2020, we have all felt the effects of significant interest in the health and well-being of the indoor environment. At no time in history over the last 100 years have so many media and consumer concerns been centered on the health of our breathing space as we have seen in the last year. COVID-19 has a profound effect on helping us to recognize the importance of the air we breathe. Not only that, but in many countries and regions, citizens were forced to spend long hours quarantined in their private dwellings and the role of indoor air quality became vitally important.

None of existing methods could work in all cases and certainly no invention could prevent all illness. However, there are many ways to improve indoor air quality. One of the methods is the use of electrical appliances such as an air cleaner in the residential space. Air cleaners were first introduced in the 1970s and 1980s with basic filter and fan functions to reduce allergens and other external pollutants. In the next 50 years since the widespread introduction of air cleaners, many countries have developed standards to measure the safety and performance of air cleaners with

different features including the United States, China, Japan, Korea, and so on. Several of these countries have had performance test method standards for more than 20 years. Differences in these standards revolve around the differences in pollutants, but also the technologies which have developed.

However, an international standard is more effective in gauging all the good features and serving consumers worldwide. IEC and ISO, the two international standardization organizations, both have technical committees responsible for standardization of air treatment appliances or equipment, including IEC/TC61 (Safety of household and similar electrical appliances), IEC/TC59 (Performance of household and similar electrical appliances), and ISO/TC142 (Cleaning equipment for air and other gases). Furthermore, IEC/TC59 and ISO/TC142 have established a joint work group (JWG) to develop standards concerning the performance of air treatment appliances.

IEC Standards of Air Cleaners

IEC Profile (<https://www.iec.ch/who-we-are>)

The IEC is a worldwide, not-for-profit membership standardization organization. It aims to facilitate technical innovation, affordable infrastructure development, efficient and sustainable energy access, smart urbanization and transportation systems, climate change mitigation, and increase the safety of people and the environment through its work in electrical and electronic fields.

Membership

The IEC members are composed of IEC National Committees (NC). They provide the management expertise and send experts to represent national needs in the global IEC standardization and conformity assessment arena. Upon admission, every IEC Member – one National Committee per country – promises to fully represent all private and public national interests in the field of electrotechnology at the global level in IEC standardization and conformity assessment activities.

For membership levels, IEC members are divided into Full Member and Associate Member. Any country which can demonstrate that its National Committee has been constituted in accordance with the **IEC Statutes and Rules of Procedure** may apply to become an IEC Full Member. IEC Full Members, after paying their yearly membership fee, have the possibility to send experts to participate actively in any technical committee/subcommittee according to their choice. They are also able to apply for management positions and functions in the IEC and have voting rights in the IEC Council. Some countries can opt to become an IEC Associate Member. IEC Associate Members can access all working documents and opt to send experts to participate in a limited number of technical committees/subcommittees. They cannot occupy management positions and functions within the IEC and do not have voting rights in the IEC Council.

Structure

The IEC brings together more than 170 countries and provides a global, neutral, and independent standardization platform to 20,000 experts globally. It administers four Conformity assessment systems whose members certify that devices, systems, installations, services, and people work as required.

Figure 1 shows the IEC management structure (till the end of 2020), where we can find that the Council is the supreme governing body of the IEC. Management is

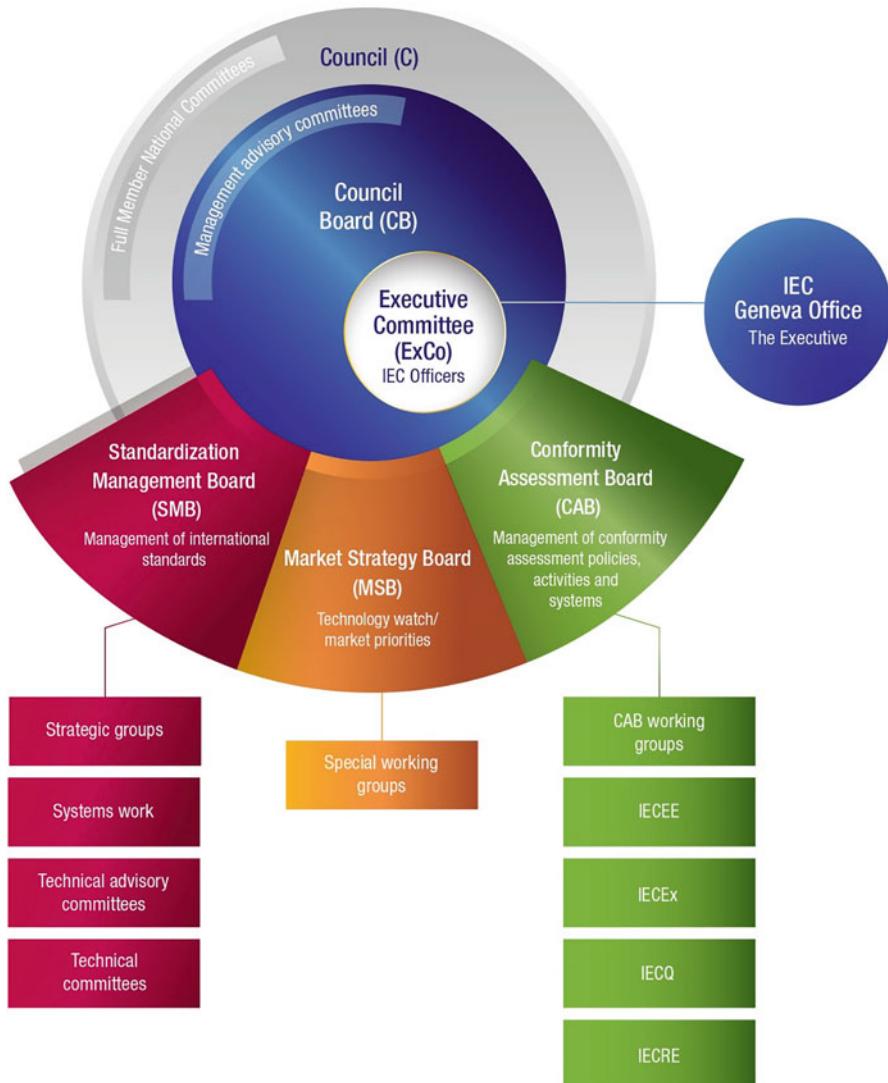

Fig. 1 IEC management structure. (Source: IEC website. <https://www.iec.ch/management-structure>)

delegated to the Council Board, the SMB (Standardization Management Board), MSB (Market Strategy Board), and CAB (Conformity Assessment Board). For the development of most standards, the direct responsible groups are Technical Committees under SMB.

Technical Committees

As an important outcome, IEC publishes International Standards, Technical Specifications, Technical Reports, Publicly Available Specifications (PAS) and Guides. Their preparation is entrusted to technical committees. Any NC interested in the subject may participate in this preparatory work. International governmental and nongovernmental organizations liaising with the IEC also participate in this preparation. IEC collaborates closely with the International Organization for Standardization (ISO) in accordance with conditions determined by agreement between the two organizations.

The IEC publishes around 10,000 IEC International Standards which together with conformity assessment provide the technical framework that allows governments to build national quality infrastructure and companies of all sizes to buy and sell consistently safe and reliable products in most countries of the world. IEC International Standards serve as the basis for risk and quality management and are used in testing and certification to verify that manufacturer promises are kept.

Thousands of experts participate in IEC standardization work in IEC technical committees and subcommittees (TC/SCs). They are chosen by their National Committee (NC) to share their technical expertise and represent the national requirements of industry, government, test and research laboratories, academia or user groups at the global level in the IEC.

The IEC offers these experts a neutral and independent platform where they can discuss and agree on state-of-the-art technical solutions with global relevance and reach. These are published as voluntary, consensus-based international standards. Each TC defines its scope and area of activity, which it submits to the IEC Standardization Management Board (SMB) for approval. A TC can form one or more SCs depending on the extent of its work program. Each SC defines its scope and reports directly to the parent TC. Till the end of December 2020, there are 109 TCs, 101 SCs, 707 WGs, 194 project teams, and 645 maintenance teams within IEC.

IEC/TC61 and IEC/TC59 are technical committees under IEC responsible for the safety and performance of household and similar electrical appliances. The standards they develop involve more than 100 household and similar electrical appliances, for example, washing machines, dishwashers, room air conditioners, range hoods, fans, air cleaners, etc. Here gives the introduction about the safety and performance standards for air cleaners and the responsible development institutions.

Participation

If you want to contribute to IEC work and are located in one of the IEC member countries, you need to reach out to your IEC National Committee (NC). They can tell you more about how you can get involved at the national level and/or the global

level in the IEC. The NC is responsible for nominating experts to participate in the development of IEC work and in the IEC Confirmation Assessment Systems.

If travelling to face-to-face working meetings is a hurdle for you, you can participate in the IEC work from the national level. Share your needs with the NC and help to make the standard more relevant for your industry.

IEC/TC 61 and Air Cleaner Safety Standards

IEC/TC 61 (https://www.iec.ch/dyn/www/f?p=103:7:0::::FSP_ORG_ID:1236)

The title of IEC/TC 61 is safety of household and similar electrical appliances. It is responsible for preparing safety requirements for electrical appliances primarily for household purposes, but also for other equipment and appliances in similar fields where there is no IEC Technical Committee in existence. The Secretariat is the United States of America.

For working structure, there are 5 SCs, 9 working groups, 3 project teams, 10 maintenance teams, 1 joint working group, 1 advisory group, and 1 editing group under TC61.

Till the end of 2020, IEC/TC61 and its subcommittees have developed 103 safety standards, among which 101 are IEC 60335 series standards.

IEC 60335 series deal with safety of household and similar electrical appliances, including 1 Part 1 standard of general requirements and more than 100 Part 2 standards of particular requirements for different kinds of household appliances. Every Part 2 standard shall be used in conjunction with IEC 60335-1. With the aim of protecting the personal and property safety of consumers, the IEC 60335 series put forward safety requirements and testing methods for household and similar electrical appliances mainly in terms of anti-shock, anti-fire, anti-scald, anti-mechanical, anti-radiation, and anti-toxicity hazard.

IEC 60335-2-65

IEC 60335-2-65, Household and similar electrical appliances – Safety – Part 2-65: Particular requirements for air-cleaning appliances is a Part 2 particular requirement standard for air cleaners. IEC 60335-2-65 has experienced two whole number editions, three amendments, and one corrigendum, and its current edition is IEC 60335-2-65:2015 (Ed2.2), see Table 1 for its evolution. IEC 60335-2-65 consists of 32 Clauses and several Annexes covering Classification; Marking and instructions; Protection against access to live parts; Starting of motor-operated appliances; Power input and current; Heating; Leakage current and electric strength at operating temperature; Transient overvoltages; Moisture resistance; Leakage current and electric strength; Overload protection of transformers and associated circuits; Endurance; Abnormal operation; Stability and mechanical hazards; Mechanical strength; Construction; Internal wiring; Components; Supply connection and external flexible cords; Terminals for external conductors; Provision for earthing; Screws and connections; Clearances, creepage distances, and solid

Table 1 Different editions of IEC 60335-2-65

No.	Editions	Title
Ed 1.0	IEC 60335-2-65: 1993	Household and similar electrical appliances – Safety – Part 2-65: Particular requirements for air-cleaning appliances
Amendment 1	IEC 60335-2-65: 1993/AMD1:2000	
Ed 2.0	IEC 60335-2-65: 2002	
Corrigendum 1	IEC 60335-2-65: 2002/COR1:2004	
Amendment 1	IEC 60335-2-65: 2002/AMD1:2008	
Amendment 2	IEC 60335-2-65: 2002/AMD2:2015	

insulation; Resistance to heat and fire; Resistance to rusting; Radiation, toxicity, and similar hazards; etc.

You can find the detailed information of this standard at IEC website <https://webstore.iec.ch/publication/1695>.

IEC/TC 59 and Air Cleaner Performance Standards

IEC/TC 59 (https://www.iec.ch/dyn/www/f?p=103:14:13818013144838:::FSP_ORG_ID,FSP_LANG_ID:19691,25)

The title of IEC/TC 59 is performance of household and similar electrical appliances. It is responsible for preparing International Standards on methods of measurement of characteristics which are of importance to determine the performance of electrical appliances for household use or of electrical appliances for commercial use and that are of interest for the user. This may include associated aspects related to the use of the appliances and aspects such as the classification, accessibility, and usability of appliances, ergonomic characteristics, and conditions for the information provided at the point of sale. The Secretariat is Germany.

For working structure, there are 7 SCs, 5 working groups, 1 project team, 1 maintenance team, 1 joint working group, 1 advisory group, 1 ad hoc group, and 1 editing group under TC 59.

Till the end of 2020, IEC/TC 59 have developed 79 performance standards.

IEC 63086 Series

IEC 63086 series standards, Household and similar electrical air cleaning appliances – Methods for measuring the performance, have a much shorter history. They are the first performance standards for air cleaners proposed by China in 2016 to develop a single performance standard and then derived into a series standard due to a strong desire of participating members to deal with different

types of pollutants. The first edition, IEC 63086-1:2020, was published on April 9, 2020.

Background

As is known to all, indoor air quality is a huge issue in many countries. With the increase of natural and man-made pollution items at home, many people, especially for vulnerable groups like children and elderly people, are experiencing health-related issues from poor indoor air quality. In many cases, consumers are now choosing to use air cleaners as the method to reduce pollutants in their own homes and apartments. This has given rise to a huge increase in these appliances and to the numbers of manufacturers worldwide. Along with this huge increase in products, also comes an increase in the claims of reduction of pollutants without a unified means of performing testing and certification. In several countries, national standards have been developed. These include standards in the United States, China, Japan, and Korea, to name a few. All of these standards share many features in testing, but there is no one international standard to gauge the performance. China has also encountered similar pollution problems in its development process and saw this need to solve the global problem. Chinese National Committee proposed to IEC/TC 59 in May 2016 to develop a performance standard for air cleaners based on its national standard GB/T 18801 Air cleaners.

Summary of Development Process or Plans

The Chinese proposal was approved by IEC/TC59 and a project team PT 63086 was formed in September 2016 with Mr. Dejun Ma from China as convenor and six original registered member experts from the Netherlands, Korea, Germany, Italy, and the UK. PT 63086 immediately launched its work through regular web meetings and face-to-face meetings in Washington, DC, Venice, Busan, Aix-en-Provence, etc. They carried out in-depth review of the scientific literature on indoor air quality, technologies on pollutant reduction and relative test methods, prepared its own draft, and organized round robin tests. Many countries showed interest and applied to join in the standardization work during its progress. Till the end of 2020, more than 80 experts from at least 11 member countries are involved, including scientists, university professors, testing lab specialists, and manufacturers. The countries include China, the United States, Germany, France, Italy, Japan, Korea, Belgium, the UK, the Netherlands, and Sweden.

Performance of air cleaners is a very complex subject. It involves testing different types of pollutants, testing chambers, energy efficiency, advanced electronic controls, remote communication through public networks, along with several types of air delivery. In 2018, PT 63086 made an important decision to develop a series standard, including one Part 1 standard with general requirements and multiple Part 2 standards for different pollutant reduction and characteristics for testing, which was then approved by IEC/TC59 in October 2018, and this PT was upgraded to a working group (WG 17). WG 17 firstly focused on Part 1 standard IEC 63086-1 and would proceed to Part 2 standards step-by-step.

Table 2 Stages of developing IEC 63086-1:2020

	Stage	Decision date
1	NP – New Proposal	May 2016
2	CD – Committee Draft	June 2018
3	CDV – Committee Draft for Voting	March 2019
4	FDIS – Final Draft of International Standard	February 2020
5	IS – International Standard	April 2020

For IEC 63086-1:2020, before its final publication early this year, WG 17 had experienced many WG meetings and several tough official stages for comments or voting from all IEC/TC59 member countries, see Table 2.

For Part-2 standards, WG 17 has mapped out a detailed plan and formed 12 sub-working groups to develop Technical Reports or Part 2 standards:

- SWG 1 – Develop a Part 2 Standard for Reduction of Particles
- SWG 2 – Develop a Part 2 Standard for Reduction of Chemical Gases
- SWG 3 – Develop a Part 2 Standard for Reduction of Microbes
- SWG 4 – Develop a Technical Report on Air Cleaners with Automatic Mode
- SWG 5 – Develop a Technical Report on Air Cleaners for Measurement of Power and Energy
- SWG 6 – Develop a Part 2 Standard for Fresh-Air, Air Cleaners
- SWG 7 – Develop a Part 2 Standard for Automobile Passenger Air Cleaners
- SWG 8 – Manage Round Robin Testing
- SWG 9 – Develop a Technical Report on Mobile/Robotic Air Cleaners
- SWG 10 – Develop a Part 2 Standard for Measuring Performance Over Time
- SWG 11 – Working with IEC TC 59 WG 2, Develop test method for measurement of Acoustical Noise
- SWG 12 – Develop a Part 2 Standard for Reduction of Ozone

Not all SWGs are active at the moment. Till December of 2020, there are three standards under development by SWG1, SWG6, and SWG11, and some others are still under preparation (Ma et al. 2020).

- IEC 63086-2-1 ED1 (NP)
Household and similar electrical air cleaning appliances – Methods for measuring the performance – Part 2-1: Particular requirements for determination of reduction of particles
- IEC 63086-2-6 ED1(NP)
Household and similar electrical air cleaning appliances – Methods for measuring the performance – Part 2-6: Particular requirements for fresh-air air cleaners
- IEC 60704-2-19 ED1(NP) (SWG11 experts join TC59/WG2 for development of this standard)

Household and similar electrical appliances – Test code for the determination of airborne acoustical noise – Part 2-19: Particular requirements for air cleaners

Joint Work Together with ISO/TC 142

WG 17 became aware of the work of ISO TC 142 in 2017. Much of the work of ISO/TC 142 has been on filters, pollutants, and special media. One of its working groups (WG 11) was interested in writing a test method for air cleaners and has long been preparing. After communication between ISO/TC142 and IEC/TC59, WG 17 was renamed JWG 17 in October 2019 as a joint working group of IEC/TC 59 and ISO/TC 142. Mr. Dejun Ma from IEC side and Mr. Tim Johnson from ISO side act as co-convenors (Ma et al. 2020).

Projects under the responsibility of JWG 17 will be developed as dual logo.

Information of IEC 63086-1:2020

IEC 63086-1:2020, Household and similar electrical air cleaning appliances – Methods for measuring the performance – Part 1: General requirements, consists of eight clauses and three annexes, see Table 3, specifying the terms and definitions, classification, test conditions, test chamber conditions, instrumentation and equipment, determination of the air exchange rate of test chamber, noise, energy efficiency, etc.

You can find the detailed information of this standard at IEC website <https://webstore.iec.ch/publication/33044>.

Work Plan and Progress of SWGs on Microbe Reduction and Fresh-Air Air Cleaners

SWG 3 on Microbe Reduction

SWG 3 started work from November 2020. It aims to develop a Part 2 standard of IEC 63086 series on determination of reduction of microbes.

Table 3 The structure of IEC 63086-1

Clauses and annexes	Title
Clause 1	Scope
Clause 2	Normative references
Clause 3	Terms and definitions
Clause 4	Classification
Clause 5	Conditions, instrumentation, and equipment for measurement
Clause 6	Determination of the air exchange rate of the test chamber
Clause 7	Measurement of noise
Clause 8	Energy efficiency
Annex A	Determination of the test chamber mixing level
Annex B	Standardization of calculation
Annex C	Test stand for wall and direct plug-in type air cleaners

During preliminary research, the group leader Ms. Xiao Zhang and her team investigated related standards and literatures from all countries and organizations, especially the literatures on the pathogen analysis of respiratory diseases in hospitals, and screened out the bacteria and molds closely related to respiratory diseases, like *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Escherichia coli*, *Klebsiella pneumonia*, MS2, and *Aspergillus fumigatus*. Although viruses are also the main cause of respiratory diseases, considering the strict restriction on laboratory biosafety levels and the difficulty of virus test operation, bacteriophages are often used in many medical device standards instead of animal viruses. Most air cleaners rely on filtration technology for microbial removal, the effect of which is closely related to the size of the microorganism, so although the pathogenicity of different kinds of microorganisms vary greatly, their size difference is not so much and thus there is no big difference of the microbe removal result of air cleaners. Therefore, considering the test cost and restrictions, it is not recommended to choose too many kinds of microorganisms for the test, but to select the typical types, such as MS2 and phi X 174 for virus. Test bacteria and molds can also be treated the same way.

Since Chinese and Japanese national standards GB 21551.3 and JEM 1467, as well as international standard ISO 16000-36 have developed test methods to remove microbes such as *Staphylococcus albus*, *Micrococcus luteus*, Phi-X174/MS2, and H1N1/H3N2, SWG3 will make full reference to the existing standards and achieve one common-consensus international standard.

According to the workplan of SWG 3, the Part 2 standard will be progressed according to the workplan listed in Table 4.

SWG 6 on Fresh-Air Air Cleaners

SWG 6 started work from April 2019. It aims to develop a Part 2 standard for fresh-air air cleaners.

In the last 10 years, air cleaners have become popular worldwide due to people's pursuit of a healthy life and the increasing air pollution problems, but longtime operation of air cleaners may result in lack of oxygen and increase of carbon dioxide in a confined space, which will affect the health and comfort of indoor users. In response to this, fresh-air air cleaners appeared and are accepted in the market. They help to remove indoor particles, VOCs, disinfect and introduce the outdoor fresh air, preventing indoor and outdoor particle pollution. They are very useful household fresh-air products.

Table 4 Workplan of SWG 3 for a Part 2 standard of IEC 63086 series

	Stage	Decision date
1	NP – New Proposal	April 2021
2	CD – Committee Draft	December 2022
3	CDV – Committee Draft for Voting	June 2023
4	FDIS – Final Draft of International Standard	December 2023
5	IS – International Standard	March 2024

From the market perspective, taking China as an example, in 2018, the sales volume of fresh-air air cleaners was 1.06 million units, a year-on-year increase of 39%, with sales of 10.2 billion yuan, a year-on-year increase of 27%. While compared to the 44.5% increase in 2017, the speed has slowed significantly (https://mp.weixin.qq.com/s/TzFpGgZRz1_PutMDVq_KA). In 2019, the sales volume of the fresh-air air cleaner industry exceeded 1.46 million units, a year-on-year increase of 39%, and sales reached 13.9 billion yuan annually (<https://mp.weixin.qq.com/s/kN3Q39I6Dxq66Yqmbiw0Bg>).

Due to a different construction, the test methods are totally different between fresh-air air cleaners and room air cleaners. For example, test chamber for fresh-air air cleaners may operate at a pressure slightly above ambient. From installation perspective, this product is intended to be installed by a professional individual or company, which may enhance the ventilation and air cleaning of the HVAC system, and it is intended to be installed in the residential dwelling, which can be used to treat the indoor environment of multiple rooms.

The NP document was put forward in June 2019 and got approved as IEC 63086-2-6 Household and similar electrical air cleaning appliances – Methods for measuring the performance – Part 2-6: Particular requirements for fresh-air air cleaners, in August the same year by IEC/TC 59.

This standard aims to include methods to measure the performance of a fresh-air air cleaner to improve the indoor environment, and is applicable to those appliances which are connected to the external environment, which provides pollutant reduced outdoor air into an indoor space but are not connected to the HVAC system of the dwelling or building. It intends to specify release of harmful substances, standby power, air volume and outlet full pressure, fresh air cleaning efficiency, clean fresh air volume, internal circulation clean air volume, air cleaning efficiency, fresh cumulate clean mass, air exchange efficiency, etc.

It is estimated that this standard will be published in December 2024.

ISO Standards of Air Cleaners

ISO Profile (<https://www.iso.org/about-us.html>)

ISO is an independent, nongovernmental membership international standardization organization. It brings together experts to share knowledge and develop voluntary, consensus-based, market relevant International Standards that support innovation and provide solutions to global challenges, covering almost all aspects of technology and manufacturing except electric and electronic aspects.

Membership

ISO is a global network of national standards bodies. Its members are the foremost standards organizations in their countries and there is only one member per country. Each member represents ISO in its country.

There are three-member categories including full members, corresponding members, and subscriber members. Each enjoys a different level of access and influence over the ISO system. This helps ISO to be inclusive while also recognizing the different needs and capacity of each national standards body.

Full members (or member bodies) influence ISO standards development and strategy by participating and voting in ISO technical and policy meetings. Full members sell and adopt ISO International Standards nationally. Correspondent members observe the development of ISO standards and strategy by attending ISO technical and policy meetings as observers. Correspondent members that are national entities sell and adopt ISO International Standards nationally. Correspondent members in the territories that are not national entities sell ISO International Standards within their territory. Subscriber members keep up to date on ISO's work but cannot participate in it. They do not sell or adopt ISO International Standards nationally.

Structure

ISO is an independent, nongovernmental organization made up of members from the national standards bodies of 165 countries.

Figure 2 shows the ISO governance structure, where we can find that the General Assembly is the overarching organ and ultimate authority of the organization. The ISO Council is the core governance body of the organization and reports to the General Assembly. The Council has direct responsibility over a number of bodies reporting to Council including President's Committee, Council Standing Committees, Advisory groups, and Policy development committees. The management of the technical work is taken care of by the Technical Management Board, which reports to Council. This body is also responsible for the technical committees that lead standards development and any strategic advisory boards created on technical matters.

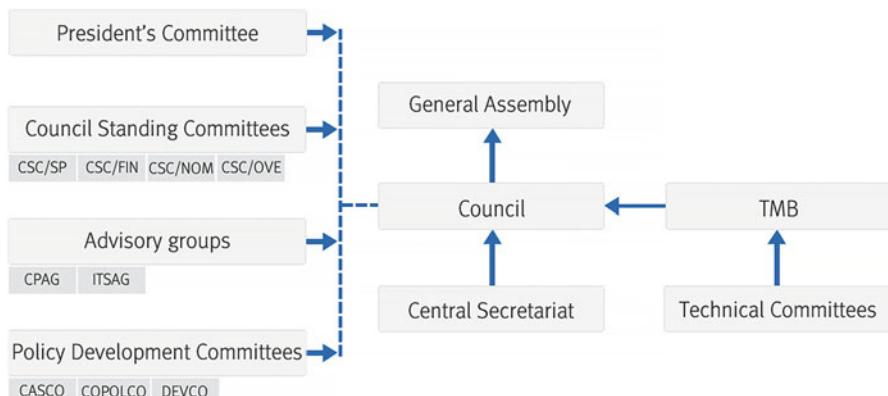

Fig. 2 ISO governance structure. (Source: <https://www.iso.org/structure.html>)

Technical Committees

Till the end of 2020, there are 254 technical committees and 539 subcommittees under ISO to take care of standards development covering food and agriculture, chemicals, building and construction, business management and innovation, energy, sustainability and environment, health, medicine and laboratory equipment, nonmetallic materials, information technology, services, and so on. The first technical committee, TC1, deals with screw threads and was created back in 1947. ISO has developed 23626 international standards covering almost all aspects of technology and manufacturing.

Participation

Individuals or companies cannot become ISO members, but there are ways that you can take part in standardization work. Please see the list below for information about the ISO member in your country.

ISO/TC 142 (<https://www.iso.org/committee/52624.html>)

The title of ISO/TC142 is Cleaning equipment for air and other gases. It is responsible for standardization in the fields of terminology, classification, characteristics, and test and performance methods for **air and gas cleaning and disinfecting equipment** for general ventilation and industrial applications with the following exclusion:

- Exhaust gas cleaners for gas turbines and IC engines in mobile equipment, this being within the scope of other ISO technical committees.
- Filters for personal protection equipment which are the field of work of technical committee ISO/TC 94.
- Cabin filters in mobile equipment covered by ISO/TC 22, 23, and 127.

Its secretariat is UNI (Ente Italiano di Normazione) with the current Chair Mr. Riccardo Romanò and Committee manager Mrs. Anna Martino. There are 12 working groups under ISO/TC142 with the following specific and detailed responsibilities, see Table 5, where **ISO/TC 142/JWG 11** is the joint working group with IEC/TC 59.

Standards of ISO/TC 142 (<https://www.iso.org/committee/52624.html>)

There are in total 22 published standards and 16 standards under development till December 2020 under the direct responsibility of ISO/TC 142, see Tables 6 and 7.

Table 5 Twelve WGs under ISO/TC142

WGs	Title
ISO/TC 142/WG 1	Terminology
ISO/TC 142/WG 2	UV-C technology
ISO/TC 142/WG 3	General ventilation filters
ISO/TC 142/WG 4	HEPA and ULPA filters
ISO/TC 142/WG 5	Dust collectors, droplet separators, and purifiers
ISO/TC 142/WG 7	Cleanable filter media used in industrial applications
ISO/TC 142/WG 8	Gas-phase air cleaning devices
ISO/TC 142/WG 9	Particulate air filter intake systems for rotary machinery and stationary internal combustion engines
ISO/TC 142/JWG 10	Joint ISO/TC 142 – ISO/TC 85/SC 2 WG: Aerosol filters for nuclear applications
ISO/TC 142/JWG 11	Joint ISO/TC 142 – IEC/TC 59 WG: Portable room air cleaners for comfort applications
ISO/TC 142/WG 12	Sustainability of air cleaning equipment and media
ISO/TC 142/WG 13	Biological equipment for waste gas treatment

Conclusion

In the internationalization practice, international standards have received more and more attention from countries all over the world as they are playing an increasingly important role in the world's economic and social development. The implementation of international standards is conducive to eliminating technical barriers in international trade, facilitating technological progress, improving product quality and efficiency, and promoting international economic and technological exchanges and cooperation.

As introduced in the above contents, for air cleaners, existing international standards have covered safety, performance, and parameters of key components, air filters, and formed a relatively complete international standard system. As many test reports and research show, air cleaners in accordance with these international standards can significantly improve indoor air quality through filtration and retention, activated carbon adsorption, ultraviolet sterilization, lysozyme and chemical fungicides, ozone, and other biological aerosol removal methods in accordance. Furthermore, it is reported that due to the impact of this epidemic and people's growing awareness of health, the standards related to microbe removal, especially virus removal, will be developed or reviewed to better solve the problems of particulate matter, gaseous and microbial pollutants in the indoor air.

Table 6 Twenty-two published standards under ISO/TC142

No.	Standard number	Title
1	ISO 10121-1: 2014	Test method for assessing the performance of gas-phase air cleaning media and devices for general ventilation – Part 1: Gas-phase air cleaning media
2	ISO 10121-2: 2013	Test methods for assessing the performance of gas-phase air cleaning media and devices for general ventilation – Part 2: Gas-phase air cleaning devices (GPACD)
3	ISO 15714: 2019	Method of evaluating the UV dose to airborne microorganisms transiting in-duct ultraviolet germicidal irradiation devices
4	ISO 15727: 2020	UV-C devices – Measurement of the output of a UV-C lamp
5	ISO 15858: 2016	UV-C Devices – Safety information – Permissible human exposure
6	ISO 15957: 2015	Test dusts for evaluating air cleaning equipment
7	ISO 16170: 2016	In situ test methods for high-efficiency filter systems in industrial facilities
8	ISO 16890-1: 2016	Air filters for general ventilation – Part 1: Technical specifications, requirements, and classification system based upon particulate matter efficiency (ePM)
9	ISO 16890-2: 2016	Air filters for general ventilation – Part 2: Measurement of fractional efficiency and air flow resistance
10	ISO 16890-3: 2016	Air filters for general ventilation – Part 3: Determination of the gravimetric efficiency and the air flow resistance versus the mass of test dust captured
11	ISO 16890-4: 2016	Air filters for general ventilation – Part 4: Conditioning method to determine the minimum fractional test efficiency
12	ISO 16891: 2016	Test methods for evaluating degradation of characteristics of cleanable filter media
13	ISO 21083-1: 2018	Test method to measure the efficiency of air filtration media against spherical nanomaterials – Part 1: Size range from 20 nm to 500 nm
14	ISO/TS 21083-2:2019	Test method to measure the efficiency of air filtration media against spherical nanomaterials – Part 2: Size range from 3 nm to 30 nm
15	ISO 29461-1: 2013	Air intake filter systems for rotary machinery – Test methods – Part 1: Static filter elements
16	ISO 29462: 2013	Field testing of general ventilation filtration devices and systems for in situ removal efficiency by particle size and resistance to airflow
17	ISO 29463-1: 2017	High-efficiency filters and filter media for removing particles from air – Part 1: Classification, performance, testing, and marking
18	ISO 29463-2: 2011	High-efficiency filters and filter media for removing particles in air – Part 2: Aerosol production, measuring equipment and particle-counting statistics
19	ISO 29463-3: 2011	High-efficiency filters and filter media for removing particles in air – Part 3: Testing flat sheet filter media
20	ISO 29463-4: 2011	High-efficiency filters and filter media for removing particles in air – Part 4: Test method for determining leakage of filter elements – Scan method

Abstract

Green and healthy buildings are currently an important goal for the construction industry. To achieve this goal, developing and implementing green building labeling systems and healthy building labeling systems is important. At present, many countries and regions have developed individual green building labeling systems and healthy building labeling systems. Leadership in Energy and Environmental Design (LEED), Building Research Establishment Environmental Assessment Methodology (BREEAM), and China Assessment Standard for Green Building (CASGB) are representative green building labeling systems. The China Assessment Standard for Healthy Building (CASHB) and the International WELL Building Institute building standard (WELL) are representative healthy building labeling systems. In these standards, the assessment of IAQ is crucial. This chapter details: (1) systematic description of the IAQ-related provisions in each system; (2) systematic analysis according to the perspective of engineering and materials control; (3) deficiencies in current IAQ management; and (4) main tasks for the future.

Keywords

CASGB · LEED · BREEAM · CASHB · WELL

Introduction

With the promotion of sustainable development goals, green and healthy procedures in the construction industry are vital. In the construction industry, green building labeling systems and healthy building labeling systems have provided direction for improved construction practices and building performance.

Many countries have developed green building labeling systems. These include Leadership in Energy and Environmental Design (LEED) from the USA, Building Research Establishment Environmental Assessment Methodology (BREEAM) from the UK, Comprehensive Assessment System for Built Environment Efficiency (CASBEE) from Japan, Deutsche Gesellschaft für Nachhaltiges Bauen (DGNB) from Germany, Haute Qualité Environnementale (HQE) from France, GBTool from Canada, and China Assessment Standard for Green Building (CASGB). The healthy building labeling systems include the International WELL Building Institute building standard (WELL) and China Assessment Standard for Healthy Building (CASHB). In this chapter, CASGB, LEED, and BREAM are introduced in detail as representative green building labeling systems and CASHB and WELL are introduced as representative healthy building labeling systems.

Green and Health Building Labeling Systems

China Assessment Standard for Green Building (CASGB)

CASGB is a Chinese national standard by which the green performance of civil buildings can be evaluated. It was first published in 2006 and was updated in 2015 and 2019 (SAMR 2019). It defines a green building as one which has high-quality performance in saving energy, reducing pollution, and consequently protecting the environment. A CASGB building provides people with healthy, flexible use, and efficient spaces and maximizes harmonious coexistence between humans and nature. There are six main aspects evaluated in the CASGB system: Safety and Durability; Health and Comfort; Occupant Convenience; Resources Saving; Environment Livability; and Promotion and Innovation. The indoor air quality requirements are defined in the Health and Comfort section (SAMR 2019).

LEED

LEED is a rating scheme developed by The US Green Building Council (USGBC) for the design, construction, and operation of high-performance green buildings. LEED has evaluation guides for different building types and different building phases, including new construction, interior fit outs, operations and maintenance, and core and shell. It was first developed as LEED v1.0 in 1998 and began its pilot program testing. Following the success of the pilot program, LEED formally launched LEED v2.0 in 2001 and then updated to LEED v2019, v4.0, and v4.1 in 2009, 2015, and 2019 separately. In this chapter, LEED v4.1 BUILDING DESIGN AND CONSTRUCTION is considered and cited (USGBC 2021). The rating system has 7 categories of requirements: Integrative Process (IP), Location and Transportation (LT), Sustainable Sites (SS), Water Efficiency (WE), Energy and Atmosphere (EA), Materials and Resources (MR), and Indoor Environmental Quality (EQ). The EQ section gives the indoor air quality environment index limitations and control requirements.

BREEAM

BREEAM is a rating system with a series of measures and associated criteria related to environmental issues, which functions as an evaluating tool to help buildings perform in a more energy-efficient and environmental-friendly way. Developed by the British Building Research Establishment (BRE), the first BREEAM scheme is launched in 1990, being one of the earliest green building-rating system in the world. It considers the sustainability in building design, construction, and use in the UK (BRE 2016). BREEAM International New Construction 2016 is discussed here. It consists of 11 sections (Management, Health and Well-Being, Hazards, Energy, Transport, Water, Materials, Waste, Land Use and Ecology, Pollution, and Innovation). Specifically, issues related to indoor air quality are addressed in the Health and Well-Being section.

China Assessment Standard for Healthy Building (CASHB)

CASHB is a social organization standard widely used in China, first published in 2016 and updated in 2021. It evaluates fully furnished and decorated buildings. CASHB is divided into pre-evaluation and operation evaluation. Pre-evaluation is carried out after the construction drawing design documents of the construction project are reviewed and approved. Operational evaluation is performed after the construction project is completed and the building is put into operation. The various building performances are quantified by evaluating a range of criteria from six perspectives, including air, water, comfort, exercise, humanity, service, and promotion and innovation (ASC 2017). Indoor air quality requirements are described in three sections (Air, Service, and Promotion and Innovation).

WELL

The WELL Building Standard is another widely used assessment system. Developed by International WELL Building Institute (IWBI), the WELL Building Standard® Version 1 (WELL v1) was launched on 2014 for the Commercial and Institutional Office building sector. The version introduced here is WELL v2 (launched in 2018) that covers all project types and sectors (IWBI 2020). To ensure the health performance of an evaluated building, WELL v2 lists both precondition requirements and optimization features for ten elements: air, water, nourishment, light, movement, thermal comfort, sound, materials, mind, and community. The indoor air quality requirements are described in the Air section. Various strategies such as source control, design and operation strategies, and human behavior interventions are presented here.

Environmental Index

Environmental Index in CASGB

The indoor air quality index in CASGB consists of mandatory prerequisites and optimization evaluation.

Mandatory Prerequisites The indoor concentration of formaldehyde, benzene, and total volatile organic compounds must meet the requirement of current national “indoor air quality standard” (GB/T 18883) (SAMR 2002). A list of the VOCs and their limit values is given in Table 1.

Optimization Evaluation

- Indoor concentrations of ammonia, formaldehyde, benzene, TVOC, and radon 10% lower than the limit value of current national standard “indoor air quality standard” (GB/T 18883), 3 points; 20% lower than the limit value, 6 points.

Table 1 Environmental requirements in GB/T 18883

Contaminant	Concentration limitation	Comments
Formaldehyde (HCHO)	$\leq 0.10 \text{ mg/m}^3$	1 h average
Benzene (C ₆ H ₆)	$\leq 0.11 \text{ mg/m}^3$	1 h average
Total volatile organic compounds (TVOC)	$\leq 0.6 \text{ mg/m}^3$	8 h average
Ammonia (NH ₃)	$\leq 0.2 \text{ mg/m}^3$	1 h average
Radon ²²² Rn	$\leq 400 \text{ Bq/m}^3$	Annual average (reference level)

Annual average concentration of PM_{2.5} does not exceed 25 $\mu\text{g}/\text{m}^3$; annual average PM₁₀ concentration does not exceed 50 $\mu\text{g}/\text{m}^3$, 6 points.

Environmental Index in LEED

The specific requirements of LEED indoor air quality for particulate matter, inorganic gases, and volatile organic compounds are listed in Table 2.

Environmental Index in BREEAM

The BREEAM requirements for indoor air quality are shown in Table 3. These include limits for formaldehyde and TVOC. They also set limits for CO₂, VOCs, PM₁₀, SO₂, NO₂, and O₃. Also, they ensure that room-conditioning systems have adequate ventilation, according to EN 13779:2007 (EN 2007).

Environmental Index in CASHB

The CASHB system standard requires that indoor air quality meet the current Chinese national “indoor air quality standard” (GB/T 18883). Although the CASHB and CASGB use the same standard (GB/T 18883), there are a few differences in these two systems because of the different objectives and edit time. The requirements with respect to indoor air quality are shown in Table 4.

Environmental Index in WELL

The WELL requirements for indoor air quality are listed in Table 5. They include standards for PM, VOCs, and inorganic gases.

Tables 1, 2, 3, 4 and 5 show that the target contaminants and concentration limits under different labeling system guidelines. Moreover, the test methods for contaminants differ based on various nations’ local standards, so the limit values are very

Table 2 Environmental requirements in LEED

Contaminant	Concentration limitation	Allowed test methods
Carbon monoxide (CO)	9 ppm; no more than 2 ppm above outdoor levels	ISO 4224 (ISO 2000a) EPA Compendium Method IP-3 (EPA 1999a) GB/T 18883-2002 for projects in China (SAMR 2002) Direct calibrated electrochemical instrument with accuracy of $\pm 3\%$ of reading and resolution of 0.1 ppm NDIR CO sensors with accuracy of 1% of 10 ppm full scale and display resolution of less than 0.1 ppm
PM ₁₀	ISO 14644-1:2015 (ISO 2015), cleanroom class of 8 or lower: 50 $\mu\text{g}/\text{m}^3$ Healthcare only: 20 $\mu\text{g}/\text{m}^3$	Particulate monitoring device with accuracy greater of 5 $\mu\text{g}/\text{m}^3$ or 20% of reading and resolution (5 min average data) $\pm 5 \mu\text{g}/\text{m}^3$
PM _{2.5}	12 $\mu\text{g}/\text{m}^3$ or 35 $\mu\text{g}/\text{m}^3$ (projects in areas with high ambient levels of PM _{2.5} (known EPA nonattainment areas for PM _{2.5} , or local equivalent) must meet the 35 $\mu\text{g}/\text{m}^3$ limit; all other projects should meet the 12 $\mu\text{g}/\text{m}^3$ limitation)	
Ozone	0.07 ppm	Monitoring device with accuracy greater of 5 ppb or 20% of reading and resolution (5 min average data) $\pm 5 \text{ ppb}$ ISO 13964 (ISO 1998) ASTM D5149-02 (ASTM 2016a) EPA designated methods for Ozone (EPA 2021)
Formaldehyde 50-00-0	20 $\mu\text{g}/\text{m}^3$ (16 ppb)	ISO 16000-3, 4 (ISO 2011, ISO 2004a);
Acetaldehyde 75-07-0	140 $\mu\text{g}/\text{m}^3$	EPA TO-11a (EPA 1999b), EPA comp. IP-6A (EPA 1990) ASTM D5197-16 (ASTM 2016b)
Benzene 71-43-2	3 $\mu\text{g}/\text{m}^3$	ISO 16000-6 (ISO 2004b);
Hexane (n-) 110-54-3	7000 $\mu\text{g}/\text{m}^3$	EPA IP-1 (EPA 1990);
Naphthalene 91-20-3	9 $\mu\text{g}/\text{m}^3$	EPA TO-17 (EPA 1999c);
Phenol 108-95-2	200 $\mu\text{g}/\text{m}^3$	EPA TO-15 (EPA 2002);
Styrene 100-42-5	900 $\mu\text{g}/\text{m}^3$	ISO 16017-1, 2 (ISO 2000b, ISO 2003);
Tetrachloroethylene 127-18-4	35 $\mu\text{g}/\text{m}^3$	ASTM D6196-15 (ASTM 2015)
Toluene 108-88-3	300 $\mu\text{g}/\text{m}^3$	
Vinyl acetate 108-05-4	200 $\mu\text{g}/\text{m}^3$	

(continued)

Table 2 (continued)

Contaminant	Concentration limitation	Allowed test methods
Dichlorobenzene (1,4-) 106-46-7	800 µg/m ³	
Xylenes-total 108-38-3, 95-47-6, and 106-42-3	700 µg/m ³	

Table 3 Environmental requirements in BREEAM

Contaminant	Concentration limitation	Comments
Formaldehyde (30 minutes)	100 µg/m ³ , be measured postconstruction (but preoccupancy)	
TVOC (8 h)	300 µg/m ³ , be measured postconstruction (but preoccupancy)	
Sulfur dioxide SO ₂ (24 h)	125 µg/m ³	WHO (1999)
Sulfur dioxide SO ₂ (1 year)	50 µg/m ³	WHO (1999)
Ozone O ₃ (8h)	120 µg/m ³	WHO (1999)
Nitrogen dioxide NO ₂ (1 year)	40 µg/m ³	WHO (1999)
Nitrogen dioxide NO ₂ (1 h)	200 µg/m ³	WHO (1999)
Particulate matter PM ₁₀ (24 h)	50 µg/m ³ Max. 35 days exceeding	99/30/EC
Particulate matter PM10 (1 year)	40 µg/m ³	99/30/EC

different. We note that some contaminant limitation values are set for “health” but others for commercially advantageous objectives that lack scientific evidence.

Formaldehyde, VOC, and SVOC Control in Labeling Systems

There are two ways to control indoor volatile chemical pollutants. The Prescriptive Index Method addresses the composition of materials and furniture. This method is often used in product manufacture and covers both emission parameters and content parameters. The second method is the Performance Index Method, which addresses how materials and furnishings will meet environmental requirements in a given building environment. The performance limits are based on emission parameters.

Table 4 Environmental requirements in CASHB

Contaminant	Concentration limitation	Comments
Carbon dioxide (CO ₂)	≤ 0.09% (optimization)	24 h average
Formaldehyde (HCHO)	≤ 0.01 mg/m ³ (precondition)	1 h average
	≤ 70% of limit value (innovation)	
Benzene (C ₆ H ₆)	≤ 0.11 mg/m ³ (precondition)	1 h average
	≤ 90% of limit value (innovation)	
Toluene (C ₇ H ₈)	≤ 0.2 mg/m ³ (precondition)	1 h average
Xylene (C ₈ H ₁₀)	≤ 0.2 mg/m ³ (precondition)	1 h average
	≤ 70% of limit value (innovation)	
TVOC	≤ 0.6 mg/m ³ (precondition)	8 h average
	≤ 90% of limit value (innovation)	
Ozone(O ₃)	≤ 70% of limit value: 0.11 mg/m ³ (innovation)	1 h average
PM ₁₀	≤ 70 µg/m ³ (precondition)	Annual average
	75 µg/m ³ (optimization)	Daily average (while 18 exceptional days is allowed each year)
PM _{2.5}	≤ 35 µg/m ³ (precondition)	Annual average
	≤ 37.5 µg/m ³ (optimization)	Daily average (while 18 exceptional days is allowed each year)
	≤ 25 µg/m ³ (innovation)	Daily average (while 18 exceptional days is allowed each year)
Radon ²²² Rn	≤ 200 Bq/m ³ (optimization)	Annual average (reference level)

CASGB

The CASGB standard uses the Performance Index Method and Prescriptive Index Method to regulate the performance of material and furniture. The Performance Index Method uses the standards JGJ/T 436 (technical specifications for indoor decoration pollution control of residential buildings) (MOHURD 2018) and JGJ/T 461 (Design Standard for Controlling Indoor Air Quality in Public Building) (MOHURD 2019). The Prescriptive Index Method uses some national mandatory standards and some national green product assessment standards, as shown in Table 6.

Table 5 Environmental requirements in WELL

Contaminant	Concentration limitation	Optimization requirement
	Precondition requirements	
Carbon monoxide (CO)	<ul style="list-style-type: none"> • $\leq 10 \text{ mg/m}^3$ • $\leq 34 \text{ mg/m}^3$, commercial kitchen spaces and industrial 	$\leq 7 \text{ mg/m}^3$
PM ₁₀	<ul style="list-style-type: none"> • $\leq 50 \text{ } \mu\text{g/m}^3$ or lower (acceptable thresholds for occupiable spaces) • $\leq 50 \text{ } \mu\text{g/m}^3$ or lower (modified thresholds in polluted regions. LEED

This guideline uses both methods. One is the Prescriptive Index Method which in practice is to use interior building materials (everything within the waterproofing membrane) that meet the low-emitting criteria. These requirements are shown in Table 7.

The LEED guideline requires experimental VOC emission evaluation. Laboratories that conduct the tests must be accredited under ISO/IEC 17025 (ISO 2007) for the selected test methods. Products used in any setting other than schools and classrooms must be modeled according to a private office scenario. For school projects, modeling as office and/or school scenario is permitted. This method is a Performance Index Method. It does not calculate or design according to the mathematical model but tests the products as a whole.

Table 6 Sources requirements in CASGB

1	Wood-based panels and finishing product	Indoor decorating and refurbishing materials – limit of formaldehyde emission of wood-based panels and finishing product (GB 18580) (SAMR 2017g)
2	Woodenware coatings	Limit of harmful substances of woodenware coatings (GB 18581) (SAMR 2020c)
3	Architectural coatings	Indoor decorating and refurbishing materials – limit of harmful substances of interior architectural coatings (GB 18582) (SAMR 2020b)
4	Adhesives	Indoor decorating and refurbishing materials – limit of harmful substances of adhesives (GB 18583) (SAMR 2008b)
5	Wood-based furniture	Indoor decorating and refurbishing materials – limit of harmful substances of wood-based furniture (GB 18584) (SAMR 2001b)
6	Wood-based panels and wooden flooring	Green product assessment – wood-based panels and wooden flooring (GB/T 35601) (SAMR 2017h)
7	Coating material	Green product assessment – Coating material (GB/T 35602)
8	Furniture	Green product assessment – furniture (GB/T 35607) (SAMR 2017b)
9	Waterproof materials sealants	Green product assessment – waterproof materials sealants (GB/T 35609) (SAMR 2017e)
10	Ceramics tiles	Green product assessment – ceramics tiles (board) (GB/T 35610) (SAMR 2017a)
11	Textile products	Green product assessment – textile products (GB/T 35611) (SAMR 2017d)
12	Wood plastic composites product	Green product assessment – wood plastic composites product (GB/T 35612) (SAMR 2017f)
13	Paper and paper product	Green product assessment – paper and paper product (GB/T 35613) (SAMR 2017c)

BREEAM

BREEAM approval requires that at least four of five product types listed in Table 8 have been tested according to standards and meet the emission limits. Exemplary-level mission criteria are listed in Table 9. Maximum TVOC content for paints and coatings are in the guideline. This is a Prescriptive Index Method.

CASHB

This standard uses both the Performance Index Method and Prescriptive Index Method. The Performance Index Method requirements are that the concentrations of formaldehyde, benzene, toluene, xylene, TVOC, and other pollutants in indoor air should be pre-evaluated, such that the indoor air quality meets the requirements of

Table 7 Sources requirements in LEED

Inherently no emitting sources	No binders, surface coatings, or sealants that include organic chemicals
Salvaged and reused materials	Meet the VOC emissions evaluation AND VOC content evaluation requirements
VOC emissions evaluation	<ul style="list-style-type: none"> • product has been tested according to California Department of Public Health (CDPH) standard method v1.2–2017 and complies with the VOC limits in Table 4-1 of the method • Laboratories that conduct the tests must be accredited under ISO/IEC 17025 (ISO 2017) for the test methods they use. Products used in any setting other than schools and classrooms must be modeled to private office scenario
VOC content evaluation	<ul style="list-style-type: none"> • statement of product compliance must be made by the manufacturer or a USGBC-approved third party • if the applicable regulation requires subtraction of exempt compounds, any content of intentionally added exempt compounds larger than 1% weight by mass (total exempt compounds) must be disclosed • paints and coatings: <ul style="list-style-type: none"> – California air resource board (CARB) 2007 suggested control measure (SCM) for architectural coatings – South Coast Air Quality Management District (SCAQMD) Rule 1113, effective February 5, 2016 • adhesives and sealants: <ul style="list-style-type: none"> – SCAQMD Rule 1168, October 6, 2017
Formaldehyde emissions evaluation	<p>Product meets one of the following:</p> <ul style="list-style-type: none"> • certified as ultralow-emitting formaldehyde (ULEF) product under EPA toxic substances control act, formaldehyde emission standards for composite wood products (TSCA, title VI) (EPA TSCA title VI), or California air Resources Board (CARB) airborne toxic control measure (ATCM) • certified as no added formaldehyde resins (NAF) product under EPA TSCA title VI or CARB ATCM • wood structural panel manufactured according to PS 1–09 or PS 2–10 (or one of the standards considered by CARB to be equivalent to PS 1 or PS 2) and labeled bond classification exposure 1 or exterior • structural wood product manufactured according to ASTM D 5456 (for structural composite lumber), ANSI A190.1 (for glued laminated timber), ASTM D 5055 (for I-joists), ANSI PRG 320 (for cross-laminated timber), or PS 20–15 (for finger-jointed lumber)
Furniture emissions evaluation	<ul style="list-style-type: none"> • product has been tested in accordance with ANSI/BIFMA standard method M7.1–2011 (R2016) and complies with ANSI/BIFMA e3–2014e or e3–2019e furniture sustainability standard, Sections 7.6.1 (for half credit, by cost) OR 7.6.2 (for full credit, by cost), OR 7.6.2 AND 7.6.3 for one and a quarter credit, by cost • Laboratories that conduct the tests must be accredited under ISO/IEC 17025 for the test methods they use

the current national standard “indoor air quality standard” (GB/T 18883). The Prescriptive Index Method consists of emission evaluation and content evaluation. Emission evaluation depends on the national standard and IAQ design. Content standards and some emission standards are shown in Table 10.

WELL

The WELL guideline uses a Performance Index Method to minimize exposure to certain chemicals, such as orthophthalates, halogenated flame retardants (HFR), and per-fluorinated compounds (PFCs) by limiting their presence in products and limiting the percent fraction of volatile organic compounds (VOCs) emitted by products in indoor air. The specific requirements are described in Table 11.

From Table 6 to Table 11, all labeling systems provide certain criteria that restrict the main sources of formaldehyde, VOCs, and SVOCs (PAEs, PCBs, PAHs, etc.), including wet-applied materials and dry-applied materials. These materials can also be divided into ceiling materials, floor materials, wall materials, and furniture. Evaluation is based on either emission or content. Emissions evaluation is the main method for restricting formaldehyde and VOC, while content evaluation is used for restricting SVOC. Developing methods to quickly evaluate SVOC emission parameters has been an important task.

Up till now, the Performance Index Method is still applied in a few guidelines to evaluate environmental concentrations and regulate material and furniture emissions. However, scenarios, material and furniture, and environmental concentration limitations are inconsistent among different standards. Moreover, without building performance evaluation, how to deal with engineering design, engineering pre-evaluation, and engineering operation will become a severe problem. Therefore,

Table 8 Emission criteria by product type in BREEAM

Product type	Emission limit* formaldehyde	Total volatile organic compounds (TVOC)	Category 1A and 1B carcinogens

improving and promoting Performance Index Method will become an important issue in this field.

Particulate Matter (PM) Control in Labeling Systems

The architectural engineering control chain consists of plan, design, construction, acceptance, maintenance and operation, and monitoring. Some guidelines describe the control chain differently: Design, Construction, Before Occupancy, During Occupancy, and Monitoring. In general, the Design and Monitoring stages focus on PM control. At present, there are qualitative and quantitative methods for indoor PM control design.

CASGB

Design

The instructions in JGJ/T 461 (MOHURD 2019) provide a quantitative design method to select suitable particle filters or air-cleaning devices for outdoor air PM₁₀ and PM_{2.5} concentration so as to meet indoor environmental PM concentration requirements. During the design process, architecture base parameters are input. These include indoor air PM concentration requirements, outdoor air quality conditions, indoor PM contaminant sources, penetration coefficient, infiltration ratio, and minimum fresh air rate. Then a design model is selected to calculate PM. Air filters and cleaners can be selected based on the calculations.

Table 10 Sources requirements in CASHB

Product type		Content limit
Floor, carpet, floor coatings, wallpaper, rolling shutter, awnings, and other products	di (2-ethyl) hexyl phthalate (DEHP)	$\leq 0.01\%$
	di-n-butyl phthalate (DBP)	
	Butyl benzyl phthalate (BBP)

A. 2020d) • 2019 CARB SCM for architectural coatings • EU ecolabel for indoor and outdoor paints and varnishes • HJ 2537–2014 (paints) (MEE, PRC 2014) • “low-emitting materials” credit of the LEED v4.1 standard
Furniture, architectural and interior products	VOCs	<ul style="list-style-type: none"> • California Department of Public Health (CDPH) standard method v1.2 • AgBB • European Union LCI VOC thresholds following EN 16516–1: 2018 testing methods • ANSI/BIFMA e3–2014, sections 7.6.1 or 7.6.2 (furniture)

Monitoring

An indoor air quality-monitoring system with PM₁₀ and PM_{2.5} concentration monitoring function is installed in the building. The system records and stores the indoor particle concentration data for at least one year.

LEED

Design

The LEED guideline uses a qualitative design method to select different particle filters or air-cleaning devices. Each ventilation system that supplies outdoor air to occupied spaces must have particle filters to filter both outdoor air and recirculated air or air-cleaning devices which meet at least one of the following filtration media requirements:

- Minimum efficiency reporting value (MERV) of 13 or higher, in accordance with ASHRAE Standard 52.2–2017 (ASHRAE 2017).
- Equivalent filtration media class of ePM1 50% or higher, as defined by ISO 16890-2016, Particulate Air Filters for General Ventilation, Determination of the Filtration Performance (ISO 2016).
- Projects in East Asia may use filtration media classified as high efficiency or higher as defined by Chinese standard GB/T 14295–2008 (SAMR 2008a).

Monitoring

Monitoring systems with sensors designed to detect the specific contaminants should be installed. An alarm must give an alert for any unusual or unsafe condition. The particulate monitoring device must have an accuracy greater than 5 micrograms/m³ or 20% of reading, and resolution (5 min average data) of +/– 5 µg/m³.

BREEAM

There are no requirements for monitoring in the BREEAM guideline. For the design period, the guideline uses a qualitative design method. HVAC systems must incorporate suitable filtration to minimize external air pollution, as defined in EN 13779: 2007 Annex A3, shown in Table 12.

CASHB

Design

CASHB uses a quantitative design method to select different particle filters or air-cleaning devices for various outdoor air PM₁₀ and PM_{2.5} concentrations in order to meet the environmental concentration requirements for PM₁₀ and PM_{2.5}. The processes are similar to the processes described for CASGB.

Table 12 Recommended minimum filter classes per filter section in BREEAM

Outdoor air quality	Indoor air quality			
	IDA 1 (high)	IDA 1 (medium)	IDA 1 (moderate)	IDA 1 (low)
ODA1	(pure air) F9	F8	F7	F5
ODA 2 (dust)	F7 + F9	F6 + F8	F5 + F7	F5 + F6
ODA 3 (very high concentration of dust or gases)	F7 + GF ^a + F9	F7 + GF + F9	F5 + F7	F5 + F6

^aGF = Gas filter (carbon filter) and/or chemical filter

Monitoring

An indoor air quality monitoring system for PM₁₀ and PM_{2.5} should be installed. The system records and stores indoor particle concentration data for at least one year. The particulate monitoring device should have accuracy greater than 25% at 50 µg/m³. In addition, the monitoring system should connect with the HVAC and air purifier system to achieve auto control of indoor air quality.

WELL

Design

WELL uses a qualitative design method. The filter operation requirements are listed below:

- (a) Media filters are used in the ventilation system to filter outdoor air supplied to the space, in accordance with thresholds specified in Table 13.
- (b) Partially recirculated air is treated with the following:
 - 1. Activated carbon filter.
 - 2. At least one of the following: (i) media filter with PM removal of $\geq 90\%$ (e.g., MERV 14 or F8), (ii) UVGI within the ducts to treat the moving air, or (iii) upper-room UVGI.
- (c) For partially recirculated air, air purification/cleaning devices are required (with a quantity appropriate to the room volume or area, based on manufacturer specifications) and must include the following:
 - 1. Activated carbon filter.
 - 2. Media filter with PM removal of $\geq 90\%$ (e.g., MERV 14 or F8) or UVGI.

Monitoring

- (a) The air quality monitoring system must have a concentration monitoring function for PM₁₀, PM_{2.5}, and CO₂. The system must store monitoring data for at least one year and have a real-time display function.
- (b) The air quality monitoring system and all indoor air quality control equipment are automatically controlled. The system sets the limit for the main pollutant concentration parameters and gives an alarm when the limit is exceeded.

Table 13 filter requirements for outdoor air in WELL

Annual average outdoor PM threshold	Minimum air filtration level (PM removal)
23 µg/m ³ or less	$\geq 80\%$ (e.g., MERV 12 or M6)
24–39 µg/m ³	$\geq 90\%$ (e.g., MERV 14 or F8)
40 µg/m ³ or greater	$\geq 95\%$ (e.g., MERV 16 or E10)

There are both qualitative and quantitative methods included in the above-mentioned guidelines. The latest WHO air quality guidelines (WHO 2006) call for an annual PM_{2.5} level of 5 µg/m³ and 24 h mean level of 15 µg/m³. Thus, whether quantitative method can still meet the increasing precision requirements of current WHO requirements needs to be further verified. Meanwhile, because of counting efficiency and weight efficiency, filter classification will become more and more complex. Clearly, quantitative methods will be required more and more and improving quantitative methods is therefore an important task.

In addition, as informatization progresses in society, PM sensor engineering will progress. Presently, some PM_{2.5} sensors from industry can be used for monitoring. In the future, it might be widely used as other sensors, for example, temperature sensors, and will be integrated in the HVAC system or elsewhere in the building.

Conclusion

1. Green, healthy buildings have taken on great importance in building construction. IAQ improvement is of prime importance in green, healthy buildings.
2. Basic scientific research in IAQ as related to human health will continue. International organizations like WHO will continue to develop guidelines for IAQ. Local indoor environmental standards are optimally based on disease burdens as they differ among various regions and countries. IAQ standards must emphasize human health.
3. Predicting pollutant concentrations in a building during acceptance and operation is for the purpose of controlling formaldehyde, VOCs, and SVOCs. The technologies need to be improved so as to (1) quantify SVOC emissions parameters quickly; (2) strengthen the Performance Index Method; and (3) develop performance sensors.
4. Controlling PM is a key task. We can anticipate that concentration limitations will become stricter. Filter classifications and the control requirements for building operation will become more complex. Thus, quantitative planning and evaluation methods for both design and operation must advance in step with increasing complexities.
5. Controlling microbial contaminants will also be an engineering task. Currently, the mainstream control methods are sterilization and disinfection. While microbial contaminants are mentioned in various guidelines, no systematic control methods have been included from Plan & Design to Maintenance & Operation.

Abstract

Labeling and certification for low-emission building materials and furniture is an effective source control strategy for reducing indoor air pollution. The labeling and certification programs rely on the results from standardized environmental chamber tests to measure the emission rates of volatile organic compounds (VOCs) and assess their impact on indoor air quality (IAQ). In this chapter, we first introduce the fundamental principles, methods, and procedures of environmental chamber testing of VOC emissions and then discuss how the chamber test results are applied in various labeling and certification programs including the process, criteria, and the corresponding standard environmental chamber testing methods. Examples are drawn from widely used material emission testing and labeling programs. Sufficient details on the emission test methods and procedures are provided for readers to develop practical applications as well as a comprehensive understanding and appreciation of the principles and processes of material emission testing and labeling. For detailed implementation, readers are referred to product-specific testing methods and labeling programs that match their interests and needs.

Volatile organic compounds (VOCs) · Source control · Environmental chamber · Emission test standard · Labeling programs · Green buildings

Introduction

Volatile organic compounds (VOCs) are a major type of pollutants found indoors, and many of them are emitted from building and furnishing materials. Many of these VOCs are mucous membrane irritants and some (e.g., formaldehyde and acetaldehyde) are carcinogenic in humans, and hence are of great indoor air quality (IAQ) concern. In order to understand and reduce indoor pollution loads caused by VOCs emissions, environmental chamber testing methods and procedures have been developed to determine the emission characteristics including: (1) identification of the VOCs emitted by different materials and (2) determination of their emission rates over time (e.g., ASTM 5116 (ASTM International 2017), ASTM 6670 (ASTM International 2018a)). Understanding the emission characteristics is an important step in developing standard testing methods and procedures for specific building materials and furnishings. The standard test methods and procedures are developed through a consensus development process involving diverse stakeholders from academic or research institution, testing laboratories, material manufactures/suppliers,

and IAQ consultants (e.g., ANSI/BIFMA 7.1 (BIFMA International 2011a)), which take into account the emission characteristics, product usage conditions, sensitivity of analytical instruments, repeatability and reproducibility, and quality assurance measures.

The standard environmental chamber testing methods and procedures provide the basis for many labeling, certification, or compliance programs that are aimed at limiting VOC emissions indoors. For example, green or healthy building rating systems such as LEED (U. S. Green Building Council 2020) and WELL (International WELL Building Institute 2020) use the emission test results to determine if the materials/products qualify for receiving credits related to indoor pollution source control. Architects, interior designers, building managers, and homeowners use emission test data and labeling/certification/compliance programs to specify low emission materials and furniture. Manufacturers use the testing and labeling/certification/compliance programs to obtain product certification and qualify their products as low-emission materials or furniture. A labeling, certification, or compliance program specifies the intended applications, emission criteria, and the standard test method and procedure that generate the data for comparison with the emission criteria.

In this chapter, we first introduce the fundamental principles, methods, and procedure of environmental chamber testing of VOC emissions (section “[Standard Environmental Chamber Testing Methods and Procedure](#)”) and then discuss how the chamber test results are applied in various labeling and certification programs including the process and criteria (section “[Establishing the Link Between Chamber Testing and Real Applications](#)”). Examples will be drawn from widely used material emission testing and labeling programs. Several examples are provided in section “[Application Examples](#)”. For detailed applications, readers are referred to the specific testing methods and labeling programs that match their interests and needs. Section “[Concluding Remarks and Future Outlook](#)” provides a summary of the current state and an outlook on future development.

Standard Environmental Chamber Testing Methods and Procedure

Overview

Environmental chamber testing methods for material emissions include small, mid-size, and large chamber test methods. The size of small chambers is typically less than 1 m³ in volume with 50 L chambers being most popularly used. They are often used for testing individual materials such as carpet, composite wood boards, vinyl flooring, paints, varnishes, adhesives, and sealants, etc. Mid-size chambers typically range between 4 and 8 m³ and are used for testing individual components or assemblies such as a chair, sofa, desk, cabinet, mid-size wall assembly, printer, computer, etc. Large or room-size chambers range from 24 to 55 m³ in volume, and are used for testing full-scale office workstations, full-scale wall sections and large equipment. Regardless of the chamber volume, they are made of inert materials such as stainless steel and glass with Teflon gasket for sealing in order to minimize

the background contamination and VOC adsorption and reemission by the chamber surfaces. The chamber is contained in a temperature-controlled enclosure, supplied with clean and conditioned air and equipped with fittings for air sampling at chamber air exhaust or inside the chamber. All materials and components in contact with the specimen, or the air stream from the chamber inlet to the sample collection point, are chemically inert and accessible for cleaning. Suitable materials include stainless steel and glass. All gaskets and flexible components are made from chemically inert materials. Example small chamber testing systems can be found in ASTM D5116 (ASTM International 2017). Examples of full-scale chamber test facilities can be found in Zhang's study (Zhang et al. 1999b), ASTM D6670 (ASTM International 2018a), and Herrmann's study (Herrmann et al. 2003).

The quantity of materials tested in the chamber is typically scaled in terms of the ratio between the emitting surface area (A , m^2) and chamber volume (V , m^3), which is called loading ratio, L in m^2/m^3 whose value is intended to mimic the typical material usage conditions. The chamber is supplied with clean/filtered air at a constant flow rate (Q , m^3/h) that is typically scaled in terms of the ratio between the supply airflow rate and the chamber volume (called air change rate, $N = Q/V$, in air changes per hour, ach, or h^{-1}) simulating typical ventilation conditions in the room space. The ratio between the air change rate (N) and loading ratio (L) is the area specific airflow rate (N/L , $(\text{m}^3/\text{h})/\text{m}^2$). Air samples are typically taken at the chamber exhaust air outlet to determine the concentrations of VOCs (C , ug/m^3) of interest. Depending on the VOCs of interest to be measured, the air samples are either taken with sorbent tubes and/or 2,4-dinitrophenylhydrazine (DNPH) cartridges, followed by thermal desorption-gas chromatography/mass spectrometry (TD-GC/MS) analysis, and/or High Performance Liquid Chromatography (HPLC) analysis, respectively, or with online sampling instruments. The measured concentration data are then used to determine the emission rates (R , ug/h) or the emission factor (E , $\text{ug}/\text{h}/\text{m}^2$) as a function of time or at specific time points of interests required by given labeling, certification, or compliance programs or as input to estimate the contribution of the materials to the indoor concentrations of interest.

In the following sections, we focus our discussions on the test principles, air sampling and chemical analyses, test procedure, and data analysis and interpretation. Readers are referred to product-specific test methods for more detailed specifications and requirements of chamber test conditions, test specimen collection and storage, specimen preparation and conditioning, air sampling intervals, selection of target VOCs for analysis, quality assurance and quality control (QA/QC), and reporting requirements.

Principles

Determination of Emission Factor

Emission factor is defined as the emission rate per unit quantity of emission source. For a chamber with a volume of V , supply airflow rate of Q , and a test specimen with exposed area A (see Fig. 1), assuming that the air is perfectly mixed inside the

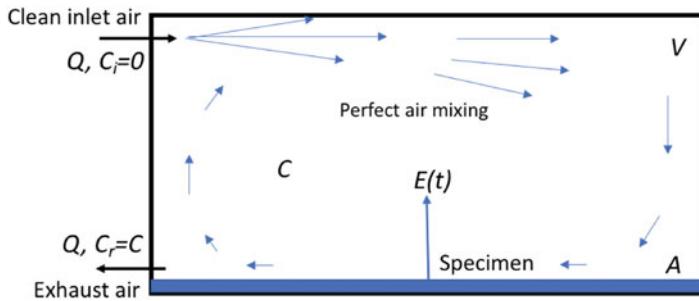

Fig. 1 Schematic of an emission test chamber containing a test specimen (a material, component/assembly or furniture system)

chamber, and the VOC concentration inside the chamber is the same as the concentration at the exhaust outlet (C_r). It is governed by the following mass balance equation:

$$V \frac{dC(t)}{dt} = AE(t) - QC(t) \quad (1)$$

where, V is air volume of the chamber excluding air volume taken by test specimens, m^3 ; t is time, h ; $C(t)$ is concentration of the emitted VOC in the air exhausted from the chamber (can be measured in chamber air or at the exhaust air duct), ug/m^3 ; A is amount of the source(s), 1, m , m^2 , kg , and m^3 , for “unit,” line, area, mass, and volume emission sources, respectively; $E(t)$ is emission factor of the source(s) in the chamber, ug/h , $\text{ug}/\text{h}/\text{m}$, $\text{ug}/\text{h}/\text{m}^2$, $\text{mg}/\text{h}/\text{kg}$, and $\text{mg}/\text{h}/\text{m}^3$ for “unit,” line, area, mass, and volume emission sources, respectively; and Q is clean air flow rate supplied to the chamber (measured at inlet air supply duct or determined by a tracer gas test), m^3/h .

Equation (1) states that the rate of change in mass of a VOC in the chamber is equal to the rate of emission from the source minus the rate at which the VOC is removed by ventilation. With the concentrations measured at pre-specified sampling time $C(t_i, i = 1, 2, 3, \dots, n)$, the emission factors can be calculated directly as follows:

$$E(t_i) = \frac{V}{2A} \left[\frac{C(t_i) - C(t_{i-1})}{t_i - t_{i-1}} + \frac{C(t_{i+1}) - C(t_i)}{t_{i+1} - t_i} \right] + \frac{Q}{A} C(t_i) \quad (2)$$

At steady-state or when the emission rate changes very slowly with time (which is the case for dry or dried building materials or furniture after a certain initial emission/conditioning period), the first term on the right is negligible, resulting in:

$$E(t_i) \approx \frac{Q}{A} C(t_i) = q_A C(t_i) \quad (3)$$

where, $q_A = Q/A$ is the source specific ventilation rate, m^3/h , $\text{m}^3/\text{h}/\text{m}$, $\text{m}^3/\text{h}/\text{m}^2$, $\text{m}^3/\text{h}/\text{kg}$, $\text{m}^3/\text{h}/\text{m}^3$ for “unit,” line, area, mass, and volume emission sources, respectively. It is also equal to the clean air change rate divided by the chamber loading ratio (N/L).

The validity of Eq. (1) depends on how well the chamber's actual operation meets the perfect mixing assumption. Therefore, the performance of the chamber must be evaluated against established criteria to obtain reliable and reproducible test results.

Material Emission Characteristics

Material emission characterization starts with the identification of VOCs emitted and selection of compounds of interests. This is often done with headspace analysis in which a material specimen is placed inside a completely sealed chamber or Teflon bag, and air samples are taken from the air space (“headspace”) above or surrounding the material when steady state is reached. The air samples are analyzed by GC/MS or HPLC to identify the VOCs emitted from the material using established protocols (e.g., U.S. EPA TO-1, TO-11, TO-15 and TO-17 (U. S. EPA 1995a, b). Target VOCs are selected for testing in accordance with their potential impact on human exposure and health or based on the requirements of labeling or certification programs. Formaldehyde and BTEX compounds (i.e., benzene, toluene, ethylbenzene, and xylene) are among the targeted VOCs in most labeling programs (see Table 3 in section “[Establishing the Link Between Chamber Testing and Real Applications](#)”). Other target VOCs differ among different labeling or certification programs and in different published studies. Table 1 shows an example list of target VOCs taken from commonly used standard methods in North America for VOC emission testing of building materials and furniture (CDPH Standard Method v1.2 (CDPH 2017), ANSI/BIFMA e3 (BIFMA International 2019), and ANSI/BIFMA X7.1 (BIFMA International 2011b)).

The VOC emission rates vary with the time, properties of VOCs, material types, and environmental conditions. Under a standard environmental chamber test condition (e.g., 23 °C, 50% RH, and 1 ach, which is typical of small chamber testing), the emission rates exhibit different patterns over time (Fig. 2). “Wet” coating materials such as paints and varnishes generally have a high initial emission rate immediately after application due to evaporation of the liquid solution. The emission rate then decreases quickly with time as the material “dries” (Chang and Guo 1992a, b; Zhang et al. 1996). The duration of the initial period is relatively short. Depending on the coating material and substrate used, it can vary from a few hours to about 10–20 h. The amount of VOC mass emitted during the initial emission period relative to the total VOC mass that can be emitted also depends on the material and substrate. The initial emission period is primarily controlled by evaporation and hence is largely affected by air velocity and turbulence over the surface. The later emission period is primarily controlled by VOC diffusion in the material and substrate, and thus is not significantly affected by the air velocity over the surface (Zhang et al. 1996), a behavior of dry or “dried” materials. The emission characteristics also differ among different VOCs, which depend on the vapor pressure and molecular weight of the VOC and its mass amount relative to other VOCs in the material (Guo et al. 1998). “Wet” installation material such as adhesives, caulk, and sealants have similar emission rate pattern as the “wet” coating materials except that the transition from the initial evaporative controlled to the in-material diffusion-controlled emission period takes a longer time to complete due to a thicker layer of the material. Dry or

Taken from CDPH Standard Method v1.2 (2017)^a, ASNI/BIFMA e3 (2019)^b, and X7.1 (2011 (R2016)^c

*Maximum allowable concentrations are one-half of the corresponding Chronic Reference Exposure Level (CREL) adopted by California Office of Environmental Health Hazard Assessment (OEHHA) except for formaldehyde, 4-Phenylcyclohexene, and 1-Methyl-2-Pyrrolidinone. For furniture, the listed maximum allowable concentrations are for workstations; the maximum allowable concentrations are one-half of those listed in the table for seating

^aThe maximum allowable concentration of 9 $\mu\text{g}/\text{m}^3$ for formaldehyde is based on full CREL. It is required in CDPH Standard Method v1.2. For furniture, the maximum allowable formaldehyde emission concentration is 62.5 $\mu\text{g}/\text{m}^3$ (50 ppb) for workstations in ANSI/BIFMA X7.1. The requirements in ASNI/BIFMA e3 depend on the credit level; the maximum allowable concentrations for workstations are 62.5 $\mu\text{g}/\text{m}^3$ (50 ppb), 16.9 $\mu\text{g}/\text{m}^3$ (13.5 ppb), and 9 $\mu\text{g}/\text{m}^3$ for Section 7.6.1, 7.6.2, and 7.6.3, respectively

^bCompounds that are listed by the International Agency for Research on Cancer (IARC) as Group 1 or 2A carcinogen are marked in this column

“dried” materials such as carpets, vinyl flooring, composite wood products (particleboards, plywood boards, and oriented strand boards), painted gypsum wallboards, ceiling tiles, desktop and cabinet panels, etc.) have low initial emission rates that also decay slowly as an in-material diffusion-controlled process.

Many empirical and mechanistic emission source models have been developed to predict the rate of emissions over time for the three different types of building and furnishing materials (Chang and Guo 1992a, b; Hu et al. 2007; Little et al. 1994; Xu and Zhang 2003; Yang et al. 2001a; Yang et al. 2001b; Zhang et al. 1999c). Interior building and furnishing materials and furniture are typically used under dry or “dried” conditions. Following an initial period of preconditioning, their emission rates decay slowly. Equation (3) can be used to determine the

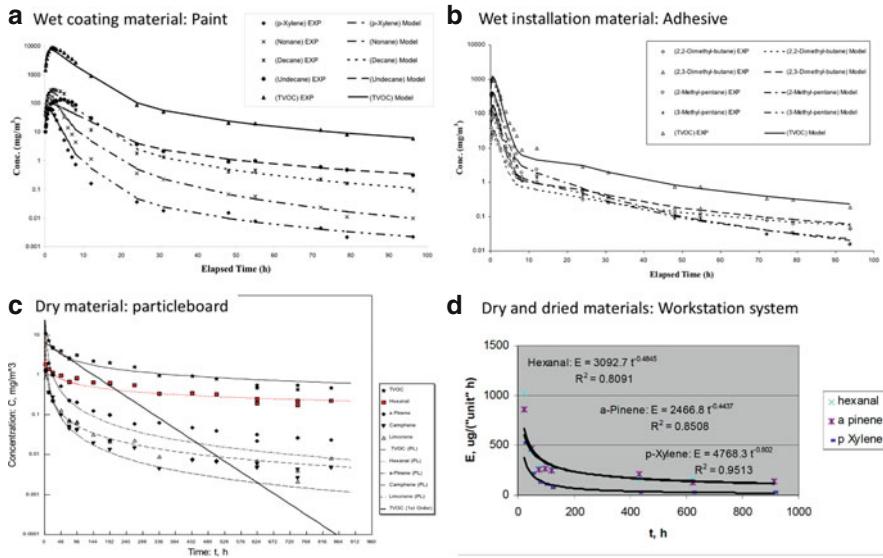

Fig. 2 Emission patterns of different material types: **a**, **b**, and **c** are measured concentrations over time from small chamber testing, Zhang et al. 1999; **d** is emission factor over time from ANSI/BIFMA M7.1)

emission factor at a given time point of chamber testing based on the measured concentration without appreciable error (Zhang et al. 1997). The measured emission factor as a function of time can be well represented by the power law model (Zhang et al. 1999c, 2006):

$$E(t) = at^b \quad (4)$$

where, a and b are model parameters to be determined from the emission test data. A decaying emission factor is reflected by $b < 0$.

Variables Affecting Emission Rates

Variables affecting emission rates include those related to the materials/products themselves (emitting source variables), those related to the environment within which they are used or tested (environmental variables) as described in ASTM D6670 (ASTM International 2018a), and those associated with VOC sampling and analysis. The environmental variables are standardized and controlled in order to reduce uncertainty. For example, for estimating the impact of the workstation systems or seating on the VOC concentration in an office environment, assumptions are made regarding the size and volume of the office environment containing the workstation, the size of the workstation and the number of seating units, clean air flow rate per system, temperature, relative humidity, and air velocities over emitting surfaces (BIFMA International 2011a).

Effect of Product Age

Since VOC emission rates of building materials and furniture typically decrease with time, the age of the specimen to be tested needs to be controlled considering the typical timelines for delivery and occupancy. For example, it is assumed 10 days typically are required between manufacturing and onsite delivery of office workstation and seating systems. Seven and fourteen days following delivery and on site assembly of the workstation and seating system are defined as the times of interest for early occupancy in furniture testing (BIFMA International 2011a).

Estimation of the Contribution of the Materials to the VOC Concentrations in Buildings

A standard reference conditions should first be defined for a specific type of building accounting for the quantity of materials used, ventilation rate, and environmental conditions. For example, for the purpose of estimating the impact of furniture on the VOC concentrations in office spaces, a standard open plan office environment and a standard private office environment are defined based on research (Table 2). These standard open plan and private office conditions define representative “worst case” conditions and combine high density (90th percentile) furniture loading conditions with minimum allowable outdoor (clean) air ventilation rates (Carter and Zhang 2007). Each accommodates one workstation system for a single occupant. The areas include traffic area and support space for copiers, files, storage, etc. The outdoor or clean air ventilation rate for each environment is the minimum required outdoor ventilation rate per ASHRAE Standard 62.1-2007 (ASHRAE 2007), which specifies a minimum ventilation rate of 2.36 L/s per person or 5 cfm per person plus 0.3 L/s per square meter of floor area (or 0.06 cfm per square foot of floor area).

For residential houses, a reference house with quantities of floor, wall, and ceiling materials and ventilation rate has been defined for evaluating the baseline indoor VOC pollution loads and the effects of various IAQ strategies on indoor

Table 2 Standard office environment parameters per ANSI/BIFMA M7.1

^aCalculated as the average for open plan and private office workstations

VOC concentrations. In both office and residential house applications, 23 °C and 50% RH have been selected as the reference conditions consistent with the standard environmental chamber test conditions, and hence the emission factors determined from the chamber tests can be directly applied to estimate the pollution loads in IAQ design.

For example, assuming that the emission factor only changes very slowly with time, the following equation is used to estimate the concentrations in a standard office environment at the time of interest for early occupancy [e.g., $t = 168$ or 336 h (7 or 14 days) after the workstation is installed]:

$$C(t) \approx \frac{A_o E(t)}{Q_o} \quad (5)$$

where, $C(t)$ is concentration in the defined office environment at the time of early occupancy ($t = 7$ or 14 days after the installation), ug/m³; A_o is source amount in the office environment (e.g., number of workstation units, and is equal to 1 in this case); $E(t)$ is estimated emission factor at $t = 168$ or 336 h (7 or 14 days) from Time Zero based on chamber testing, mg/h per workstation unit; Q_o = clean air ventilation rate in the office environment for the standard open plan or private office environments as defined in ANSI/BIFMA 7.1. (BIFMA International 2011a, b)

For the residential reference house application, the concentration of a VOC emitted by multiple materials is calculated by:

$$C(t) \approx \frac{1}{Q_o} \sum_j^n [A_j E_j(t)] \quad (6)$$

where, subscript j represents a material that emits the specific VOC, A_j is the quantity of material j , and E_j is the emission factor determined from the chamber testing.

Other Important Considerations

The goal of a standard test method is to achieve consistent, accurate, reliable, and repeatable test results while making the test procedure practical for implementation. Several important considerations are discussed below:

1. Standard Test Conditions. Chamber conditions of 23 ± 0.5 °C and $50 \pm 5\%$ RH are commonly used in small, mid-size, and large-scale chamber testing methods (ASTM International 2017, 2018a) as they represent typical indoor thermal condition that are well within the thermal comfort zone for occupants. Small-scale chamber test methods commonly adopt an air change rate of 1.0 ACH and a specimen loading ratio of 0.3 to 0.7. Mid-size and large-scale chamber test methods have a broader range of air change rate and specimen loading, depending on the purposes and applications of testing (e.g., office spaces or residential houses). Mimicking the usage conditions also leads to a realistic VOC concentration range in the test chamber, which helps specify the requirements for air sampling and chemical analysis.

2. Requirements for Environmental Chamber Control. A test chamber should have inner interior surfaces with minimal adsorption effects. Polished 304 or 316 stainless steel sheets are often used for chamber construction. They are electropolished for small chambers to further reduce the sorption on chamber surfaces. Test chambers should also be airtight with an air leakage less than 1% of the supply air flow rate. They should be kept at a slightly positive air pressure during testing (e.g., about 10 Pa above the ambient air in the lab space) to avoid any possible contamination by the air in the laboratory. The chamber needs to be supplied with clean/filtered air and the chamber background concentrations should satisfy the following criteria:

- TVOC $\leq 10 \mu\text{g}/\text{m}^3$ for small chamber, and $\leq 50 \mu\text{g}/\text{m}^3$ for mid- and full-scale chambers
- Any individual compound to be measured $\leq 0.5 \mu\text{g}/\text{m}^3$ for small chamber, and $\leq 2.0 \mu\text{g}/\text{m}^3$ for mid- and full-scale chambers
- Particulate $\leq 100 \text{ particles}/\text{m}^3$ of $0.5 \mu\text{m}$ diameter or larger, which is the Class M2 clean room requirement for $>0.5 \mu\text{m}$ diameter particles (ASHRAE 1995)
- Ozone and other potentially reactive species (NO_x, SO_x, etc.) $\leq 3 \mu\text{g}/\text{m}^3$ for small chamber, and $\leq 10 \mu\text{g}/\text{m}^3$ for mid- and full-scale chambers

Good air mixing should be achieved via air diffusers or mixing fans to ensure that the concentration difference between the chamber exhaust outlet and chamber air is less than 5%. Table 3 shows the required control accuracy and precision for the temperature, RH, pressure, and airflow rate. More detailed guidance on the requirements and methods to evaluate the chamber's performance against the established criteria can be found in ASTM 5116, 6670 and Herrmann's study (ASTM International 2017, 2018a; Herrmann et al. 2003).

3. Test Specimen Collection and Storage. Different product-specific test methods may have different requirements. For example, ANSI/BIFMA M7.1 (BIFMA International 2011a) includes the following requirements:

- The complete test item – all components or component assemblies of a workstation system, workstation component, or seating unit – must be

Table 3 Required accuracy and precision limits parameters

Parameter	Accuracy (as bias)	Precision
Temperature (°C)	± 0.5	± 1.0
Relative humidity (%)	± 5	± 5
Air flow rate (%)	± 3	± 5
Area of the testing surface of the specimen (%)	± 1.0	± 1.0
Time (%)	± 1.0	± 2.0
Organic concentration (% RSD ^a)	—	± 15.0
Emission factor (% RSD ^a)	—	± 20.0

^aRSD = Relative standard deviation = $(s/m) \times 100\%$, where, s = estimate of the standard deviation; and m = mean

received by the testing laboratory not more than 15 days after the date of manufacture of the first workstation component. The manufacturer should attempt to minimize the total elapsed time from manufacture to receipt of the sample at the lab in a way that best represents their standard manufacturing, packaging and shipping processes. The manufacturer's most air-tight packaging option for that workstation component, component assembly, or seating unit should be used unless the manufacturer prefers to use a more airtight means of packaging (Typically the most airtight packaging will fully encase the product in plastic coverings (polybags, shrink-wrap, etc.). Corrugated (cardboard) packaging materials, even if combined with shrink-wrap that does not fully enclose the product, are generally less airtight than fully encasing plastic materials. Blanket wrapping is generally not considered to be airtight and is discouraged for use as a packaging material for emissions testing. More airtight packaging may be preferred to prevent the potential for cross-contamination during shipping if such contamination is suspected).

- When testing component materials for screening purposes, the material samples should be packaged at the time of sample collection, and should be sealed or packed in a fashion to limit emissions (e.g., double-layer aluminum foil wrap with shiny side out and placed in a polyethylene bag, or directly placed in a Mylar or Tedlar bag and sealed). Samples should remain in their packaging until prepared and placed in a test chamber. Sample collection should occur within 24 h of manufacture.
 - Each system, component, or material shipped must be accompanied by a chain-of-custody (COC) form that contains the full identification of the item, the dates of manufacture, collection and shipping, and individuals handling the item.
 - Upon receipt, the test specimen should be stored in a conditioned and ventilated room of 23 ± 3 °C and not to exceed 60% RH without unpacking, or unpacked and immediately installed in the conditioned chamber for testing. The test specimen must be unpacked and installed for testing within 25 days of the manufacture date of the first sample. The concentrations of TVOC, individual VOCs, and particles in the storage room should be controlled by limiting indoor sources using appropriate filtering (e.g., granulated activated carbon filter and high efficiency particle filter) on the HVAC system. Compliance with the following criteria should be verified at the initial commissioning and again if the storage area or surrounding environment changes in a way that may affect these values.
 - $\text{TVOC}_{\text{Toluene}} \leq 100 \mu\text{g}/\text{m}^3$
 - Any individual compound to be measured in the chamber $\leq 10.0 \mu\text{g}/\text{m}^3$
 - Particulates $\leq 35,200 \text{ particles}/\text{m}^3$ of $0.5 \mu\text{m}$ diameter or larger, and $<0.5 \mu\text{g}/\text{m}^3$ in mass concentration and
 - Ozone and other potentially reactive species (NO_x , SO_x , etc.) $<10 \mu\text{g}/\text{m}^3$
4. Testing Period and Air Sampling Time Points. Testing period and air sampling time points should be selected to either represent the complete emission rate patterns of individual VOCs of interest or the pollution load at the beginning of

product usage or early occupancy stage for the purpose of IAQ design and management as required in the relevant labeling or certification criteria. As an example, Fig. 3 shows the different testing periods and air sampling time points for furniture emission testing in relation to the emission criteria set in relevant labeling or certification programs for formaldehyde. The Greengard Test required 4 days of testing and extrapolated the test results to estimate the emission rate on day 7. The Zhang/BIFMA Test relied on duplicate air samples at 72 and 168 h (day 3 and 7) to determine the coefficients of the power-law model and use the model to predict the emission rate at 14th day for comparing with the LEED-CI limit at 7th day and CA-1350 limit at 14th day, respectively.

- Scaling. Emission test data for individual materials from small chamber testing can be scaled up per the emission surface area to estimate the emission factor of a workstation system or component. The direct scaling approach (i.e., based on the emitting surface area) tends to be conservative in predicting the emission rates of a workstation system or component (Hodgson et al. 2009). The data indicate that small chamber tests should focus on the measurement of VOC emissions from component assemblies rather than from isolated surfaces because sealing of a primary face can alter the emission characteristics of some compounds. Also, relatively detailed knowledge of material construction is required to select the most appropriate items for testing at small scale. Using such techniques, the study

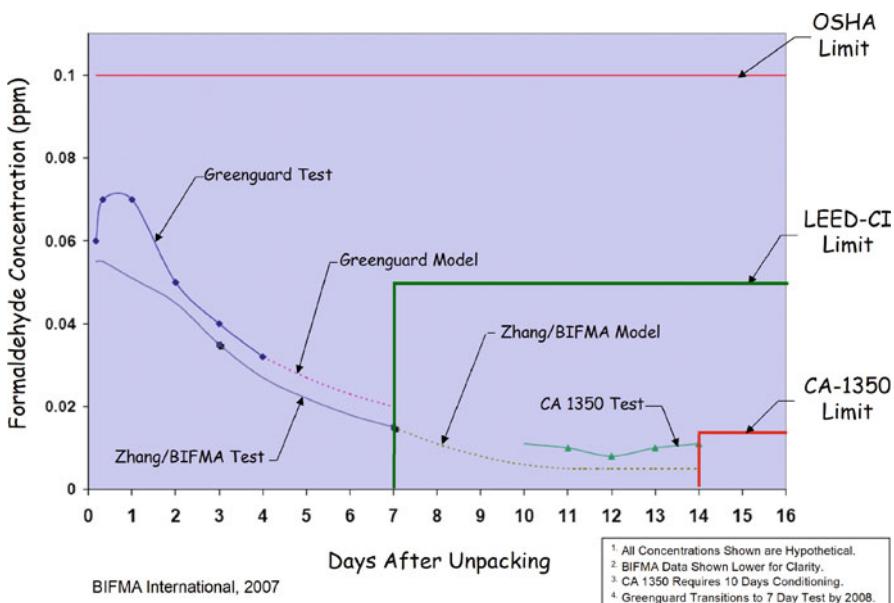

Fig. 3 Testing periods and sampling time points in relation to relevant labeling and certification programs

demonstrated that the scaling of VOC emissions from the small-scale tests to the full system and to its major components either produced comparable projections or overpredicted the emissions for the system and units tested in the mid-scale and large-scale chambers.

6. Quality Control and Quality Assurance. Due to the complexity of source emissions testing, careful planning is usually required to ensure meaningful data. A quality assurance plan identifies the critical data needed to meet testing goals and provides a framework for collecting data that will help ensure that the data are of sufficient quantity and quality to meet the goals of the testing program. Certain kinds of quality control data are necessary to assess the performance of sampling and analysis systems. These data include results of periodic flow rate checks of sampling systems, analysis of replicate samples, analysis of field and lab blanks, spiked field control samples, daily tuning criteria for MS systems, and results of daily mid-range calibration check samples. Guidance on developing a quality assurance and quality control program (QA/QC) plan is available from several sources (USEPA QA/R-5 (U. S. EPA 2001), ASTM D5116 (ASTM International 2017) and ASTM D6670 (ASTM International 2018a)). The QA/QC plan should be based on established data quality objectives and acceptance criteria, which are specified in product-specific test methods such as ANSI/BIFMA M7.1 (BIFMA International 2011a).

Air Sampling and Chemical Analysis

Air sampling and chemical analysis is a vital part of environmental chamber testing and evaluation of product emissions.

Sampling Methods

VOC emissions from sources that impact IAQ include very volatile, volatile, semi-volatile, polar, nonpolar, oxygenated, and other species of organic compounds. Sampling systems include syringes, sampling loops, sorbent traps, cryogenic traps, whole air canisters, and other devices that collect and concentrate analytes of interest. The choice of sampling systems depends upon the nature and concentration of the analytes as well as testing goals. Very volatile compounds may be sampled with whole air canisters, sampling loops, or adsorbents such as Carbosieve SIII[®]. Many VOCs emitted from solvents or oil-based products may be collected on adsorbents or combination of adsorbents such as Tenax[®], charcoal, or Carbotrap[®]. Semi-volatile VOCs may be collected on adsorbent media such as XAD[®] resin or Carbotrap C[®]. Oxygenated compounds may be collected on silica gel coated with DNPH, or other suitable adsorbent. Traps to remove particles or reactive compounds such as ozone may be required upstream of the adsorbent. Whenever a sampling line or probe is placed upstream of the sample collection device, it may be necessary to demonstrate quantitative recovery of analytes to make sure that no adsorption takes place in the sampling line. Several methods are generally applicable to the collection and analysis of VOC emissions from products in chamber tests:

- *Collection on sorbent media:* Collection on sorbent media is currently the most commonly used approach for indoor air source sampling and in standard environmental chamber testing. Sorbents such as Tenax® or graphitic carbon are packed in glass or metal tubes and known volumes of air are drawn through them. Analytes collected on these traps may be thermally desorbed to a concentrator unit or extracted with appropriate solvent for liquid injection. Thermal desorption is the most common approach due to ease of use and lower method detection limits. For selected low molecular weight aldehydes and ketones, compounds are collected and derivatized on cartridges containing silica gel coated with 2,4-dinitrophenylhydrazine (DNPH). The derivatized compounds are solvent extracted and determined by HPLC with UV or photo diode array detection. The air sampling system should include a sorbent tube (or cartridge), an air sampling pump, and an airflow controller, which can measure and control the air flow rate through the sampling system to within $\pm 5\%$ of a specified value. All system components between the chamber and the sorbent tube (or cartridge) should be constructed of chemically inert materials. The sorbent tube or cartridge should be connected directly to the sampling location at the chamber return/exhaust or inside the chamber by using a short (<0.4 m) stainless steel or Teflon tube/connector. The pump should be operated in suction mode downstream of the sorbent tube or cartridge to avoid contamination of air samples by the pump.
- *Online sampling* can be achieved by using near-real-time sampler and analyzer such as proton-transfer mass spectrometer (PTR-MS) with quantitation limit at 1 ppb or less depending on the compounds. Automated systems consisting of a concentrator (i.e., sorbent media as VOC traps) and a GC configured with a gas sampling valve, actuator, sample loops, and detector can also be developed for online sampling. In a typical online concentration system, there are two VOC traps. The sample air is pulled through one trap during the desorption/analysis phase of the other trap. Each trap may contain a single adsorbent or combination of materials (glass beads, Tenax, carbon adsorbents). The range of analytes that can be collected and recovered from the traps will depend upon the composition of the traps and efficiency of transfer of analytes from the traps to the GC. Online sampling methods are mostly used in research where fine time resolution is needed to capture the change of emissions over time and secondary emissions resulting from chemical reactions. They are rarely used in standard material emission tests due to the high cost of equipment.
- *Whole air samples:* Whole air samples may be collected for subsequent off-line analysis using gas sampling syringes, Tedlar or Teflon bags, or stainless steel Summa® polished canisters. Whole air samples permit sample storage and repeated analyses of the same sample. Gas sampling syringes have limited applicability to emission source testing due to their relatively small volume capacity, poor reproducibility, and potential for losses to syringe surfaces. Tedlar® and Teflon® bags provide an adequate volume of air for concentration but analytes may diffuse through the bag or be lost to bag surfaces. Canister technology has been proven to be effective for many volatile compounds at ambient concentrations. Source testing often generates atmospheres with high concentrations of

pollutants and generates pollutants of less volatility than those for which the canister technology has been developed and demonstrated. Therefore, as with any sampling system, it may be necessary to determine the appropriate application of the technique for a particular source.

Sampling Volume and Flow Rates

Sampling volumes and flow rates for sorbent traps used to collect VOCs are selected based on analytical detection limits and breakthrough volumes of compounds of interest, acceptable pressure drop across the sampling traps, and time resolution required for calculation of emission rates from chamber concentration data. Recommendations of the sorbent tube or cartridge manufacturer/supplier should be followed. The lowest concentration to be measured quantitatively should be higher than three times the detection limit of the analytical method. For example, if the detection limit of a GC/MS analytical system is 0.001 µg per tube sample for a VOC of interest, and the lowest concentration to be measured is 1.0 µg/m³, a minimum of 0.003 m³ or 3 L (i.e., $0.001 \times 3/1.0$) air sample should be obtained. A proper sampling volume should be determined through a pre-screening analysis for specific materials or products. In standard chamber testing methods for VOC emissions, typical sampling airflow rates are 100–200 mL/min for VOC sorbent tubes, and 500–1000 mL/min for DNPH cartridges. For a 5 L air sample collected by a VOC sorbent tube, the sampling time would be 25 min if sampling at 200 mL/min.

Chemical Analysis Systems

The appropriate instrumentation for the determination of emissions from products and processes depends upon the nature of the emissions and testing goals. A GC equipped with capillary column and flame ionization (FID) or mass spectral detector (MSD) is commonly employed for identification and quantification of VOC emissions. Due to the complexity of emissions from many types of sources, a GC MS system may be considered essential for identification of VOC emissions from the majority of sources. A GC FID system is often useful for quantification of emissions due to the sensitivity and broad linear dynamic range of the detector. Other GC detectors such as electron capture (ECD) or photo ionization detector (PID) are useful for specific types of compounds. Low molecular weight aldehydes and ketones, collected on silica gel coated with DNPH, may be determined by liquid chromatography with ultraviolet or photo diode array detectors. Additional guidance is provided in product-specific test methods for analyzing VOCs of interest. For example, ANSI/BIFMA M7.1 (BIFMA International 2011a) included the following directions based on the experience gained from an inter-lab comparison study (Zhang et al. 2009):

1. Thermal Desorption-Gas Chromatograph/Mass Spectrometer (TD-GC/MS) System and Methods.

Analytical System Optimization. The TD-GC/MS system and associated analytical method should be optimized for the quantitative recovery and analysis of individual VOCs of interest within a volatility range bounded, at a minimum,

by *n*-hexane and *n*-hexadecane (C6-C16). Note that some criteria may require the analysis of VOCs over a different volatility range. The MS should be an electron impact ionization (70 eV) instrument operated in the scanning mode over a mass range of at least m/z 35–450 at ≤ 0.5 Hz. The system and method should have sufficient sensitivity to quantify chamber concentrations of target analytes $\geq 2 \mu\text{g m}^{-3}$. ASTM D7339 (ASTM International 2018b) and US EPA Methods TO-1 and TO17, or equivalent methods, are used as the basis for configuring the instrument and establishing instrument operating parameters.

Identification of Individual VOCs by TD-GC/MS. An individual VOC is identified by comparing the chromatographic retention time and mass spectrum of the unknown peak to the corresponding parameters for the pure compound analyzed using the same instrument and method. For a confirmed identification, the retention times of the unknown and the standard must agree within 0.25%, or better, of the total run-time and the match quality of mass spectrum of the unknown to the mass spectrum of the standard must be $\geq 90\%$. All VOCs specifically named in an acceptance criterion and present in samples should be positively identified. If confirmation is not obtained, the unknown spectrum is compared to spectra contained in the NIST electronic library. A trained analyst should decide if the identification is likely based on the match quality and the reasonableness of the retention time. Typically, a match quality $\geq 85\%$ is sufficient for tentative identification. If no such identification is obtained, the compound is designated as unknown.

Tuning of TD-GC/MS System. Tuning and mass standardization of the MS is performed using perfluorotributylamine (PFTBA) as the calibrant. The instrument parameters should be adjusted to achieve target relative ion abundances such as given in ASTM D7339. The MS should be tuned as needed to achieve relative ion abundances that are repeatable from day to day.

Internal Standard. The use of one or more internal standard is recommended. An internal standard serves to adjust the MS instrument response for small run-to-run and day-to-day variations. Toulene-d8 and 1-bromo-4-fluorobenzene are commonly used as internal standards. An identical amount of the internal standard is added at the time of analysis to both samples and standards.

Calibration of TD-GC/MS System for Target VOCs. Standard calibration curves are required for all VOCs specifically named in an acceptance criterion. Initially, the TD-GC/MS system should be calibrated using pure compounds with a minimum of five calibration levels spanning the anticipated mass ranges of the individual target VOCs. Prepare calibration levels by injecting aliquots of standard solutions or known volumes of calibration gas mixtures onto clean VOC sorbent samplers. The calibration standards should not exceed the capacities of the sorbent sampler, the analytical column, or the MS detector. Analyze the spiked samplers using parameters identical to be used for the analysis of chamber air samples. If using an internal standard, analyze at least one calibration check standard with each batch of samples analyzed. If not using an internal standard, perform at least a three-level calibration with each batch of samples. Processing of calibration standard and sample data files

requires the extraction of characteristic ions from the total ion-current (TIC) chromatograms for each VOC. Use one quantitative (i.e., primary) ion and at least one confirming (i.e., secondary) ion for each compound including any internal standard. The extracted ion peaks are integrated. The ratio of the area of each confirming ion peak to the area of the quantitative ion peak for a VOC is determined. These ratios and peak retention times serve to provide positive identification of target VOCs. Refer to USEPA TO-15 (U. S. EPA 1995a), Table 2 for characteristic primary and secondary ions for some common air contaminants. The calibration curve for a VOC is constructed using the peak area responses of its quantitative ion in the standards. Apply a linear least squares fit or an average response factor fit to a plot of peak area versus mass of compound injected. If the response is not linear, a quadratic fit may be required. Assuming a zero intercept and linear response, the slope of the plot is the response factor in area/mass injected. When using an internal standard, the response factor is normalized by the internal standard mass and the peak area response of the quantitative ion for the internal standard.

Quantification of Nontarget VOCs. If reporting of nontarget VOCs is required by an acceptance criterion, such VOCs that can be positively identified should be quantified using pure compound calibrations. If a VOC cannot be positively identified, its Total Ion Current (TIC) peak area response should be quantified using toluene as the surrogate standard. Initially, construct a multipoint (\geq five points) calibration for toluene using the TIC areas of toluene in the standards as the response. For routine control, analyze a single-point calibration for toluene for every batch of air samples. Normalize the calibration if an internal standard is used. Calculate the response factor and use this to make semiquantitative estimates of the masses of tentatively identified and unidentified peaks in a sample. VOCs quantified by this surrogate method should be clearly reported.

Quantification of TVOC_{Toluene}. For the purposes of this method, TVOC_{Toluene} is defined as the combined, toluene-equivalent mass of all VOCs in a sample eluting on a nonpolar polydimethylsiloxane analytical column over a volatility range bounded by *n*-hexane and *n*-hexadecane. If a more polar analytical column is used, the equivalent volatility range should be utilized. First, determine the TIC areas of all chromatographic peaks within the defined range using appropriate parameters that achieve baseline-to-baseline integration and then sum these areas. Using a toluene TIC response factor, estimate the toluene-equivalent mass represented by this summed area.

2. High Performance Liquid Chromatography (HPLC) System and Methods.

Analytical System Optimization. The HPLC system and associated analytical method should be optimized for the quantitative recovery and analysis of formaldehyde and other low molecular weight aldehydes of interest. Base the method on ASTM D5197 (ASTM International 2016), or an equivalent method. The HPLC system should be equipped with a UV detector operating at 360 nm and a C18 reverse phase analytical column providing full resolution of the formaldehyde hydrazone derivative from unreacted DNPH in a sample.

The system and method should have sufficient sensitivity to quantify chamber concentrations of analytes $\geq 2 \mu\text{g m}^{-3}$. Note that unsaturated low molecular weight aldehydes such as acrolein are not accurately determined by this method unless special procedures are used. Higher molecular weight aldehydes approximately beginning with butanal can be analyzed by TD-GC/MS.

Identification of Individual Aldehydes by HPLC. The aldehydes in a sample are identified by comparing their retention times with those of standard DNPH derivatives analyzed using the same instrument and method. The retention times of the unknown and the standard must agree within 0.25%, or better, of the total run-time.

Calibration of HPLC System for Target Aldehydes. A calibration standard stock solution is prepared with accurately weighed amounts of each individual DNPH-aldehyde derivative. Purified crystals or solutions of DNPH-aldehyde derivatives are available from commercial sources. Calculate stock solution concentrations as the mass of free aldehyde per unit volume. Prepare calibration standards (at least five levels) spanning the anticipated response ranges of interest by dilution of the stock solution. Construct the calibration curve for an aldehyde by plotting the peak area responses of the standards versus their DNPH aldehyde concentrations. Apply a linear least squares fit to the plot to obtain the response factor. Analyze at least one mid-level standard with each batch of samples.

Quantification of Total Aldehydes. The criteria specified in ANSI/BIFMA X7.1 (BIFMA International 2011b) require the measurement of Total Aldehydes. For the purposes of this method, Total Aldehydes is defined as the sum of the molar volume concentrations of all normal aldehydes from formaldehyde through nonanal plus benzaldehyde. Analyze formaldehyde and acetaldehyde by HPLC. The remaining aldehydes should be analyzed by TD-GC/MS as this method has the advantage of providing positive peak identification. For individual compounds that can be clearly identified and accurately quantified by HPLC those values can be used in place of the corresponding values measured by GC/MS.

Test Procedure

A logical and practical test procedure is critical to ensuring accurate, reliable, and repeatable test results. Test procedures may vary among different product-specific standard test methods, but should generally include the following components as exemplified in ANSI/BIFMA M7.1 (BIFMA International 2011a):

Chamber Operation

All tests should be conducted under tightly controlled and constant environmental conditions typically at 23.0 ± 1.0 STD °C, $50\% \pm 5\%$ STD RH, and 10.0 to 25.0 ± 5 STD Pa of positive pressure relative to the surrounding area. These control parameters should be monitored and maintained throughout the test period.

The ventilation air flow rate depends upon the scale of the chamber that is used to perform the test. Specifications in product specific test methods should be followed.

Measurement of Background VOC Concentrations

Chamber background VOC concentrations should be measured within 1 week prior to the initiation of a test. The chamber should be configured and operated exactly as it will be operated for the corresponding test, but without the test specimen. Before collecting the background samples, the chamber should be operated at the specified test conditions for a minimum of three full air changes. This removes approximately 95% of the background contamination that may have been introduced when the chamber door was open, stabilizes test parameters, and creates a near-steady-state condition for the collection of air samples. Following this purge, air samples for the analysis of VOCs and aldehydes should be collected using procedures identical to those used for the collection of test samples except that it is acceptable to use single samples rather than duplicate samples. The samples should be analyzed to confirm that chamber background VOC concentrations meet the criteria. If background concentrations exceed these criteria, investigate the cause, eliminate the source(s) of contamination, and repeat the background measurement before proceeding with the test. The measured background concentration of any component is denoted as C_{bk} , and is used in data analysis. The chamber should be operated continuously after the background sample is collected and prior to initiating the test. Chamber conditions should be monitored with the data acquisition system throughout this period.

Unpackaging and Transfer of Test Piece to Chamber

The objective is to remove the test piece from its factory packaging, perform any specimen preparation and assembly operations, and transfer the test piece into the chamber as quickly as possible. Supply airflow into the chamber should be maintained during transfer to reduce intrusion of laboratory air. The required dimensional measurements may be made at this time if they can be accomplished within the specified time limit or the measurements may be made at the conclusion of the test. The sequence and details of these operations depend upon the scale of the test:

- For a workstation system, unpack the workstation components outside the chamber and then immediately move them into the chamber for assembly. Complete the entire assembly process within 6 h or less. During this time, operate the chamber at the specified air flow rate and temperature/humidity conditions recognizing that opening of the chamber door and the presence of workers in the chamber will alter these conditions. Installers should not use greasy tools and should wear disposable clean room booties to minimize contamination.
- For workstation components, individual furniture items, and seating, unpack the test piece outside the chamber. Perform all required assembly operations within one hour or less and then immediately place the piece into the chamber.

- Prepare the specimen of a component assembly or component material within 1 h including sealing the edges of the boards.

Place Test Specimen in Chamber

For workstations, workstation components, individual furniture items, component assembly, component material, and seating units, the test piece should be assembled following the manufacturer's instructions so that its components and parts are in their correct orientations and relative positions. The test piece should be located in the center of the full- or mid-scale chamber so that air inlets and outlets are not obstructed and there is at least a 0.4-m air space between the piece and chamber walls. Adjustable feet on components should be set so the bottom edges are approximately 2 cm above the chamber floor. Seating should be placed in an upright position with feet resting on the chamber floor. All workstation and component doors and drawers should be closed for testing. For small-scale chamber tests, the prepared specimen should be placed inside chamber and supported on a stainless steel stand (e.g., three supports each 0.64 cm diameter or less) or rack to minimize the contact area so that all intended emitting surfaces are exposed to chamber air. Photographically recording the installation is recommended.

Record Time Zero

The chamber door should be closed and sealed immediately after installing/loading the test piece. This marks the initiation of the test and the time should be recorded as Time Zero for the test.

Collect Air Samples

Duplicate VOC samples and duplicate aldehyde samples should be collected at 72 and 168 h elapsed time after the initiation of a test. Additional air samples may be taken during or beyond the 7-day elapsed time period to meet other objectives. For example, if a test is conducted to determine if a workstation system would comply with emission criteria specified at day 14, one may extend the test period to 14 days. Two different methods for air sampling and chemical analysis of VOCs are utilized. Air samples for the analysis of TVOC and individual VOCs including higher molecular weight aldehydes are collected on sorbent tubes and are analyzed by thermal desorption (TD)-GC/MS. Air samples for the analysis of low molecular weight aldehydes (e.g., formaldehyde and acetaldehyde) are collected on chemically treated cartridges and are analyzed by HPLC. Refer to ANSI/BIFMA M7.1 (BIFMA International 2011a) for more specific guidance on VOC and aldehyde samplers, sampling flow rates and volumes, and sampling procedure.

Perform Chemical Analysis

VOC sorbent samplers are analyzed for individual VOCs and total VOCs (TVOC) by two-stage, thermal desorption GC/MS (TD-GC/MS). Aldehyde samplers are analyzed for formaldehyde, other individual aldehydes, and total aldehydes by HPLC. Generally, the VOCs (including aldehydes) of interest are those organic chemicals in the volatile range that either are used in the production of furniture or

are present as residuals in component materials. Selection of the specific chemicals or chemical classes to be measured is dictated by acceptance criteria for furniture VOC emissions, for example the criteria specified in ANSI/BIFMA X7.1 (BIFMA International 2011b). Other criteria may be established by government agencies, certification bodies, customers, etc., as discussed in section “[Establishing the Link Between Chamber Testing and Real Applications](#)”. Refer to ANSI/BIFMA M7.1 (BIFMA International 2011a) for more specific directions on TD-GC/MS and HPLC analyses.

Unloading and Background Verification

The test specimen should be removed after the last air sample has been taken, and the chamber air be purged for three air changes. An air sample should be taken from the chamber exhaust. If the concentration of the selected VOCs exceeds 15% of the minimum concentration measured during the test, the problem should be identified and corrected, and the test should be repeated.

Data Analysis and Interpretation

It usually includes the calculation of concentration of chamber air and emission rates of the test specimen (also called chamber source emission rates), and the quantities required for compliance of the established criteria in relevant labeling and certification programs. For example, ANSI/BIFMA M7.1 (BIFMA International 2011a) includes multiple paths to qualify for low-emission product labels, and requires the following data analyses:

Chamber Concentration

Individual VOCs (including individual aldehydes) and TVOC chamber concentrations are calculated by:

$$C_{\text{chamber}}(t_i) = \frac{m(t_i)}{V_s} - C_{bk} \quad (7)$$

where, $C_{\text{chamber}}(t_i)$ is chamber concentration of the compound at time t_i , $\mu\text{g}/\text{m}^3$; $m(t_i)$ is mass amount measured, μg ; t_i is elapsed time from Time Zero; V_s is sampling volume (equal to the air sampling airflow rate times the air sampling period), m^3 ; and C_{bk} is background concentration of the compound in the chamber measured before the test, $\mu\text{g}/\text{m}^3$. In the BIFMA M7.1, the concentrations at $t_1 = 72$ h and $t_2 = 168$ h are calculated as the averages of the duplicate air samples, and denoted as $C(t_1)$ and $C(t_2)$, respectively.

Chamber Source Emission Rate

Workstation systems, workstation components, individual furniture items (including seating units) and their materials can be treated as sources with a constant or near-

constant emission rate after the initial (72 h) conditioning period. The chamber source emission rates are calculated by:

$$R_{\text{chamber}}(t_i) = Q_{\text{chamber}} \times C_{\text{chamber}}(t_i) \quad (8)$$

where, $R_{\text{chamber}}(t_i)$ is chamber source emission rate at time t_i , $\mu\text{g}/\text{h}$; Q_{chamber} is chamber clean air supply flow rate, m^3/h ; and $C_{\text{chamber}}(t_i)$ is concentration of the compound at time t_i , $\mu\text{g}/\text{m}^3$. This calculation applies to individual aldehydes, including formaldehyde.

Chamber Emission Factor

Individual VOC (including individual aldehydes) and TVOC chamber emission factors are calculated by:

$$E(t_i) = \frac{R_{\text{chamber}}(t_i)}{A_{\text{chamber}}} \quad (9)$$

where, $E(t_i)$ is emission factor at time t_i , $\mu\text{g}/(\text{unit h})$, $\mu\text{g}/(\text{m h})$, $\mu\text{g}/(\text{m}^2 \text{ h})$, $\mu\text{g}/(\text{m}^3 \text{ h})$, and $\mu\text{g}/(\text{kg h})$ for unit, line, area, volume, and mass sources, respectively; $R_{\text{chamber}}(t_i)$ is chamber source emission rate at time t_i , $\mu\text{g}/\text{h}$; and A_{chamber} is amount of materials/products tested in the chamber, unit, m, m^2 , m^3 , and kg for unit, line, area, volume, or mass emission sources, respectively.

Calculation of Power-Law Model Coefficients

The emission factors for individual VOCs (including individual aldehydes) from $t_1 = 72$ h and $t_2 = 168$ h may be used to determine the two coefficients of a power-law model, which describes the emission factor as a function of time at any point from 72 h to 336 h (14 days):

$$b = \frac{\ln E(t_1) - \ln E(t_2)}{\ln t_1 - \ln t_2} \quad (10)$$

$$a = E(t_1)t_1^b = E(t_2)t_2^b \quad (11)$$

where, $E(t_i)$ is emission factor at time t_i ($i = 1, 2$), $\mu\text{g}/(\text{unit h})$, $\mu\text{g}/(\text{m h})$, $\mu\text{g}/(\text{m}^2 \text{ h})$, $\mu\text{g}/(\text{m}^3 \text{ h})$, and $\mu\text{g}/(\text{kg h})$ for unit, line, area, volume, and mass sources, respectively; $t_1 = 72$, h; and $t_2 = 168$, h. The procedure described above is adopted because it is simpler to use and provides sufficient accuracy. If more air samples are taken between 72 and 168 h, regression analysis can also be used to determine a and b . Users should refer to ASTM Guide D6670 (ASTM International 2018a) for the detailed calculation procedure.

Determinations of Compliance

Determinations of compliance for workstations, workstation components, or individual furniture items should be made using the open plan and/or private office standard

environments, depending on the product type, application, and intended use. Determinations of compliance for seating units should be made using the seating standard environment. The choice of which standard environment(s) to use for compliance is specified by the requestor (typically the product manufacturer). The parameters of the standard office environments for estimating the impact of workstations, workstation components (including seating units), and individual furniture items on the VOC concentrations in office spaces are summarized in Table 2. BIFMA M7.1 (BIFMA International 2011a) includes three approaches to determine compliance:

1. Estimated Building Concentration Compliance Approach.
 - For a complete standard workstation or complete seating unit tested in whole, the estimated building concentration of each relevant VOC (including individual aldehydes, total aldehydes, and TVOC) should be calculated by:

$$C_{\text{bldg}}(t) = \frac{A_o E(t)}{Q_o} \quad (12)$$

where $C_{\text{bldg}}(t)$ is estimated building concentration of the compound at time t , $\mu\text{g}/\text{m}^3$; t is any time point between 72 h and 336 h, including 72 and 336 h; A_o is 1 workstation or seating unit; $E(t)$ is the emission factor calculated from the direct measurements (Eq. 9) or by the power-law model (Eqs. 4, 10, and 11); $Q_o = 15.0 \text{ m}^3/\text{h}$ (i.e., 4.17 L/s or 8.84 cfm) for the standard open plan office environment, or $Q_o = 34.6 \text{ m}^3/\text{h}$ (i.e., 9.63 L/s or 20.4 cfm) for the standard private office environment, or $Q_o = 24.9 \text{ m}^3/\text{h}$ (i.e., 6.89 L/s or 14.6 cfm) for a seating unit as defined in Table 2.

- For a standard workstation, where several workstation components are tested independently, the estimated building concentration of each relevant VOC (including individual aldehydes, total aldehydes, and TVOC) should be calculated by:

$$C_{\text{bldg}}(t) = \frac{\sum_i^n A_i E_i(t)}{Q_o} \quad (13)$$

where n is the number of workstation components in the standard workstation; A_i is the number of i workstation components used in the standard workstation system (e.g., one file cabinet is tested but workstation contains two identical file cabinets, so $A_i = 2$ “units”); $E_i(t)$ is the emission factor i workstation component; and Q_o is the ventilation rate for the standard open plan office environment, or the standard private office environment, as defined in Table 2.

2. Emission Factor Compliance Approach. When VOC emissions compliance requirements are specified as maximum concentration limits under standard

conditions (i.e., airflow rates and standard source quantities in “units,” surface area, volume, or mass), the concentration limits may be converted to emission factor limits by:

$$E_{\max}(t) = \frac{Q_{\text{std}}}{A_{\text{std}}} C_{\max}(t) \quad (14)$$

where $E_{\max}(t)$ is Emission Factor Limit at time t , $\mu\text{g}/(\text{“unit” h})$, $\mu\text{g}/(\text{m h})$, $\mu\text{g}/(\text{m}^2 \text{ h})$, $\mu\text{g}/(\text{m}^3 \text{ h})$, and $\mu\text{g}/(\text{kg h})$ for unit, line, area, volume, and mass sources, respectively; Q_{std} is standard airflow (ventilation) rate defined with $C_{\max}(t)$, m^3/h ; $C_{\max}(t)$ is maximum allowable concentration of the compound under the standard conditions at time t , $\mu\text{g}/\text{m}^3$; and A_{std} is standard source amount defined with $C_{\max}(t)$, “unit,” m , m^2 , m^3 , and kg for “unit,” line, area, volume, and mass sources, respectively. The emission factors directly measured from the chamber testing (Eq. 9) or predicted by the power-law model (Eqs. 4, 10, and 11) are then compared with $E_{\max}(t)$ used to determine if compliance is achieved for the workstations, workstation components, or individual furniture items tested in whole.

3. Scaling from Component Assemblies. Small-scale (or larger) chamber test results of component assemblies may be used to determine if a workstation system, workstation components, or individual furniture items (including seating units) are compliant with the VOC emissions concentration or emission factor requirements of a given standard such as ANSI/BIFMA X7.1 (BIFMA International 2011b). The following procedure should be used:

- (a) Analyze the design, materials, and construction of the product to identify all component assemblies of the product and the exposed material area, A_i , source amount of each component assembly in the finished product state. When demonstrating compliance for a workstation using the building concentration approach, the material areas should be for the workstation components identified when establishing the standard workstation(s) (refer to ANSI/BIFMA M7.1 (BIFMA International 2011a) for specific definitions of typical types of workstations).
- (b) Test a representative sample of each component assembly and determine the emission factor, $E(t)$ for each compound and for the identified source type (i.e., face, edge, etc.) of each component assembly.
- (c) Calculate the emission rate for each component assembly in the fully assembled product state by:

$$R_i(t) = A_i E_i(t) \quad (15)$$

where $R_i(t)$ is emission rate of the component assembly in the fully assembled product state for the compound of interest at time t , $\mu\text{g}/\text{h}$ or $\mu\text{mol}/\text{h}$.

- (d) For each compound of interest, calculate the sum of the emission rates from all component assemblies in the product (i.e., workstation, workstation component, individual furniture item, or seating unit), as the total emission rate of the product, R_{tot} ; in $\mu\text{g}/\text{h}$ or $\mu\text{mol}/\text{h}$, i.e.,

$$R_{\text{tot}}(t) = \sum_i^n R_i(t) \quad (16)$$

- (e) Determine compliance for a workstation, workstation component, or seating unit by calculating the estimated building concentration for each compound of interest by:

$$C_{\text{bldg}}(t) = \frac{R_{\text{tot}}(t)}{Q_o} \quad (17)$$

where $C_{\text{bldg}}(t)$ is estimated building concentration for the compound of interest at time t , $\mu\text{g}/\text{m}^3$ to be compared with the limits set in relevant labeling or certification programs for compliance.

4. Substitution of Component Assemblies or Materials. Emission test results for component assemblies may be used to assess if an alternative component assembly would result in a significant change of the emissions from a product (i.e., workstation, workstation component, individual furniture item, or seating unit). Assuming that a product has an original/reference emission factor of $E_{\text{original}}(t)$, and a component assembly with an emission factor of $E_{i_original}(t)$ is replaced by an alternative component assembly with an emission factor of $E_{i_alternative}(t)$, the VOC concentrations due to emissions from the revised product with the alternative assembly may be calculated by:

$$C(t) = \frac{E_{\text{original}}(t) - A_{i_original}E_{i_original} + A_{i_alternative}E_{i_alternative}}{Q_o} \quad (18)$$

where $A_{i_original}$ and $A_{i_alternative}$ are, respectively, the amount of the original and alternative component assembly material used in complete furniture or seating unit, m^2 . Application of this method requires that the original component assembly be tested separately, ideally at the same time the product is tested to minimize material variations. It may be tested at a later time if the materials have not changed. The approach may be used for screening of component materials (such as fabric, fiberglass, foam, particleboard with or without surface finish, etc.) to identify the relative potential impact of alternative component materials on the emissions of the product or component assembly. The results of this approach may be used to identify which component material may be tested as part of a product or component assembly to represent more than one possible alternative material.

Establishing the Link Between Chamber Testing and Real Applications

Overview of the Process

Low VOC-emitting product criteria are included in many green or healthy building rating systems, purchasing programs, and sometimes government regulations. Multiple steps are involved for designating compliant products based on chamber testing of a single or group of product samples. Figure 4 shows a schematic program that highlights this process.

Guidance documents or standards are developed first by governmental bodies or standard development organizations, which specify the selection of representative product samples, the chamber (or other laboratory) testing method, the exposure modeling scenario, and the acceptance criteria for chemicals of concern and their maximum allowable concentrations. They also often include the quality assurance and accreditation requirements of testing laboratories (i.e., accredited to ISO 17025 (ISO 2017)) and certification bodies (i.e., accredited to ISO 17065 (ISO 2012)). Not all components are required in a single guidance or standard. The requirements on chamber testing and the evaluation schemes (or acceptance criteria) can be integrated into one document or be kept separately. Additionally, some standard set the acceptance criteria directly based on the VOC emissions factors (EFs, in units of mg/h·m²) obtained from chamber testing without defining a modeling scenario.

Based on a guidance or standard chosen depending on the region and product category, companies (or manufacturers) can test representative samples of their products to demonstrate they meet the acceptance criteria and then make product claims. This is most often accomplished by participating in a third-party labeling/

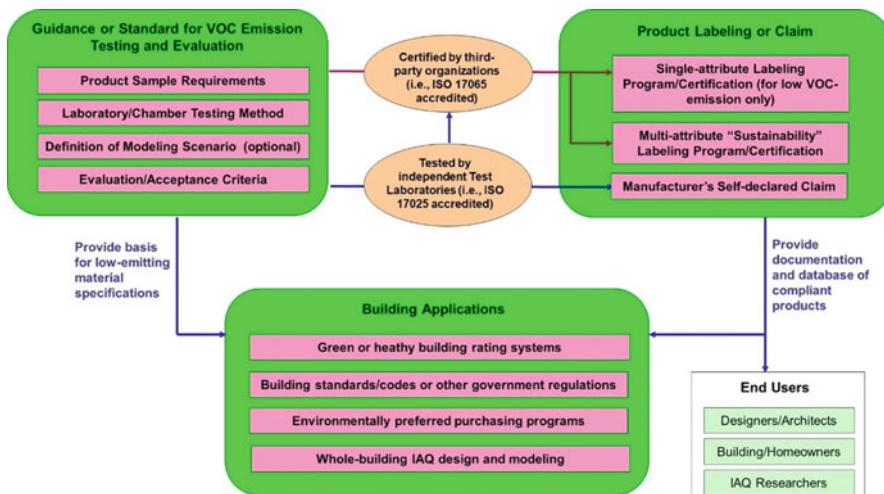

Fig. 4 Schematic diagram for designating low-emitting products in building applications

certification program. Alternatively, the manufacturers can also make their own first-party declaration if they assume full responsibility for their product claims (i.e., based on ISO 14021 (ISO 2016)). Regardless of the type of labeling or claim, a big challenge is always to keep the process (or information) transparent and to make the documentation (including actual emission test data) of low-emitting products more readily accessible to architectural projects and other end users.

Finally, the low VOC-emitting products need to be specified for use in real building applications and their IAQ benefits need to be demonstrated and documented. Although participation is voluntary, the green or healthy building rating systems that provide low-emitting material (LEM) credits for using such products seem to be the largest market-driven force for this purpose (McArthur and Powell 2020). Most of these rating systems directly specify the guidance/standards used for VOC testing and evaluation in their credit language. Some LEM requirements have also been written into government regulations, purchasing programs, and building codes, making the compliance mandatory. For example, many countries have established regulatory formaldehyde emission requirements for composite-wood-based products.

Standard Methods, Evaluation Criteria, and Labeling Schemes

Various standards and guidance documents have been developed in different regions/countries and for different product categories. The environmental chamber testing methodology and the method for determining VOC EFs are similar in these documents and have been discussed thoroughly in section “[Standard Environmental Chamber Testing Methods and Procedure](#)”. However, the target VOCs differ and the time points specified for reporting VOC EFs also vary. As for the evaluation criteria, some guidance and labeling schemes directly compare the reported VOC EFs to acceptable EF levels. Others convert the measured EFs into estimated airborne VOC concentrations by applying a mass balance for a defined modeling scenario. The modeling scenario here refers to a standardized single room (or a house if it can be considered as a single well-mixed zone) with a set of defined parameters (e.g., room dimensions, air change rate, and product loadings) that are typical or representative for the products being considered. These estimated VOC concentrations are then compared to existing occupant inhalation exposure reference values where such guidance is available. Both the modeling scenario definition and the inhalation exposure reference values can vary among different guidance and labeling schemes. Table 4 compares major standards and labeling schemes in the USA, Europe, and Asia and illustrates how they differ in the above-discussed features. Although not included in Table 4, other types of standards that are not based on environmental chamber testing (e.g., flask, perforator, or desiccator method) are also available for quantifying formaldehyde emissions from wood-based products. The formaldehyde emissions measured with these test methods have shown some correlations with chamber testing results. The variations can be explained by differences in test conditions and sample treatments (Rishholm-Sundman et al. 2007).

Table 4 Examples of VOC emission testing and evaluation methods and labeling schemes in the USA, Europe, and Asia

		Descriptions		If criteria based on estimated VOC concentrations		Applicable product category	
Document title	Region or country	Target chemicals of concern	Time point for reporting EFs	Acceptable EF levels if criteria directly based on VOC EFs	Modeling room definition	Acceptable reference exposure levels	
CDPH SM v1.2, 2017 (CDPH 2017)	USA	A list of 35 individual VOCs with CRELs; additionally, ten VOCs having the highest EFs (most abundant VOCs) need to be quantified	At day 14 (including 10-day conditioning period)	N/A	Private office (30.6 m ³ , 0.68 ACH) or school classroom (231 m ³ , 0.82 ACH); voluntary whole-house (547 m ³ , 0.23 ACH)	≤CREL (9 µg/m ³ or 7.3 ppb) for formaldehyde; ≤1/2 of the CREL for all other VOCs	Building materials (general)
ANSI/BIFMA M7.1, 2011 (R2016) (BIFMA International 2011a)	USA	N/A	At day 3 (72 h) and day 7 (168 h)	N/A	Open plan workstation (16.3 m ³ , 0.92 ACH); Private office (34.68 m ³ , 0.53 ACH)	N/A	Furniture and seating

ANSI/BIFMA X7.1, 2011 (R2016) (BIFMA International 2011b)	USA	Formaldehyde, 4-Phenylcyclohexene (PCH), total aldehydes, TVOC	At day 7 (168 h)	N/A	Reference room defined in ANSI/BIFMA M7.1, 2011 (R2016)	Workstation Systems: formaldehyde ≤ 50 ppb, 4-PCH ≤ 0.0065 mg/m ³ , total aldehydes ≤ 100 ppb, TVOC ≤ 0.5 mg/m ³ ; Seating: one half of the above threshold values	Furniture and seating
ANSI/BIFMA e3, 2019 (BIFMA International 2019)	USA	A list of 30 individual VOCs (including formaldehyde), 4-PCH, total aldehydes, TVOC	At day 7 and day 14 (modeled)	N/A	Reference room defined in ANSI/BIFMA M7.1, 2011 (R2016)	Workstation Systems: Credit 7.6.1: same as BIFMA X7.1; Credit 7.6.2: same as CDPH SM v1.2 (except formaldehyde ≤ 13.5 ppb plus 1-Methyl-2-pyrrolidinone ≤ 350 μ g/m ³ ; Credit 7.6.3: formaldehyde ≤ 7.3 ppb; Seating: one half of the above threshold values	Furniture and seating
EN 16516:2018 (European Collaborative Action 2018)	EU	N/A	At day 28 or at both day 3 and 28	N/A	Reference room (30 m ³ , 0.5 ACH)	N/A	Building materials (general)

(continued)

Table 4 (continued)

Document title	Region or country	Target chemicals of concern	Time point for reporting EFs	Descriptions		If criteria based on estimated VOC concentrations	Applicable product category
				Acceptable EF levels if criteria directly based on VOC EFs	Modeling room definition		
AgBB, 2018 (Committee for Health-related Evaluation of Building Products 2018)	Germany	TVOC, TSVOC, carcinogenic substances in EU categories 1A and 1B, a list of individual VVOC, VOC, and SVOC with LCIs, odorous VOCs subject to sensory testing (optional)	At day 3 and 28	N/A	Reference room defined in EN 16516: 2018	At day 3: TVOC $\leq 10 \text{ mg/m}^3$; carcinogenic substances in EU categories 1A and 1B $\leq 0.01 \text{ mg/m}^3$. At day 28: TVOC $\leq 1 \text{ mg/m}^3$, TSVOC $\leq 0.1 \text{ mg/m}^3$, carcinogenic substances in EU categories 1A and 1B $\leq 0.001 \text{ mg/m}^3$; individual VVOC, VOC, and SVOC with listed LCIs: $R = \text{sum of } (C_i / LCI_i) \leq 1$; sum of VOCs with unknown LCIs $\leq 0.1 \text{ mg/m}^3$	Building materials (general)

M1 (The Building Information Foundation RTS 1996)	Finland	TVOC, formaldehyde, ammonia, carcinogenic compounds (IARC category 1), odor (dissatisfaction with odor below 15% is deemed as “no odor”)	At day 28	TVOC (mg/m ² ·h): <0.2 for M1, <0.4 for M2, and >0.4 for M3; formaldehyde (mg/m ² ·h): <0.05 for M1, <0.125 for M2, and >0.125 for M3; ammonia (mg/m ² ·h): <0.03 for M1, <0.06 for M2, and >0.06 for M3; carcinogenic compounds (mg/m ² ·h): <0.005 for M1 and M2; no odor for M1 and M2.	N/A	N/A	Building materials (general)
French VOC Label (ANSES 2016)	France	A list of ten individual VOCs and TVOC	At day 28	N/A	Reference room defined in EN 16516: 2018	VOC emissions classes are categorized as “A+,” “A,” “B,” and “C” (see the regulation document for details of allowable concentrations of individual VOCs and TVOC for each class)	Building materials (general)
GB 18580-2017 (Standardization Administration of China 2017a)	China	Formaldehyde	After reaching steady state, at most 28 days	Formaldehyde (mg/m ² ·h): <0.124 ^a in GB 18580, <0.12 ^a in China environmental label	N/A	N/A	Building material (wood-based panels and products)

Eco-label 172 (according to KS I ISO 16000-9) (Ministry of Environment of Korea 2017)	Korea	Formaldehyde, toluene, VOCs	At day 7	Formaldehyde (mg/m ² ·h): <0.12, toluene (mg/m ² ·h): <0.080, VOCs (mg/m ² ·h): <0.4	N/A	N/A	Furniture
Green Label (Singapore Environment Council 2013)	Singapore	Formaldehyde, TVOC	After reaching steady state	Formaldehyde (mg/m ² ·h): <0.063 ^a for hardwood plywood wall paneling, 0.141 ^a for particleboard panel, 0.229 ^a for medium density fiberboard, 0.462 ^a for particleboard door core, TVOC (mg/m ² ·h): <0.5	N/A	N/A	Furniture and wood products

^aThe standard for building materials directly specifies the allowable VOC concentration in the test chamber and the reported EF is calculated based on $EF = Q \times C/A$, where Q is the ventilation rate (m³/h), C is the allowable concentration in the chamber (mg/m³), A is the emission area (m²)

^bThe standard for wooden furniture directly specifies the allowable VOC concentration in the test chamber and the reported EF is calculated based on $EF = Q \times C/V$, where Q is the ventilation rate (m³/h), C is the allowable concentration in the chamber (mg/m³), V is the volume of furniture (m³)

Product Labeling Programs

Numerous labeling programs exist. The first labeling program that focused on VOC emission from indoor materials was Blue Angel in Germany initiated in 1978 (Federal Ministry for the Environment 2021). In the 1990s, various labeling programs began to appear in Europe, such as M1 and AgBB. (Committee for Health-related Evaluation of Building Products 2018; The Building Information Foundation RTS 1996) The labeling programs in the USA started from 2000, such as BIFMA. (BIFMA International 2011a) Recently, labeling programs also developed very quickly in Asian countries, including Japan, Korea, China, and Singapore. Some labeling programs mentioned above are single attribute, focusing only on VOC emission, while others are multi-attribute “environmentally preferable” (or “sustainability”) programs with more comprehensive health and environment components including VOC emission evaluation as prerequisites or credit options. A labeling program can be owned or managed by government agencies, nonprofit environmental advocacy organizations, or private sector entities, while the testing and certifications for VOC content or emission are often provided by third-party organizations and independent testing laboratories.

The labeling programs and the availability of products that are evaluated and certified by these programs mostly depend on the region/country. The national product evaluation and certification programs for low-emitting materials in the USA, Europe, and Asia have been summarized in previous research (Levin 2010; Willem and Singer 2010). Although these programs continue to evolve, the general process and underlying principles remain similar over the past decade.

Application in Building Rating Systems

Many green or healthy building rating systems provide LEM credits for products with low VOC contents or emissions. McArthur and Powell (McArthur and Powell 2020) systematically reviewed these rating systems available in today's market. They found that almost all rating systems prohibit or prescribe strict limits of VOCs within the indoor environment, with a strong focus on source elimination through the selection of low-emitting products.

The LEED rating system, which is probably the most widely used globally today, is analyzed here. In the latest version of LEED v4.1 (U. S. Green Building Council 2020), there are eight product categories eligible for LEM credits, including Paints & Coatings, Adhesives & Sealants, Flooring, Wall panels, Ceilings, Insulation, Furniture, and Composite wood. The general VOC emissions evaluations for building materials are all based on the CDPH Standard Method v1.2 (2017) (CDPH 2017). The furniture VOC emission evaluations are based on ANSI/BIFMA M7.1–2011 (R2016) (BIFMA International 2011a) and ANSI/BIFMA e3-2019e (BIFMA International 2019). The criteria for formaldehyde emission from composite wood products are based on EPA Toxic Substances Control Act, Formaldehyde Emission Standards for Composite Wood Products (U. S. EPA 2016) or California Air Resources Board (CARB) Airborne Toxic

Control Measure (CARB 2008). Besides VOC emissions, the VOC content requirements for paints, coatings, adhesives, and sealants are also included, which are based on California regulations (CARB 2007; SCAQMD 2016, 2017). Without more complex IAQ modeling, the number of credits given is then simply determined based on the quantity of products in compliance with the above specified standards/regulations, either as the percent of cost or surface area (for dry materials and furniture) or as the percent of volume or surface area (for web-applied products). Considering the feasibility of implementation, the threshold ranges for compliance are set as $\geq 75\text{--}\geq 90\%$ of total product quantities depending on the product category. Overall, the LEED system provides a good example of how to specify LEM credits based on the standard methods and government regulations for product evaluation.

Whole Building Approach for Modeling the Impact of Product Emission on IAQ

In the above-mentioned labeling and green building rating systems, product emission data are obtained under standardized test conditions and the indoor air VOC concentrations are estimated based on a simplified single room model (e.g., the reference room defined in EN 16516 (European Collaborative Action 2018) or the private office and classroom scenarios defined in CDPH Standard Method v1.2 (CDPH 2017)). The actual impact of product VOC emissions on IAQ in real buildings, however, can be much more complex due to the use of multiple materials with different loading factors, the building source/sink characteristics, and the variation of environmental conditions such as temperature and relative humidity. Predicting such impacts will need a whole building/house approach using appropriate IAQ simulation tools and with accessible VOC emission database of various types of products. An example implementation of this approach using either prescriptive index or performance index has been demonstrated in a recently published Chinese technical standard for interior decoration pollution control of residential buildings (Ministry of Housing and Urban-Rural Development of China 2018).

Various IAQ simulation programs have been developed over the last 30 years. Some programs (e.g., MEDB-IAQ) focus only on modeling the impact of VOC emission and include embedded material emission data base (Zhang et al. 1999a). Others are more comprehensive models that are able to estimate building concentration levels of various contaminants (e.g., CONTAM) (Dols and Polidoro 2015) or combine further with building energy modeling. However, they often require additional effort from the user to identify appropriate material emission rates (for empirical models) or derived characteristic emission parameters (for mechanistic VOC emission models) as inputs. Although product emission tests are common practice today, detailed information on VOC emission rates and emission parameters is generally not publicly available due to the nondisclosure agreements between the testing laboratories/labeling programs and product manufacturers (Willem and Singer 2010). Efforts of developing openly accessible product emission database

have been made by multiple research groups. A series of databases were identified in the International Energy Agency's Annex 68 (Rode et al. 2019). Further efforts are needed to establish more comprehensive and regularly maintained databases and to better assess the effectiveness of source control strategies on whole-building IAQ starting from the design stage.

Application Examples

A few more commonly used standards or guidance procedures are briefly discussed below:

ANSI/BIFMA e3 Furniture Sustainability Standard and ANSI/BIFMA M7.1 and X7.1

ANSI/BIFMA e3 Furniture Sustainability Standard (BIFMA International 2019) is a voluntary standard intended to provide measurable market-based definitions of progressively more sustainable furniture by establishing performance criteria addressing environmental and social impacts throughout the supply chain. It addresses product-based characteristics in the general areas of environmental, health and wellness, and social impacts. The standard was designed to allow for multiple levels of achievement and to provide an open alternative to proprietary protocols. It references ANSI/BIFMA M7.1 and X7.1 standards (BIFMA International 2011a, b) for testing and determining compliance regarding VOC emissions from office furniture systems, components, and seating.

CDPH Standard Method v1.2

In the USA, the CDPH Standard Method V1.2 (2017) (also known as Section 01350) is a widely used voluntary guideline for testing and evaluation of VOC emissions for building materials in the USA (CDPH 2017). It applies to all major building material categories including paints and coatings, adhesives and sealants, flooring (i.e., hard surface flooring and carpet), wall panels, ceilings, and insulation. This standard method covers all the steps necessary for a product evaluation, including selection of representative product samples, description of environmental chamber testing method, definition of modeling scenarios and acceptance criteria, and establishment of claims for compliant products. In this standard, the VOC measurements after 14 days (including a 10-day precondition period in a conditioning chamber followed by a 96-h test period in a test chamber at more precisely controlled conditions) are used to determine the acceptance of a product. The maximum allowable concentrations for chemicals of concern are based on the CRELs developed by OEHHA, which are solely based on health considerations. A list of certifications and labeling programs that use this method can be found on the website of CDPH IAQ program (CDPH 2019).

EN 16516 Test Method with EU-LCI Values or German AgBB Evaluation Scheme

In Europe, different countries have different guidance documents and labeling schemes (see Table 4). As part of the European Collaborative Action (ECA), efforts have been made to harmonize the chamber emission testing method (European Collaborative Action 2018), the indoor material labeling schemes (Kephalaopoulos et al. 2005), and the health-based evaluation using the European Union (EU) Lowest Concentration of Interest (LCI) concept (Kephalaopoulos et al. 2013). The EN 16516 testing method together with the EU-LCI values or German AgBB evaluation scheme seem to be the most widely used and recognized by building rate systems such as LEED and WELL for projects out of the USA. EN 16516 measures VOC emissions after 28 days (or after both 3 and 28 days depending on the legislation) in an environmental test chamber and defines a reference room for modeling indoor air VOC concentrations. The EU-LCI values are then used for assessing the acceptance of a product based on its emissions after 28 days. These EU-LCI values are health-based and are considered likely not to cause adverse effects over the longer term by use of the model room as a reference. German AgBB uses the same LCI values, but includes additional evaluation criteria on TVOC, TSVOC, as well as carcinogenic substances in EU categories 1A and 1B (Committee for Health-related Evaluation of Building Products 2018).

VOC Emission Testing and Labeling Systems in China

There are three important voluntary labeling systems concerning building materials and furniture in China: environmental labeling, ecolabeling, and green product labeling. The environmental labeling is the most widely used. It applies China's national standard GB 18580 (Standardization Administration of China 2017a) to test the formaldehyde emission from wooden panels and products (Ministry of Ecology and Environment of China 2010), which requires that the material be conditioned in a ventilated chamber until stable (usually very slowly decreasing) concentrations in the chamber are achieved to measure the concentrations of formaldehyde. Additionally, the environmental labeling requires that the material be conditioned in a ventilated chamber for 72 h before measuring the concentrations of TVOC. The measured concentrations are multiplied by the clean air supply flow rate to the chamber to obtain the emission rates for TVOC and formaldehyde, respectively. The limit of emission rate in this labeling is stricter than the national standard itself. Content-based limits are also provided in this labeling for wallpapers, coatings, and adhesives. Additionally, this labeling system requires that wooden furniture use the wooden panels, coatings, and adhesives that meet the above requirements, instead of directly testing the emission from furniture in the chamber as a whole (Ministry of Ecology and Environment of China 2016).

The ecolabeling system is established by China Quality Certification Centre. This label regulates that wooden furniture should satisfy China's national standard GB 18584 (Standardization Administration of China 2001), which employs the

desiccator method (China Quality Certification Center 2018). The formaldehyde concentration absorbed into water after 24-h emission in a closed desiccator is used to determine whether the furniture is acceptable. Unlike environmental chamber testing, the desiccator method only tests the emission characteristics of small pieces of materials cut from the whole furniture and cannot provide the emission rate of the whole furniture. Therefore, GB 18584 is under revision and will be changed into emission chamber test method as well. Other new national standards for furniture in China, such as GB/T 38723 (Standardization Administration of China 2020), are also based on chamber method to acquire the emission rate of furniture.

The last labeling system is the China green product labeling proposed in 2018. The green product labeling conforms to another Chinese national standard GB/T 35601 (Standardization Administration of China 2017b) to limit the VOC emission from building materials. The testing method for formaldehyde is the same as that in China environmental labeling, but this label additionally focuses on benzene, toluene, xylene, and TVOC emitted from building materials. The final concentrations of these four pollutants in the chamber after 72 h are used to evaluate the emission rates of building materials. For furniture, the green product label demands that the furniture is directly exposed in a ventilated chamber for 20 h after 120-h pre-conditioning, according to GB/T 35607. (Standardization Administration of China 2017c) This is the only label for furniture in China that tests the emission characteristic of the whole furniture directly.

Unlike the USA and Europe, there have been no available testing standards and labels based on the estimated VOC concentration in a modeling room in China. To overcome this shortcoming, Liu et al. (Liu et al. 2013) proposed a labeling system for VOC emission from furniture based on reference rooms. Via a survey of 1500 homes in Beijing, they established a reference bedroom and a reference living room with the information of furniture type and loading factor. Later, C-history method (Xiong et al. 2011; Zhang et al. 2018) is recommended to obtain the emission characteristic parameters of the furniture rapidly. At last, the predicted VOC concentration in the reference room due to emission from furniture is compared with the national standard on indoor air quality in China, GB/T 18883 (National Health Commission of China 2002), to evaluate whether this furniture can qualify for the label. This labeling method takes the association between furniture and realistic indoor environment into account. It suggests a new direction for developing standard and labeling system in China.

Eco Mark Labeling System in Japan

In Japan, Eco Mark is one of the most widely used labeling system for building materials and furniture (Japan Environmental Association 2019). This label limits the formaldehyde emission from furniture and wood materials via two methods. The first is the desiccator method, which requires placing the material or part of the furniture in a closed desiccator for 24 h and then measuring the amount of formaldehyde absorbed into water at the bottom of the desiccator (Japanese Standards

Association 2021). The allowable limit value for this label (i.e., 0.3 mg/L average and 0.4 mg/L maximum) is much stricter than China (<1.5 mg/L) (Standardization Administration of China 2001). Another method is the chamber method, which allows the material to emit formaldehyde in a ventilated chamber for 28 days (Japanese Standards Association 2015). The limit of formaldehyde emission rate is set as 5 $\mu\text{g}/\text{m}^2\cdot\text{h}$. Applying the same chamber method, Eco Mark also restricts the emission rate of benzene, toluene, ethylbenzene, and styrene from adhesives or coatings used in furniture. Similarly, an alternative content-based standard is given for these four VOCs in the adhesives or coatings.

Concluding Remarks and Future Outlook

The environmental chamber test method for testing VOCs emissions from building materials and furniture has been well established. It has been applied to various labeling, certification, and compliance programs to significantly reduce the indoor pollution loads resulting from material emissions over the last 30 years. The threshold values of area-specific emission rates (either directly specified or derived from the specified concentration threshold values, ventilation rate, and surface area) in various emission standards or labeling and certification programs can be used as the upper limit of indoor pollution loads for IAQ design of green buildings and healthy buildings.

The target VOCs and their threshold values are expected to change over time as the understanding of the impact of VOC mixtures as well as individual VOCs improves or as product formulations or manufacturing processes change. Retesting of products (e.g., every 2–3 years when no changes are made in the manufacturing process) is necessary for keeping low-emission certification up-to-date.

While the principles of environmental chamber testing are universal, the way they are applied in product-specific testing standards and labeling and certification programs vary among countries. Harmonization of the test methods and programs or establishing equivalencies or correlations among them will help international collaboration and trading on low-emitting products.

Standard chamber testing of material emissions generates useful data for design and helps drive the development and application of low-emitting products. However, it does not provide sufficient information to estimate the impact of environmental conditions (temperature, humidity, and airflows) on the pollution loads, nor does it provide long-term predictions on the impact of the VOC emissions on IAQ. A model-based testing and evaluation approach is needed. In such an approach, mechanistic models of emissions are established with their parameters determined by standardized tests (Zhang et al. 2019). For example, the VOC emissions from dry or dried building materials can be represented by in-material diffusion to material surface and then by convective mass transfer to the air. Assuming uniform distribution of VOCs in the material, the diffusion and convective mass transfer processes are governed by the Fick's Law of diffusion and convective mass transfer principle with four model parameters: the initial concentration in the material (C_{m0}), the

diffusion coefficient (D_m), the partition coefficient (i.e., the ratio between material phase and air phase concentration at equilibrium, K_{ma}), and the convective mass transfer coefficient (k_m) (Zhang et al. 1999c). k_m depends on the airflow conditions above the material surface, which is a constant for a given chamber or room condition. C_{m0} , D_m , and K_{ma} can hence be used to fully characterize an emission source. China Healthy Building Assessment Standard adopted an apparent C_{m0} , D_m , and K_{ma} approach and used software (Hu et al. 2007; Xu and Zhang 2003) to determine if the VOC emissions are below the established criteria. As part of the IEA Annex 68 effort, a procedure has been developed to estimate the apparent C_{m0} , D_m , and K_{ma} from the emission data obtained from the standard environmental chamber tests (Liu et al. 2021). The mechanistic models for predicting emissions under material usage conditions should also account for the effects of local air temperature, relative humidity, airflow, and material aging on the emission rates. Further efforts are needed to establish universal guidance/standards for the model-based testing and evaluation and to apply it for better assessing the effectiveness of source control strategy in real applications.

In addition to VOCs emissions from building materials and indoor furnishings, IAQ analysis and design are needed to consider chemical emissions from occupants (bio-effluents) and occupant activities, and secondary emissions resulting from ozone initiated indoor air and surface chemistries, which can also be investigated using environmental chambers. In such investigations, it is necessary to include realistic settings of ventilation, material usage, and environmental conditions to test the combined effects of primary and secondary emissions on IAQ.

Abstract

Ventilation is to provide unconditioned outdoor air or conditioned, combined, outdoor, and recirculated air for suitable indoor comfort and acceptable air quality. Ventilation can be categorized into natural ventilation, mechanical ventilation, and their hybrid form. Due to the pros and cons of each ventilation mode, a ventilation mode may suit to a pertinent indoor space in a specific climate region or location. The purpose of this chapter is to examine the impacts of ventilation modes on indoor air quality in different indoor spaces, such as residential buildings, office buildings, and transportation vehicle cabins with the dense commercial aircraft cabin as an example. The evaluated ventilation modes include natural ventilation, mechanical ventilation, and the occasional hybrid ventilation. The mechanical ventilation is further divided into mixing ventilation, displacement ventilation, stratum ventilation, and personalized ventilation in an office building or aircraft cabin. Ventilation of residential buildings in the situation with outdoor PM_{2.5} pollution has been systematically addressed. The indoor air quality performance in terms of ventilation rate, concentrations of CO₂, formaldehyde, TVOC, and PM_{2.5} was evaluated. In addition to indoor air quality, the possible airborne infection transmission, thermal comfort, energy consumption, and affordability of each ventilation mode have also been examined.

Keywords

Natural ventilation · Mechanical ventilation · Residential building · Office building · Transportation vehicle cabin

Introduction

Ventilation is to displace the polluted air indoors to the outside and deliver fresh air into indoor space to maintain a healthy and comfortable environment. Generally, ventilation can be classified as “natural ventilation,” “mechanical ventilation,” or their combination as “hybrid ventilation.” Natural ventilation relies on natural forces like the wind from the surrounding environment as well as buoyancy forces that develop due to temperature gradients within the building. In natural ventilation, outdoor air flows into a building through planned openings (such as louvers, doors, and windows) or unplanned cracks or holes. Mechanical ventilation is driven by fans. Mechanical ventilation systems may include supply fans (which push outdoor air into a building), exhaust fans (which draw air out of the building), or a combination of both (which thereby cause equal ventilation flow into a building).

Natural ventilation is generally thought to be able to reduce energy usage in buildings, benefiting from passive cooling. The acceptable thermal comfort range for naturally ventilated buildings is significantly larger than that for buildings with mechanical heating, ventilating, and air-conditioning (HVAC) systems (De and Brager 2002; Yu et al. 2012). Furthermore, natural ventilation has been shown

being able to reduce sick building syndrome (SBS). However, natural ventilation is nearly uncontrollable and thus unable to provide ventilation at an exact demanding rate and in the expected time. The natural ventilation is subject to the climate region, terrain, surrounding buildings, the studied building geometry, ventilation opening shape, size, and direction, as well as the occupant behaviors (Lai et al. 2018a, b). Note that natural ventilation is unsuited to noisy, polluted, or harsh climate regions.

In contrast, mechanical ventilation is robust and can nearly be applied where power is available. Mechanical ventilation rates are nearly independent of outdoor climates. Most mechanical ventilation systems are designed with fixed ventilation rates that shall satisfy the typical ventilation demand. Except for simplified mechanical ventilation for providing only the unconditioned outdoor air or only exhausting the internal air, a more advanced mechanical ventilation system or HVAC system is welcomed in recent years, which can simultaneously heat, cool, humidify, or dehumidify the ventilated air and even filtrate particles or deodorize. The HVAC system requires devices and thus involves certain initial investment. The running expense of an HVAC system is not trivial for both operating energy consumption and dis-functional component replacement.

Even if a building is installed with mechanical ventilation systems, the mechanical ventilation can also be turned off during the transitional seasons for energy conservation if the windows are openable. This forms switching between natural and mechanical ventilation and hence constitutes hybrid ventilation (Cho et al. 2020). Either the manual or automatic switch of the ventilation mode can be used. The automatic switch requires sophisticated sensors and actuators. The hybrid ventilation may help reduce building energy consumption without sacrificing indoor air quality (Rey-Hernández et al. 2020; Gomis et al. 2020). Hybrid ventilation can set natural ventilation as the priority mode. Once the natural ventilation cannot assure indoor air quality or thermal comfort, then the mechanical ventilation is turned on. It was claimed that hybrid ventilation in residential buildings can reduce the cooling load but not cut much the utility costs (Zhang et al. 2018).

The purpose of this chapter is to evaluate the impacts of ventilation on indoor air quality in residential buildings, office buildings, and transportation vehicle cabins. Most residential buildings adopt natural ventilation by infiltration and opening windows/doors. Some residential buildings also use mechanical ventilation for the rigorous demand of outdoor air. The residents may sometimes switch the mechanical ventilation and natural ventilation for hybrid use. Hence, the impacts of three different ventilation modes on indoor air quality are evaluated in residential buildings. Most office buildings use mechanical ventilation, though natural ventilation may occasionally be utilized in some countries. Various forms of mechanical ventilation modes are examined in office buildings. Transportation vehicles such as trains and airplanes use only mechanical ventilation, and thus only mechanical ventilation is addressed in transportation vehicle cabins. In addition to indoor air quality, the airborne infection risk, thermal comfort, energy consumption, running expense, and the initial investment of each ventilation mode have also been examined.

Residential Building

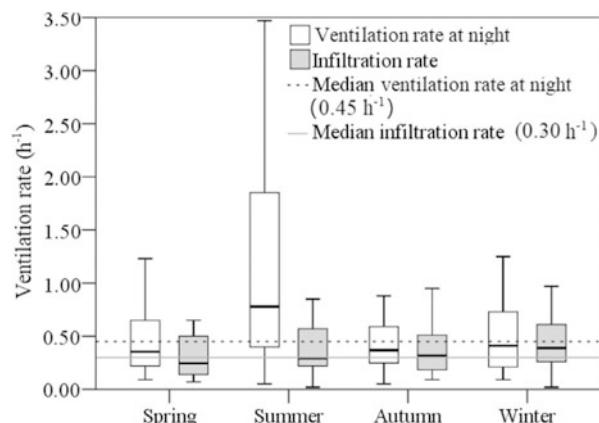

According to ANSI/ASHRAE Standard 62.2-2014 (ASHRAE 2014), single, detached residential buildings are required to meet a whole-house ventilation rate based on the number of bedrooms in the house, the number of occupants, in addition to the infiltration. There are a variety of ways to meet this standard, either by natural ventilation or mechanical systems.

Natural Ventilation

Natural ventilation is the most widely used ventilation in residential buildings. Many homes rely on infiltration for background ventilation and open windows to provide increased ventilation when needed. Note that the discussion is limited to natural ventilation by infiltration and opening windows/doors. It does not include designed natural ventilation with designed variable openings. Infiltration means that outdoor air enters the room through gaps in the building envelope due to the difference in the sum of the wind and stack pressures between the indoor and outdoor. No window or door is opened when evaluating the infiltration rate. The residents tend to close windows and doors when encountering harsh climate or heavy outdoor air pollution. A recent survey (Sun et al. 2019) shows that the median infiltration rate of 294 apartments in China was only 0.30 h^{-1} , as shown in Fig. 1, which is lower than the recommended air change per hour (ACH) of 0.5 h^{-1} (Dimitroulopoulou 2012) for sufficient ventilation of homes. Because most residents tend to close windows during the nighttime with only the infiltration allowed, 90% of the surveyed Chinese bedrooms were found with insufficient ventilation rate (Dai et al. 2018). This implies that the infiltration may not assure acceptable indoor air quality.

On average, residents in China keep their windows open for one-third of the time. The occupants use natural ventilation when the outdoor air temperature is between

Fig. 1 Ventilation rates at night (without intervention regarding windows and doors opening) and infiltration rates (with closed windows and doors) in bedrooms (Sun et al. 2019)

15 °C and 26 °C (Lai et al. 2018a, b). When the outdoor air temperature is out of this range, people tend to close windows (Hou et al. 2018). Figure 2 illustrates the association between outdoor air temperature and opened windows at night in different climate zones in China. The window opening varies greatly with the outdoor air temperatures and climate zones. According to Liddament (2001), windows are most likely to be opened under the following conditions: sunny days, higher occupant density, higher outdoor temperature, low wind speed, during cleaning or cooking activities, and when smoking. That is, the windows are opened when residents feel they need ventilation. However, there are many circumstances when opening a window is not practical, such as with noise, rain or high winds, outdoor pollutants, cold drafts, privacy, security and safety issues, and energy loss, or the window may be difficult to operate. This suggests that window opening or closing is not always in response to ventilation needs. Even with the opened windows, natural ventilation may still not provide sufficient outdoor air to dilute the hourly average indoor CO₂ concentration below 1000 ppm. Song et al. (2019) claimed that the indoor hourly average CO₂ concentration was above 1000 ppm in 40–54% of the total occupied time and varied with the city in different climate zones, as shown in Table 1. The outdoor air rate will be further insufficient once the window is closed due to a couple of reasons (Zhao et al. 2018). The high CO₂ concentration is very common in bedrooms in China, especially in the cold climate zone. In winter,

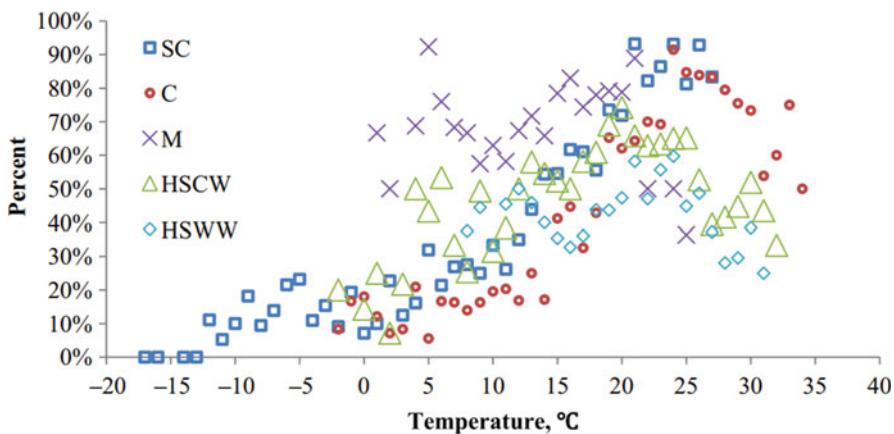

Fig. 2 Percentage of opened windows at night in 46 homes versus the outdoor air temperatures (C, cold zone; HSCW, hot summer, and cold winter zone; HSWW, hot summer, and warm winter zone; M, mild zone; and SC, severe cold zone) (Lai et al. 2018a, b)

Table 1 Time ratios of the hourly average indoor CO₂ concentrations above 1000 ppm for the apartment in a city with different climate zones when adopting natural ventilation (Song et al. 2019)

Item	Shenyang	Tianjin	Chengdu	Shenzhen	Kunming
Time ratio of CO ₂ ≥ 1000 ppm (%)	54	53	43	44	40

severe outdoor environmental conditions prevent occupants from opening windows at night. When occupants sleep with only the infiltration, the CO₂ concentration often reaches extremely high levels in the morning.

Note that the metabolic CO₂ is innocuous. However, the high concentration of CO₂ may indicate insufficient ventilation to dilute chemical pollutants, because unqualified building materials and furniture may emit poisonous gases, such as formaldehyde and other harmful volatile organic compounds (VOCs) (Yin et al. 2019). The formaldehyde was found to contribute to increased risk of asthma, allergies, airway diseases, and sick building syndrome symptoms as well (Doi et al. 2003; Garrett et al. 1999; Wieslander et al. 1996). The maximum allowable formaldehyde concentration was 0.10 mg/m³ for the Chinese threshold (GB/T 18883-2002, 2002). The survey showed that more than 69.4% of all the newly built or decorated housing from 2002 to 2004 in China had indoor formaldehyde concentrations exceeding the Chinese-specified value (Tang et al. 2009). The median indoor formaldehyde concentration after renovation from 2002 to 2015 in homes of Chinese cities was 125 µg/m³, which is still above the Chinese threshold (Huang et al. 2017). Generally, low ventilation rates in residential buildings would result in elevated concentrations of formaldehyde and VOCs, and an increased prevalence of SBS symptoms (Sun et al. 2019).

Figure 3 illustrates the indoor formaldehyde concentrations in 25 residential buildings in different seasons under normal daily conditions and the condition with closed doors and windows (Yin et al. 2019). The daily median formaldehyde

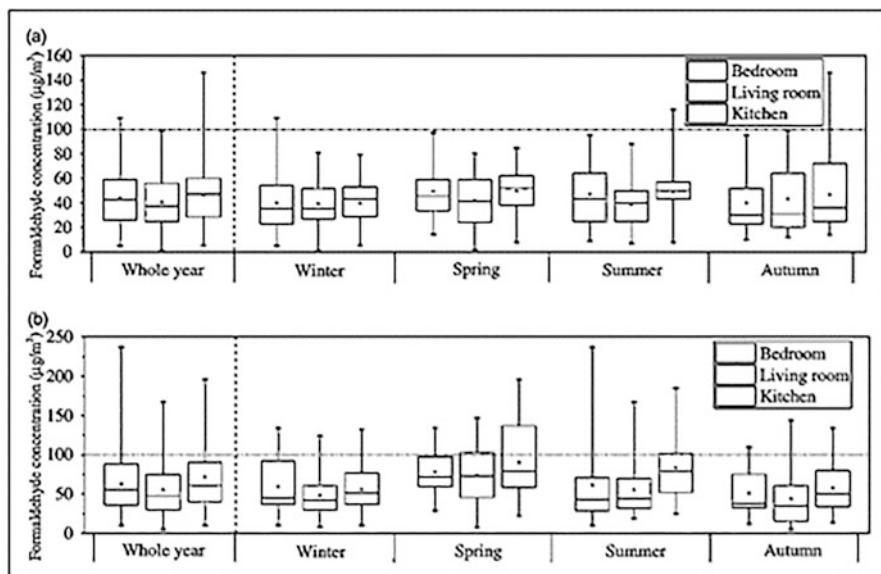

Fig. 3 Indoor formaldehyde concentration of 25 residential buildings in different seasons (the order of the three box plots for each season: bedrooms, living rooms, and kitchen): (a) under the normal daily condition; (b) under the condition with doors and windows closed (modified from Yin et al. 2019)

concentrations in bedrooms, living rooms, and kitchens monitored over four seasons were $42.5 \mu\text{g}/\text{m}^3$, $37.5 \mu\text{g}/\text{m}^3$, and $47.0 \mu\text{g}/\text{m}^3$, respectively. The indoor formaldehyde concentration under the normal daily condition in most naturally ventilated residential buildings in northwestern China can meet the Chinese formaldehyde threshold of $0.10 \text{ mg}/\text{m}^3$ (GB/T 18883-2002, 2002). The ratio of the indoor formaldehyde concentrations between daily and closed conditions in three room types were 0.77, 0.78, and 0.77, respectively. The main difference between these two conditions was that the residents may open windows under the normal daily condition. Natural ventilation with opened windows normally can remove approximately 23% of indoor formaldehyde. Hence, daily natural ventilation is a straightforward approach to reduce indoor formaldehyde exposure.

The indoor formaldehyde concentrations were measured in over 2000 residential buildings (Ye et al. 2017), which included newly decorated homes and not in 22 cities of China. The measured formaldehyde concentration ranges within the first 3 months, 3–6 months, and 6–12 months are $10\text{--}33,300 \mu\text{g}/\text{m}^3$, $10\text{--}1420 \mu\text{g}/\text{m}^3$, and $10\text{--}1620 \mu\text{g}/\text{m}^3$, respectively. Most of the formaldehyde concentrations within the first 6 months exceed the 30-minute average concentration guideline of $100 \mu\text{g}/\text{m}^3$ by the Chinese standard (GB/T 18883-2002, 2002). The peak concentrations keep appearing even for the buildings decorated one year ago. Pei et al. (2020) measured the total VOCs (TVOCs) concentrations in 251 Chinese homes in different seasons. The average TVOCs concentration in China is within the range of $104\text{--}1151 \mu\text{g}/\text{m}^3$. As compared with the specified Chinese TVOCs threshold of $600 \mu\text{g}/\text{m}^3$ (GB/T 18883-2002, 2002), 20% of the residences were over the limit. However, as compared with the $300 \mu\text{g}/\text{m}^3$ limit by ISO17772-1 (2017) for very low pollution buildings, up to 48% of the residences were unqualified (Fig. 4).

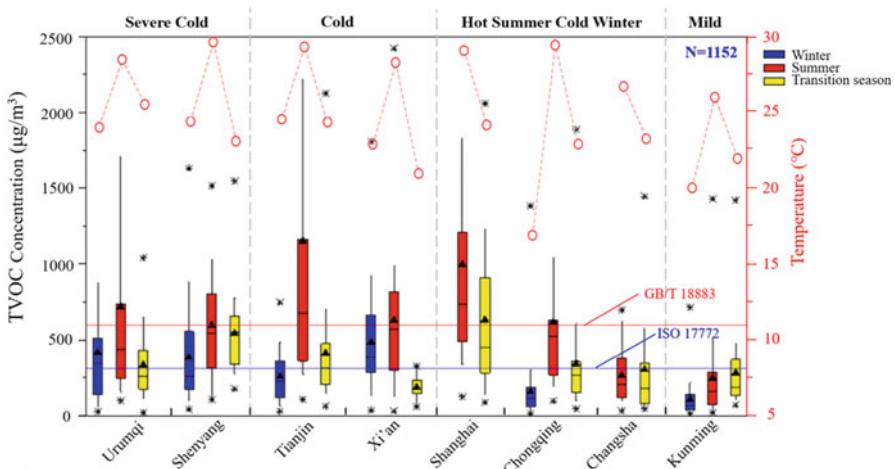

Fig. 4 TVOCs concentrations and average temperatures of surveyed Chinese cities in different seasons. Note: Each boxplot represents the minimum, 10th, 25th, 50th, 75th, 90th, and maximum concentration (Pei et al. 2020)

The outdoor air in developing countries, such as in China, is sometimes polluted with exceeding PM_{2.5} concentrations in the last decade. On severely polluted days, the outdoor PM_{2.5} concentrations in several major cities in China could be three to ten times that in cities of developed countries, such as London, Tokyo, and New York (Cao et al. 2016). In situations with outdoor PM_{2.5} pollution, the outdoor air cannot be directly introduced to residential buildings for ventilation. An onsite monitoring study (Dai et al. 2018) shows that only approximately 2% of the Chinese homes in 2017 maintained indoor PM_{2.5} concentrations below 75 µg/m³. In about half of the homes, more than 10% of days exhibited whole-day averaged PM_{2.5} concentrations higher than 75 µg/m³. No homes maintained indoor PM_{2.5} concentrations below 25 µg/m³. Another study (Zhao et al. 2018) shows that nearly half of the time in winter from 2017 to 2018, the outdoor PM_{2.5} concentrations in Tianjin, China, were above 35 µg/m³. During this period, natural ventilation cannot be used.

Natural ventilation is theoretically unhealthy to use in areas with severe outdoor pollution unless the indoor air has been properly cleaned. Taking PM_{2.5} pollution in China in 2016 as an example, without indoor particulate filtration, the indoor PM_{2.5} concentrations were above 35 µg/m³ in more than 39% of the total occupied time in Shenyang, Tianjin, and Chengdu in China (Song et al. 2019). Indoor particle filtration is an affordable solution to indoor PM_{2.5} pollution. A combination of natural ventilation and portable demand-controlled particulate filtration has the lowest operating cost (Zhao et al. 2018). The ratio of clean air delivery rate (CADR) to room volume (h⁻¹), which can be considered as an equivalent air change rate, has an impact on the indoor particle concentrations (Ye et al. 2017). The CADR-to-room volume ratio (an “equivalent air change rate”), together with the CADR, needs both to be accounted for when selecting air cleaners or implementing natural ventilation of residential buildings.

Pros and Cons of Natural Ventilation

Natural ventilation is simple, energy-saving, and economic. In addition, natural ventilation can provide a high ventilation rate to displace indoor pollutants if the outdoor air is clean, the outdoor wind is strong enough, and buildings have large openings. Therefore, it is suggested to utilize natural ventilation when the outdoor environment is favorable.

However, natural ventilation is varied and depends on outside climatic conditions. It is unstable and not fully under control. The ventilation cannot be provided with the exact demanding rate at the expected time. Furthermore, in the situation with outdoor PM_{2.5} pollution, the natural ventilation may bring too much outdoor particulate matters to indoor space, which worsens indoor air quality. Therefore, pure natural ventilation cannot completely guarantee good indoor air quality.

Mechanical Ventilation

There are a variety of mechanical ventilation systems for the residential building, including exhaust ventilation, supply ventilation, and balanced ventilation systems,

as shown in Fig. 5. Any of these may be in continuous operation or operated intermittently, they may have single-port or multiports, or the system may be integrated into an existing HVAC system. A properly designed mechanical ventilation system in a residential building provides a reliable, controllable, and probably comfortable indoor environment. However, the operation of mechanical ventilation consumes energy and may generate noise. It also has a much higher initial investment cost and would involve nontrivial expense for dis-functional component replacement.

Generally, mechanical ventilation can maintain relatively good indoor air quality. The PM_{2.5} concentration was measured by Zhao et al. (2018) in a naturally ventilated dwelling, a naturally ventilated dwelling with an air cleaner, and a mechanically ventilated dwelling, respectively. They found that pure natural ventilation could not maintain acceptable indoor air quality when the outdoor PM_{2.5} concentration is high, as shown in Fig. 6. An air cleaner must be in operation to filtrate the indoor PM_{2.5}. The finding is consistent with the conclusion by Zhang et al. (2018) that indoor particulate filtration must be utilized in northern Chinese dwellings during the outdoor PM_{2.5} pollution season. The mechanical ventilation system with particle filtration in ducts prevented the entry of outdoor particles, but it could not remove the cooking-generated pollution well. Filtrating the recirculated air inside the home is more energy-efficient, because of lower pressure resistance when recirculating air than introducing the outdoor air. There is no substantial difference in the indoor PM_{2.5} concentrations with the same CADR between the introduced outdoor air filtration and the recirculated air filtration.

Although the indoor air quality in the dwellings with mechanical ventilation is generally better than those in the naturally ventilated dwellings, residents may not

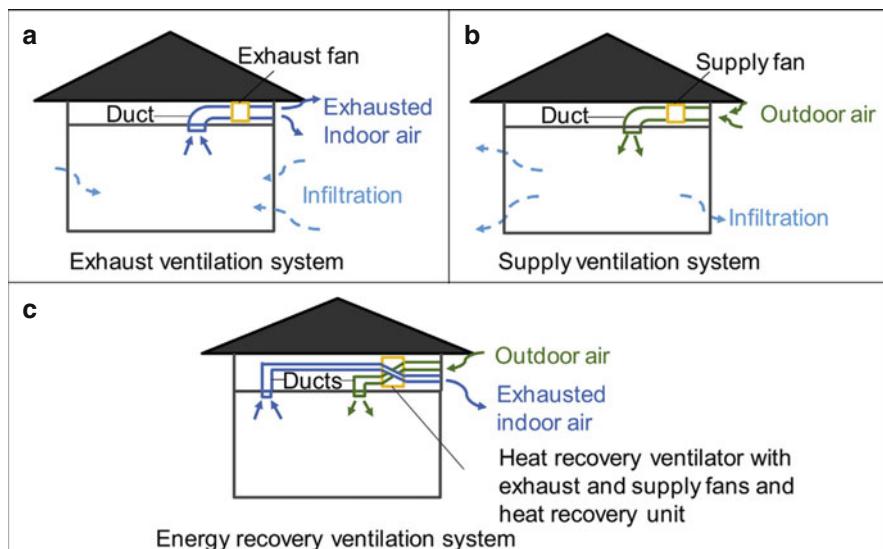

Fig. 5 Schematics of mechanical ventilation for residential buildings: (a) exhaust ventilation; (b) supply ventilation; and (c) balanced ventilation (Lai et al. 2018a, b)

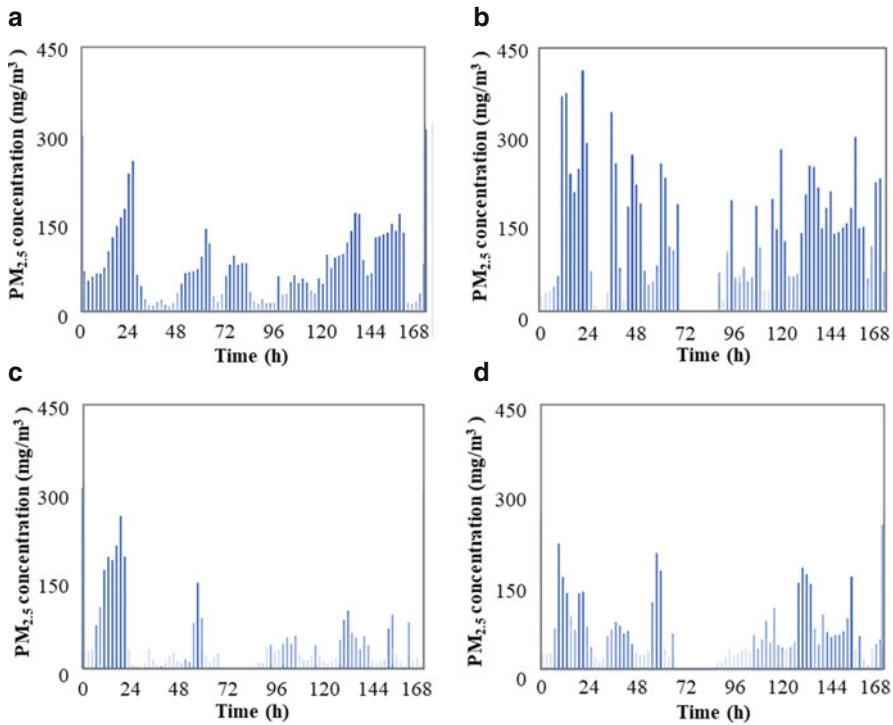

Fig. 6 Two-hour average PM_{2.5} concentration of: (a) the outdoor air; (b) the indoor air with natural ventilation; (c) the indoor air with natural ventilation plus air purifier; and (d) the indoor air with mechanical ventilation (Zhao et al. 2018)

continuously run the mechanical ventilation due to the energy costs and thermal comfort concerns (Lai et al. 2018a, b). The average daily running duration of mechanical ventilation generally decreases with the daily average outdoor air temperature. Energy saving is a possible reason for the reduction of the running hours of mechanical ventilation. When the outdoor air temperature is mild, people prefer natural ventilation over mechanical ventilation. There are large differences in the running time of the mechanical ventilation among different climate regions and seasons. From north to south in China, the running hour of mechanical ventilation decreases. The mechanical ventilation running duration is the longest in winter and the shortest in summer. Generally, occupants prioritized their thermal comfort needs over indoor air quality. The type of mechanical ventilation system also impacts the running hours. The occupants would turn off the simple outdoor air blower without temperature conditioning or set it to the minimum air rate in the bedroom during nighttime. The noise is another reason to make it hard to be accepted (Zhao et al. 2018).

Most current household mechanical ventilation uses the so-called centralized system, i.e., a single system to ventilate the whole family. That is, if any of the rooms is occupied, the system must be turned on to ventilate all of the rooms.

Contrarily, the decentralized mechanical ventilation operates only during the occupied period for a specific room so that it has a great potential to cut utility costs (Zhang et al. 2018). Furthermore, the mechanical ventilation in demand-controlled operation and its hybrid with natural ventilation can reduce energy consumption. Most household mechanical ventilation has indoor air overfiltrated because the CADR is usually designed to handle the most polluted situations. Song et al. (2019) compared the energy consumption, and utility bill, using different ventilation modes in nearly the same residential apartments located in five cities in different climatic zones of China, as shown in Table 2. They found that natural ventilation without indoor particulate filtration uses the least energy and is the cheapest. Indoor particulate filtration does not consume much energy. Mechanical ventilation together with indoor particulate filtration uses the most energy and is the most expensive. Similarly, Zhao et al. (2018) reported that the daily energy consumption of mechanical ventilation is about 1.5 times that of the natural ventilation with a portable air cleaner.

Pros and Cons of Mechanical Ventilation

Mechanical ventilation is robust to deliver the designed airflow rate and varies little with the outdoor climate. In addition, filtration can be embedded in mechanical ventilation to filtrate airborne particles and dilute indoor chemical pollutants. Furthermore, mechanical ventilation can be nearly applied anywhere with electricity.

However, mechanical ventilation may often work in compromised performance or may occasionally be interrupted due to equipment failure, maintenance, or even poor design, or incorrect management. Initial investment and maintenance costs of mechanical ventilation are high, which may be unaffordable especially in developing countries. Therefore, it is beneficial to combine mechanical ventilation with natural ventilation.

Hybrid Ventilation

Hybrid ventilation has been long recommended to benefit from both natural ventilation and mechanical ventilation. Well-operated hybrid ventilation may help reduce building energy consumption without sacrificing indoor air quality. The hybrid ventilation may set the natural ventilation as the prior mode. Once the natural ventilation cannot assure indoor air quality or thermal comfort, then the mechanical ventilation is turned on, and vice versa.

Hybrid ventilation can provide adequate ventilation rates even when weather conditions are unfavorable due to the use of mechanical ventilation as a backup (Yoshino et al. 2003). However, sophisticated hybrid ventilation requires a controller to switch modes between natural and mechanical ventilation. Thus, an elaborate control system, such as CO₂ sensors, room temperature thermostats, airflow sensors, motorized windows, and even a weather station, may have to be adopted. The rationality of the control logic and accuracy of the intelligent control system have a large influence on the performance of this system.

Table 2 The energy consumption and running cost for the apartment in cities of different climate zones (Song et al. 2019)

City	Ventilation	Heating/kWh	Cooling/kWh	Filtration/kWh	Fan/kWh	Appliances/kWh	Running cost/CNY

Comparing with mechanical ventilation, hybrid ventilation consumes less energy and saves utility costs. However, it may not be always the case for residential buildings. One investigation (Zhang et al. 2018) compared the annual energy consumption and utility bills of natural ventilation, mechanical ventilation, and hybrid ventilation in a northern city in China. The hybrid ventilation was found to have approximately the same heating load, but lower cooling load and mechanical fan energy consumption. This is because hybrid ventilation benefited from the passive cooling of natural ventilation in transitional seasons or nighttime in summer. However, the utility bills of hybrid ventilation were only slightly lower than those of mechanical ventilation. The hybrid ventilation in northern Chinese residential buildings reduces the cooling load but does not cut much the utility costs, as shown in Table 3.

Pros and Cons of Hybrid Ventilation

Hybrid ventilation takes advantage of both natural ventilation and mechanical ventilation. Therefore, hybrid ventilation has the potential to reduce energy consumption without sacrificing indoor air quality.

However, the control system of hybrid ventilation is complex. This adds an extra cost to the system's initial investment and maintenance. In addition, the effectiveness of hybrid ventilation depends on the control logic and accuracy of the sensor. Furthermore, hybrid ventilation in residential buildings may reduce the cooling load but not cut much the utility cost.

Office Building

Office buildings mainly adopt mechanical ventilation. However, in developing countries, natural ventilation may also be used in office buildings. In this section, natural ventilation is discussed a little bit first, while putting a major focus to address

mechanical ventilation in terms of mixing ventilation, displacement ventilation, stratum ventilation, and personalized ventilation, accordingly.

Natural Ventilation

Natural ventilation is also used in office buildings, especially in developing countries. When the outdoor climates are benign, windows and/or doors may be opened for natural ventilation. Otherwise, both windows and doors are closed and heating, cooling, or air-cleaning devices may have to be run to condition the indoor air. The windows and doors may occasionally be opened for intermittent ventilation if the infiltration rate is not sufficient. Natural ventilation has been well summarized in the literature (Chen 2009; Chen et al. 2010). The advantages and disadvantages of natural ventilation in office buildings are similar to those of residential buildings. These have been discussed in section of “[Residential Building](#)” and are thus not repeated here.

Mechanical Ventilation

Comparing with residential buildings, the office building is commonly more crowded. For a continuous and robust ventilation supply, more and more office buildings adopt mechanical ventilation. Like mechanical ventilation for residential buildings, the mechanical ventilation in an office building may also be divided into extract ventilation, supply ventilation, and balance (combined of extract and supply) ventilation (Russell et al. 2007). Modern offices use balance ventilation because airflow patterns between the supply and the extract are controllable. The mechanical balance ventilation can be classified into mixing, displacement, stratum, and personalized ventilation according to the different airflow patterns. Their basic principles and impacts on indoor air quality are addressed as follows.

Mixing Ventilation

Mixing ventilation is one of the earliest mechanical ventilation types. As shown in Fig. 7, conditioned air in mixing ventilation is normally supplied from ceiling diffusers at a relatively high velocity (typically ≥ 1.5 m/s) with a suitable temperature for heating or cooling. The air-supply jet mixes with the ambient room air through entrainment, and the jet speed is reduced. Meanwhile, the conditioned air dilutes the indoor contaminants.

Contaminant concentrations in the occupied zone are relatively uniform in mixing ventilation. In an office, as shown in Fig. 8, the formaldehyde concentration was found relatively uniform in the room with the ceiling-supply and floor-exhaust mixing ventilation (Zhang et al. 2020), though the complete mixing had not reached. Note that the mixing is favorable to thermal comfort but may result in cross mixing of airborne contaminants. There are a couple of standards (CEN Standard 1998; ISO EN 7730 Standard 2005; EN 15251 Standard 2007) and guidebooks (Muller et al. 2013) that addressed mixing ventilation performance.

Fig. 7 Diagram of mixing ventilation in an office

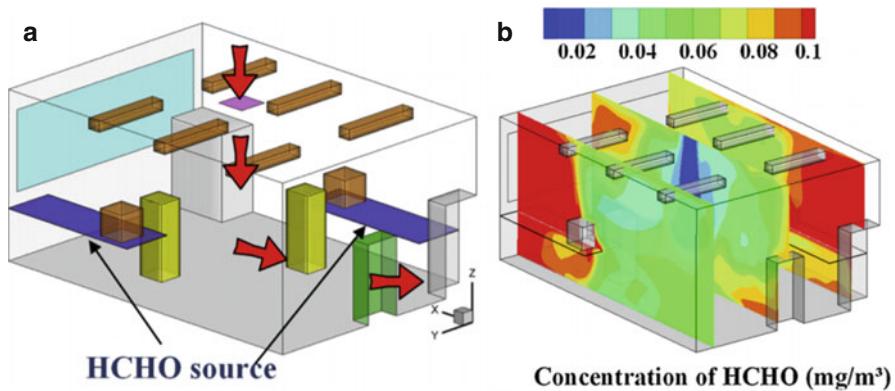

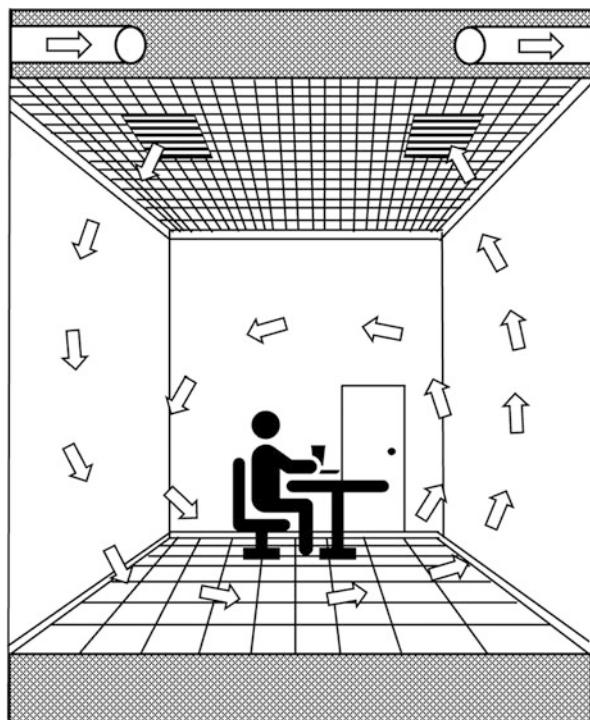

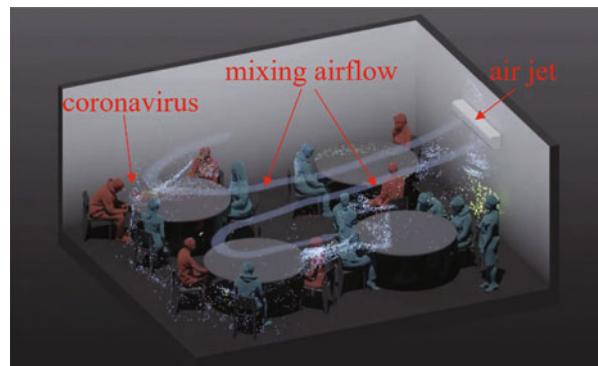

Fig. 8 Simulated formaldehyde concentration in an office with mixing ventilation: (a) office geometry; (b) formaldehyde concentrations on three vertical sections (Zhang et al. 2020)

More critically, mixing ventilation may induce a certain risk of airborne infection transmission. Figure 9 shows the potential spread of coronavirus in a restaurant with an air conditioner (Tom et al. 2020), which somewhat resembles an office case. The computational modeling showed that the exhaled virus particles can move over a

Fig. 9 The potential spread of coronavirus in mixing ventilation (modified from Tom et al. 2020)

long distance in the room, with the infected particles circulating everywhere in the room. The particles might cause inhalation exposure or induce surface touch risk once some particles were deposited to tables or chairs that had high chances for hand touch. To minimize the airborne infection risk, a large ventilation rate of cleaned air is required, so that the virus can be quickly diluted to a sufficiently low concentration. It was claimed that a dilution ratio of over 10,000 is required to prevent airborne infection (Jiang et al. 2009), which may be unaffordable in most operations.

Pros and Cons of Mixing Ventilation

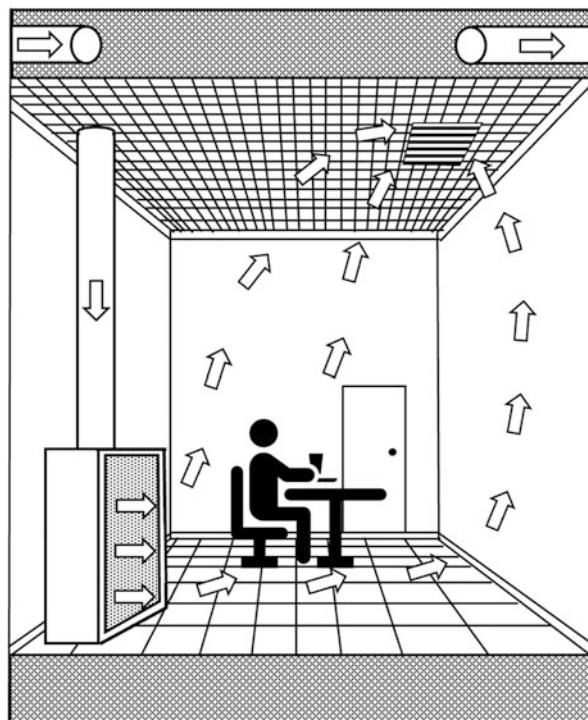

Mixing ventilation promotes a uniform indoor environment. This means the vertical temperature difference between the head and ankles is small, which is welcomed from the perspective of thermal comfort. Additionally, mixing ventilation has a large cooling or heating capacity.

However, mixing ventilation also has some limitations. The conditioned air is mixed before being delivered to the breathing zone, meaning low ventilation effectiveness. Besides, the conditioned air jets with high speed may cause draft risk to occupants.

Displacement Ventilation

Different from mixing ventilation, displacement ventilation supplies conditioned air from a low position while extracting the room air from a high position. Figure 10 shows the diagram of displacement ventilation in an office. Conditioned air is supplied into the room from a wall-mounted diffuser near the floor. The supply air temperature is slightly lower than the desired room air temperature, and the supply air velocity is low (typically $< 0.5 \text{ m/s}$). Due to the low temperature of the supplied air, the supplied air is spread over the floor and then rises as it is heated by some heat sources in the occupied zone. These heat sources (e.g., persons and computers) create upward buoyancy flows toward the exhaust located at or close to the ceiling. Consequently, both air temperature and concentration of airborne pollutants released

Fig. 10 Diagram of displacement ventilation in an office

from the middle height, such as the exhaled pollutant, are stratified. If the indoor space needs heating, a separate heating system, such as baseboard heaters, must be used to allow for a slightly lower temperature of the supplied air than the indoor air. Otherwise, the upward displacement flow would be destroyed. That is, displacement ventilation can only be adopted for cooling rather than heating.

Figure 11 presents the flow path lines of the supplied air in an office with displacement ventilation (Zhang et al. 2010a, b). The supplied air goes downward from the wall-mounted diffuser to the floor, as shown in Fig. 11a. It moves forward until the heat sources or walls, and then goes upward to the ceiling exhaust. Even with the underfloor grilles as shown in Fig. 11b, the upward supplied air goes down first due to the high density of the low-temperature supplied air. The air then moves to the sides and finally goes upward by thermal buoyancy. Figure 12 shows the tracer gas concentration profiles along the height, where the SF₆ gas is released from the head of an occupant. Both CFD simulation and the measurement results show that the tracer gas concentration is stratified with a relatively low concentration in the seated occupational zone and a high concentration near the ceiling. Such concentration stratification is very helpful for reducing airborne pollutant exposure to the occupants. The high concentration near the ceiling improves the pollutant exhaust efficiency. Therefore, from the perspective of indoor air quality, displacement ventilation prevails over mixing ventilation.

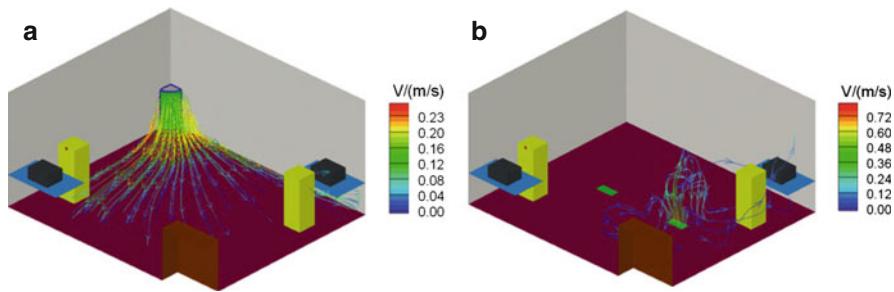

Fig. 11 Flow path lines of displacement ventilation in an office: (a) with a wall-mounted diffuser; (b) with underfloor grilles (Zhang et al. 2010a, b)

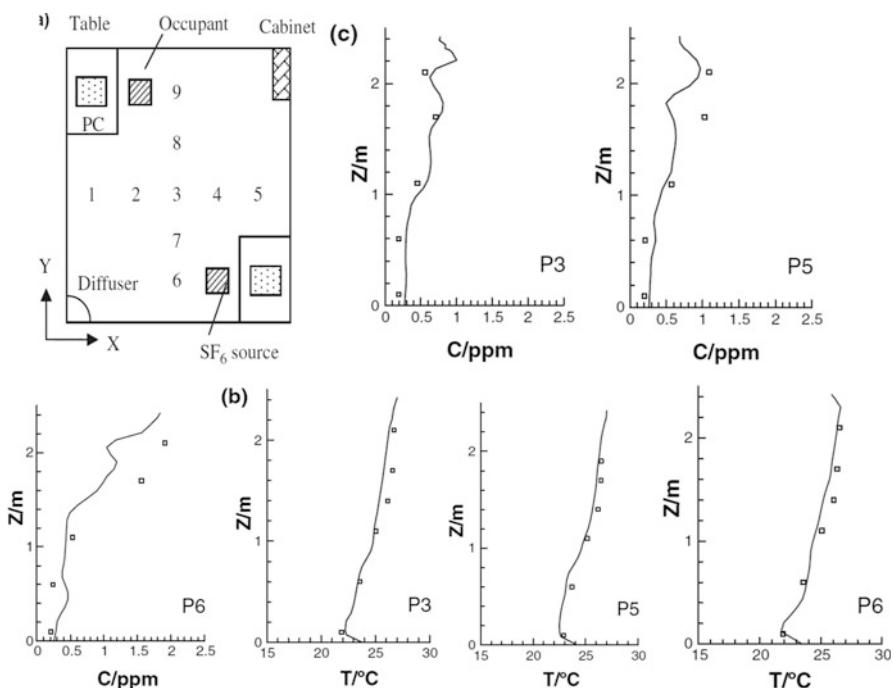

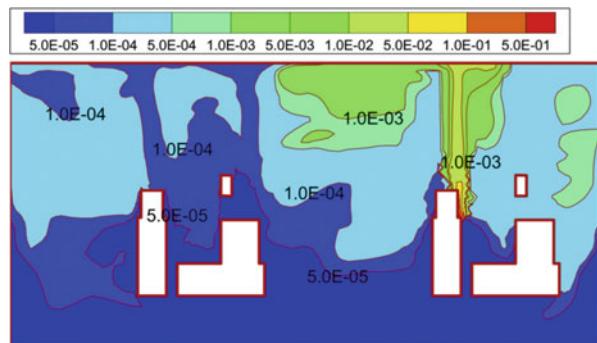

Fig. 12 Vertical profiles of tracer gas concentrations and air temperatures in an office with wall-mounted displacement ventilation, lines for CFD-simulated results, and symbols for the measurement data (Zhang et al. 2010a, b)

Displacement ventilation has also a good performance in reducing airborne infection. Figure 13 shows the concentrations of particles in 0.8 μm in an office with displacement ventilation, in which one patient and one uninfected person shared the office. The exhaled particles from the patient moved upward, which formed a high concentration near the ceiling but a low concentration in the breathing zone. The stratification of particle concentration helps to protect the uninfected

Fig. 13 Particle concentration in a vertical slice in an office with displacement ventilation (He et al. 2011)

person. Thus, the displacement ventilation prevails over the mixing ventilation in minimizing infection from the airborne route.

However, displacement ventilation also creates temperature stratification, with a low temperature near the floor and high temperature near the ceiling. Figure 12 shows that the air temperature profiles resemble the concentration profiles. Indeed, most occupants prefer warm feet and slightly cool head, especially people from east Asia. The temperature gradient along height is one of the most criticized points for displacement ventilation. The ASHRAE Standard 161 (2007) has circumscribed the temperature gradient within 2 °C/m to make displacement ventilation acceptable.

Pros and Cons of Displacement Ventilation

If properly designed, displacement ventilation can take advantage of the contaminants carried by the thermal plumes and thus has a high ventilation efficiency. Furthermore, displacement ventilation maintains a relatively low concentration in the occupied zone for pollutants released from the middle to high heights and thus has a great potential to minimize airborne infection. Moreover, displacement ventilation has also high efficiency in removing heat because of air temperature stratification. The slightly high temperature of the supplied air is also helpful for reducing cooling energy in summer.

The temperature gradient along height is one of the most criticized points of displacement ventilation. In addition, special attention should be paid to the pollutants that are released from the low height or floor, since the displacement ventilation may create mixing similar to the mixing ventilation. Besides, displacement ventilation does not have a large cooling capacity as the mixing ventilation. In heating seasons, separate heating devices are needed to allow for a cool air supply in order not to destroy the upward displacement flow.

Stratum Ventilation

Different from the mixing ventilation with the air supply near or at the ceiling, displacement ventilation with the air supply near or on the floor, the stratum

ventilation supplies air in the middle height and usually near the human breathing zone. Figure 14 shows the diagram of stratum ventilation in an office. Conditioned air is supplied into the room at a high speed (typically 1.2 m/s) from a side wall diffuser in the middle height. The air flows through the working zone and finally to the air exhaust.

Different from displacement ventilation, stratum ventilation can be adopted for either cooling or heating. Figure 15 shows the airflow patterns for heating in an office with stratum ventilation (Zhang et al. 2019). The warm air was directly supplied at a proper downward direction to the occupied zone by configuring the air-supply terminal on walls/columns slightly above the head of occupants. The high-speed conditioned air reaches the occupied zone and then circulates inside the room. The air exhaust outlet is located below the air supply inlet and avoids short-circuiting of warm supply air. Figure 15b shows the CO₂ concentration on a vertical section. The plume flow around the human body is effectively disrupted by the air supply jet. As a result, the exhaled CO₂ is rapidly diluted with a low concentration in the inhaling zone.

Figure 16 presents a case for the stratum ventilation in removing airborne particles in a classroom (Zhang et al. 2012a, b). The air supply was located on the front wall, and the air exhaust was on the back wall. Figure 16b shows the concentration of particles released by one infected student seated in the first row.

Fig. 14 Diagram of stratum ventilation in an office

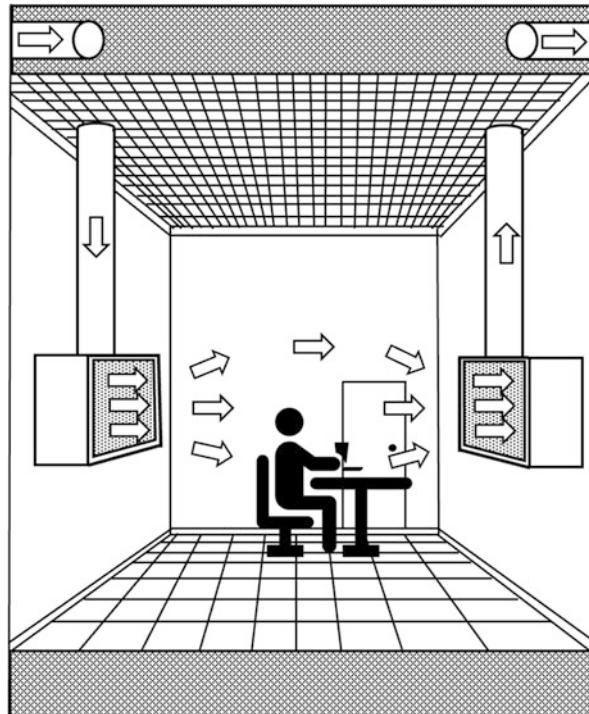

Fig. 15 Air temperature and CO₂ concentration in an office with stratum ventilation: (a) flow path lines and air temperature; (b) CO₂ concentration (Zhang et al. 2019)

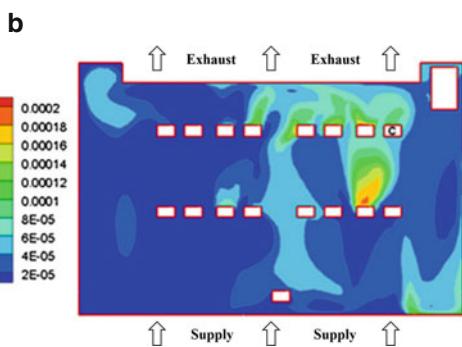

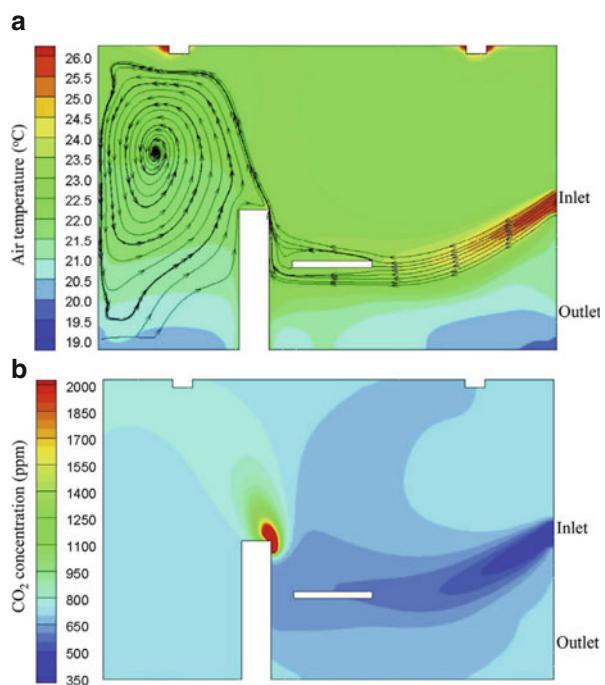

Fig. 16 Droplets concentration in a classroom with stratum ventilation: (a) the investigated classroom; (b) droplet concentration distributions at a horizontal direction near the breathing zone (Zhang et al. 2012a, b)

The whole classroom has a relatively low particle concentration except for the downstream region of the infected student. This indicates that the stratum ventilation may still result in a certain risk of cross-infection unless the infected person sits near the air exhaust.

Because conditioned air is directly delivered to the breathing zone in stratum ventilation, a higher temperature of supply air is required than the mixing ventilation to prevent draft risk. There may be reversed temperature gradient in the occupied zone when cooling the office, i.e., with the low air temperature at the head-chest level but the high temperature at the ankle level.

Pros and Cons of Stratum Ventilation

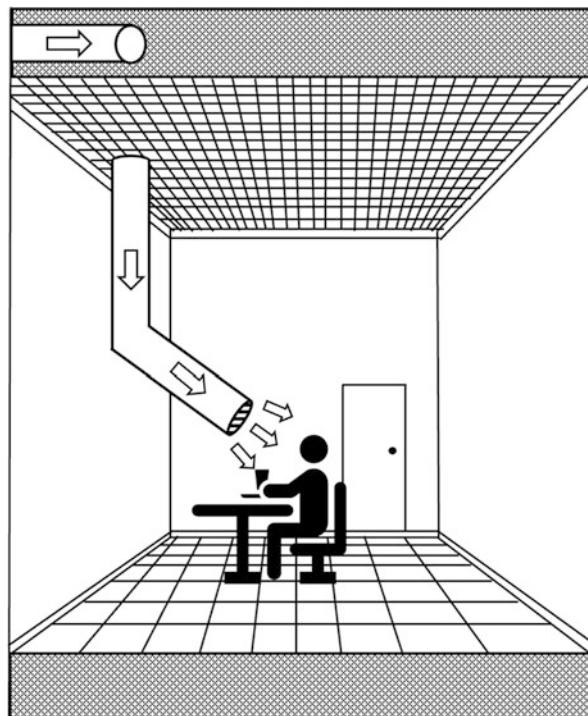

Stratum ventilation supplies conditioned air directly to the breathing zone, which lowers the inhaled pollutant concentrations and improves indoor air quality. The high ventilation efficiency is also beneficial for heat removal.

However, the stratum ventilation may induce cross-contamination in offices with many occupants, because the horizontally supplied-air sweeps the breathing zone of all the occupants. If inappropriately controlled, the stratum ventilation may also create draft risk. Additionally, the stratum ventilation does not provide cooling capacity as high as the mixing ventilation.

Personalized Ventilation

For many years, attempts have been performed to improve the air quality of a person's microenvironment via personalized ventilation. As shown in Fig. 17, in personalized ventilation, conditioned air is directly supplied to the proximity of an

Fig. 17 Diagram of personalized ventilation in an office

occupant. Personalized ventilation creates a microclimate in the context of a macroclimate (entire indoor space). The building occupants can regulate the air supply device to achieve a desired thermal comfort and indoor air quality performance.

Personalized ventilation can be applied for either cooling or heating. Figure 18 shows the airflow patterns for cooling the microenvironment with personalized ventilation (Douaa et al. 2017). The slightly low-temperature air is directly supplied at a mild speed by the terminals near the occupant. The air jet sweeps the thermal plume boundary flow for delivering the conditioned air for inhalation and facial comfort. The short distance between the air-supply terminal and occupant avoids much the mixing of conditioned air with the surrounding air for the microenvironment control. Figure 19 presents the CO₂ concentration in a vertical section (Douaa et al. 2018). Even though the surrounding air has a CO₂ concentration above 1000 ppm, the CO₂ concentration in the inhalation zone is maintained below 750 ppm, which shows superior performance to improve the inhaling indoor air quality.

Personalized ventilation can also reduce airborne infection risk. Even in a situation with coughs by an infected person, personalized ventilation can protect the uninfected person with a properly designed ventilation rate (Elvire et al. 2021). Figure 20a shows the maximum particle concentration exposure to the right person after the left patient released particles by coughs. The cleaned air jet of the personalized ventilation successfully shielded away from the particle plume to the right uninfected person. Figure 20b further shows that the particle plume could be cleaned after a short while, with the residual plume of particles released by only the breath from the left patient. Imagine that the right person was not equipped with personalized ventilation, the particles would be spread to their breathing zone considering the very short distance between these two persons. This shows that personalized ventilation may protect uninfected persons no matter when an infected person releases virus particles by coughing or breathing.

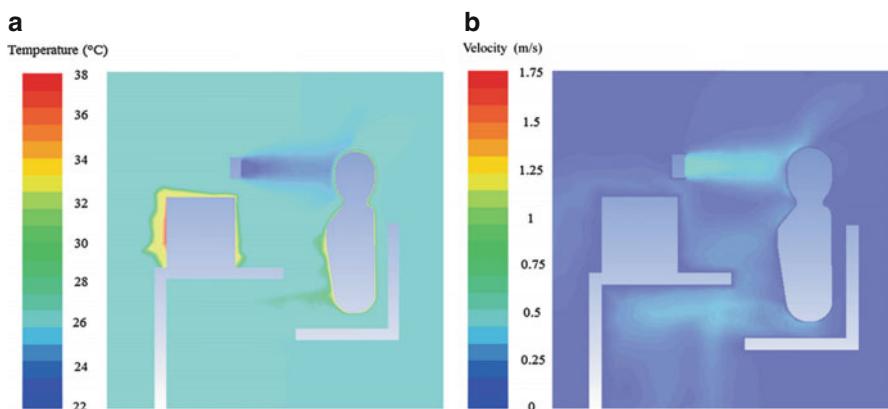

Fig. 18 Temperature and velocity distribution in an office with personalized ventilation (Douaa et al. 2017)

Fig. 19 CO₂ concentration in an office with personalized ventilation (Douaa et al. 2018)

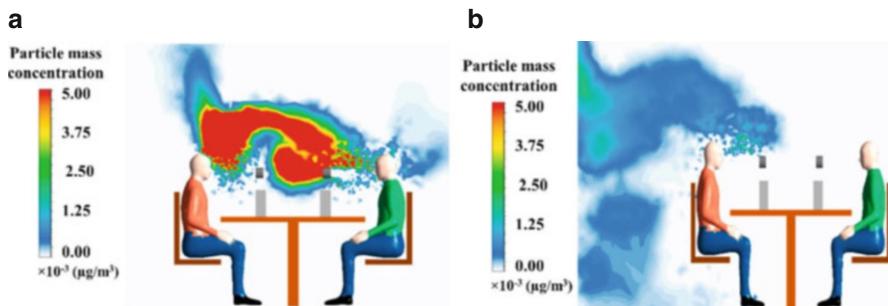

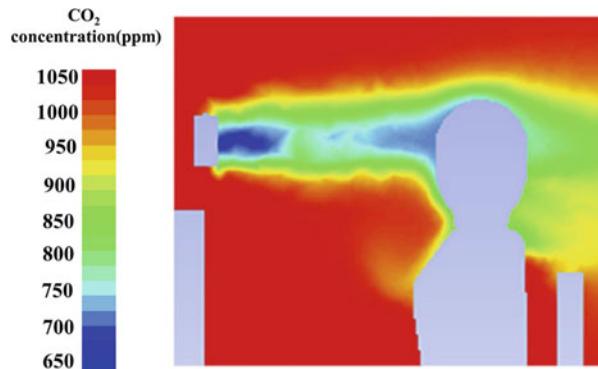

Fig. 20 Particle mass concentration contour in an office with personalized ventilation: (a) maximum particle exposure to the right person once the particles were released from the left person by coughs; (b) particle concentration distribution a short while after the coughs (Elvire et al. 2021)

In contrast to one setting for an entire space with total ventilation, the personalized ventilation is individually controlled, which allows individual occupant to adjust the air to their desired conditions. However, this means that multiple air supply terminals must be used so that the initial investment is high. In addition, the short distance between the ventilation system and occupants means the noise may not be trivial. Meanwhile, the air-supply jets may result in draft complaints.

Pros and Cons of Personalized Ventilation

The personalized ventilation improves air delivery efficiency and perceivable air quality and consequently creates an individual preferred comfortable environment. Another advantage is that the system targets a local microenvironment, and thus has a great potential for energy saving.

However, personalized ventilation is more expensive than total ventilation. In addition, the ventilation devices close to the working zone occupy space and may interrupt working activity. The draft risk may also be a problem if the air-supply jets are not well controlled.

Transportation Vehicle Cabin

Commonly, mechanical ventilation is the only ventilation mode for transportation vehicles such as trains and airplanes. The air ventilation system plays roles including distributing air appropriately, cleaning up contaminated air, and minimizing cross airborne disease transmission, toward creating a comfortable, healthy, and safe cabin environment for passengers and crews. Among transportation vehicles, a commercial aircraft cabin is a mostly confined space. In this section, the aircraft cabin is thus selected to illustrate various forms of mechanical ventilation in transportation vehicles. The mixing ventilation, displacement ventilation, and personalized ventilation are addressed in the following sections, with the schematics shown in Fig. 21 (modified from Elmagraby et al. 2018).

Mixing Ventilation

Currently, mixing ventilation is prevalently used on commercial aircraft. The supplied conditioned air is a mixture of approximately half outdoor air and half filtered recirculated air. The conditioned air is commonly supplied into the aircraft cabin from slot openings located above or below the luggage compartment, as shown in Fig. 21a. The air circulates in the cabin under the combined inertial, viscous, and body (such as buoyancy induced by thermal plumes from the occupants' bodies) forces (Liu et al. 2013) and exits from the grilles at the floor level on both sides of the cabin. Each passenger is provided with the air mixture at a flow rate of approximately 9.4 L/s (20 cfm). Due to the compact size of the cabin, the internal air is displaced roughly 2–3 mins, though the ventilation rate is much smaller than that in buildings.

The mixing ventilation creates an extensively mixed air environment on airplanes. The air temperature is highly uniform, which is welcomed from the perspective of thermal comfort. However, to promote air mixing, the conditioned air has to be supplied at a relatively high speed at approximately 2.5 m/s (Hunt et al. 1995). The high momentum jets near the occupied zone may induce draft complaints

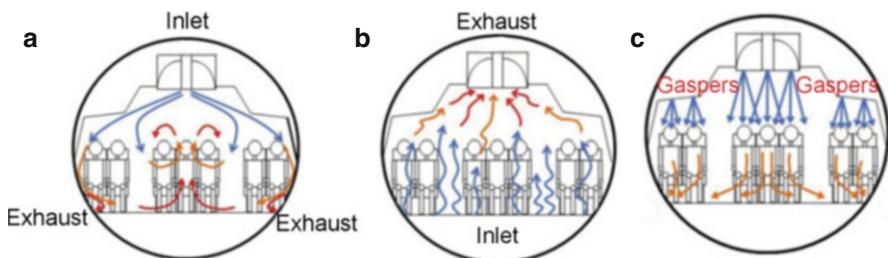

Fig. 21 Schematics of different modes for mechanical ventilation of aircraft cabin: (a) mixing ventilation; (b) displacement ventilation; and (c) overhead individual personalized ventilation (modified from Elmagraby et al. 2018)

(Hinninghofen and Enck 2006). The mixed air not only spawns numerous complaints regarding cabin air quality (Nagda and Hodgson 2001; Spengler and Wilson 2003) but also imposes threats to physical health (Lindgren and Norbäck 2005). More critically, it may result in risks of airborne infectious disease transmission (Leder and Newman 2005).

As shown in Fig. 22, the CO₂ concentration in a Boeing 767 aircraft cabin with mixing ventilation is very uniform (Zhang et al. 2010a, b). Due to the air-supply jets near the ceiling, the region near the ceiling and windows has a slightly lower CO₂ concentration. The strong air motion inside the cabin has refrained the CO₂ plumes from rising far away except for the middle passenger who is seated in the air recirculation zone. Generally, within a small region after CO₂ release, the gas has been diluted immediately. As shown in Fig. 22b, the concentration in the inhaling region or above the passengers has no significant difference. It reveals that the highly mixed air is formed in the mixing ventilation.

Figure 23 shows temporal distributions of the released particles from an index patient during a single cough in a seven-row B767 cabin (Cao, 2010). The particles reach the window seats in about 10–12 s after being released. The passengers near windows in the same row of the index patient have a higher risk of infection for this aircraft model. The particles could be transported to the entire seven-row cabin within 1 min, but most particles were confined to the three rows surrounding the index patient, i.e., in the same row of the patient, in one row ahead, and in one row behind the patient. The risk of infection for the passengers sitting in these three rows can be significantly higher than those sitting in the other rows. Approximately 88% of the released particles were exhausted out of the cabin within 4 min.

The aerosol dispersion and deposition were measured on flights of two twin-aisle aircraft (B767 and B777) using fluorescent and DNA-tagged microspheres (Silcott et al. 2020). The particles were released and measured in multiple rows of seats throughout each aircraft. It was found that the longitudinal spread of particles was subjected to the utilized tracer and the tracer released location. The exposure risk of widespread aerosol is minimal on long-haul flights but not zero. The exposure risk is notably highest in the row of an index patient, while the rows in front and behind the index patient have the next highest risk. Such finding is consistent with that reported by Gupta et al. (2011) and Cao (2010).

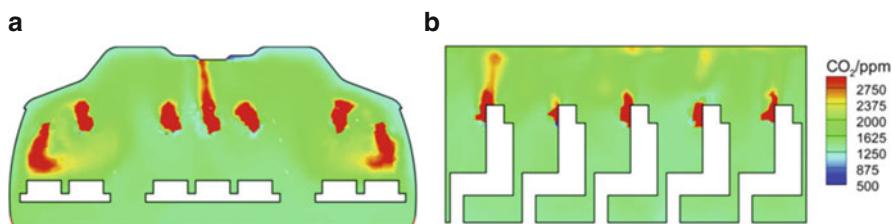

Fig. 22 Distribution of CO₂ concentration in mixing ventilation: (a) in a cross section of the cabin; (b) in the midlongitudinal section (Zhang et al. 2010a, b)

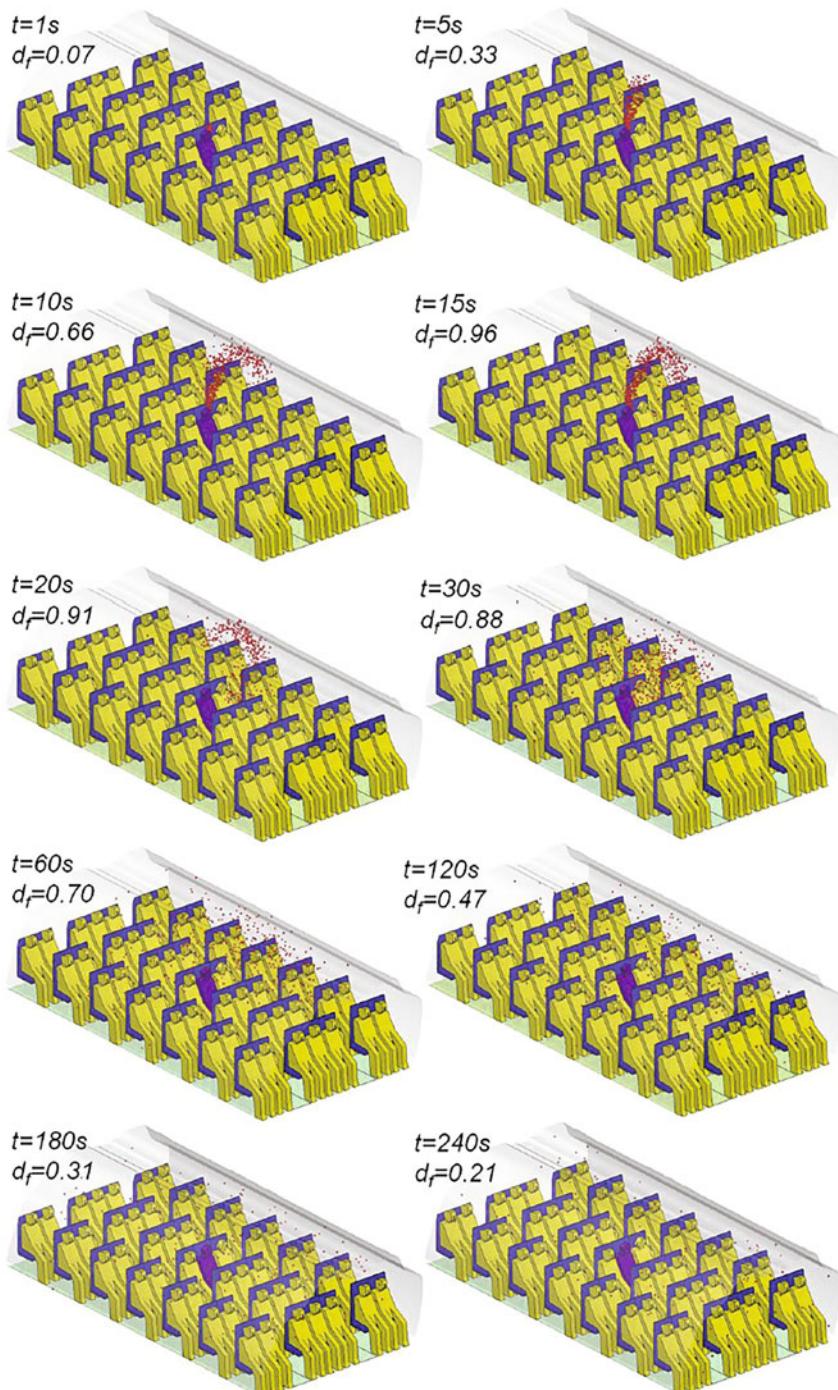

Fig. 23 Temporal distributions of droplets due to a single cough from the index patient (Cao, 2010)

Pros and Cons of Mixing Ventilation

The mixing ventilation creates an extensively mixed air context, in which the air temperature can be quite uniform. Besides, the mixing ventilation has a large cooling and heating capacity.

However, the mixing ventilation forms a large-scale circulation around the passengers in the cross section, which spawns risks of airborne infectious disease transmission. In addition, the high-speed air supply near the occupied zone may cause draft complaints.

Displacement Ventilation

Displacement ventilation was developed as an alternative ventilation mode for the aircraft cabin. Displacement ventilation with sidewall air supply near the floor (Zhang et al. 2017), underaisle-perforated panel air supply (Zhang et al. 2010a, b), and underseat downward air supply (Maier et al. 2017) have been proposed. The supplied cool air at low momentum heats as it rises in the cabin due to thermal buoyancy. The heat is from occupants and electric appliances. Consequently, air temperature stratification is formed and the warm air is extracted by the overhead exhaust vents on the ceiling. Meanwhile, airborne contaminants are trapped by this rising air toward the air exhausts.

Figure 24a presents displacement ventilation with sidewall air supply near the floor and the air exhaust at the central ceiling in a single-aisle aircraft cabin mock-up (Liu et al. 2021). The cabin mock-up contained seven rows of seats. The DEHS particles in 1 μm were released with very low momentum from the head of the manikin seated in the middle seat of the fourth row in the right half cabin. Figure 24b shows that the high concentration in the cross section was just concentrated above the manikins seated in the middle and near the aisle. Once the particles were released from the source, they were spread away along with the uprising flow. These particles were finally discharged out by the outlet in the middle ceiling. The particle

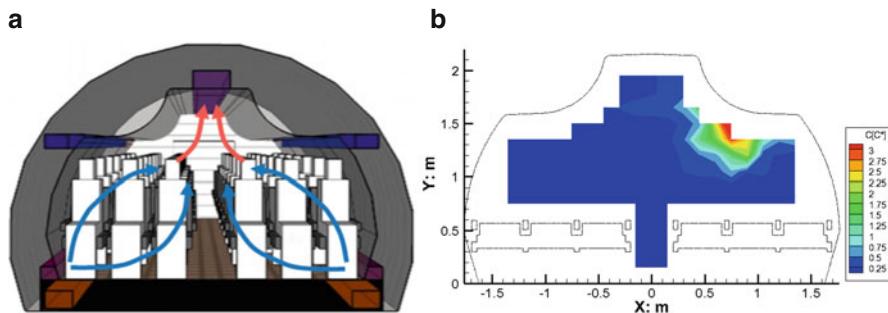

Fig. 24 Particle distribution in an aircraft cabin mock-up with displacement ventilation: (a) schematics of the ventilation mode; (b) dimensionless particle concentration (Liu et al. 2021)

concentrations in the breathing zone of the passengers seated adjacent to the particle source were quite low. Few particles enter the left half cabin.

Figure 25a presents underaisle air-supply displacement ventilation for a twin-aisle Boeing767 aircraft cabin (Zhang et al. 2010a, b). This modified underaisle displacement ventilation supplies a warm air mixture of conditioned outdoor air and recirculated air from the underaisle-perforated panels. It also supplies fully conditioned outdoor air through a narrow channel passage along both side walls to the middle height of the internal cabin just beneath the stowage bins. The air channel warms the cabin to decrease the draft complaints for passengers seated near windows. The contaminated air is extracted by both ceiling exhausts. Figure 25b and c show the CO₂ concentration distribution in a cross section and the midlongitudinal section, respectively. With the rising air streams, the plumes of CO₂ go up to the ceiling and are diluted by the surrounding air. Below the exhalation height, the CO₂ is maintained at a relatively low level without being contaminated by the passengers. Above the head level, the CO₂ concentration rises rapidly. The cross mixing among the passengers in the same row, or in the longitudinal section containing different rows, is very weak. The conditioned, outside air supply from both channel inlets helps somewhat dilute the CO₂ concentration on both sides of the cabin. Comparing with the mixing ventilation, the displacement system was found to decrease the CO₂ concentration in the cabin by 30%.

Similar to CO₂ concentration stratification, the air temperature inside the cabin as shown in Fig. 25d is also stratified. Near the floor, the air temperature is relatively low at approximately 23 °C, while the air temperature is close to 27 °C near the ceiling. The stratified air temperature shall be precisely controlled to prevent draft

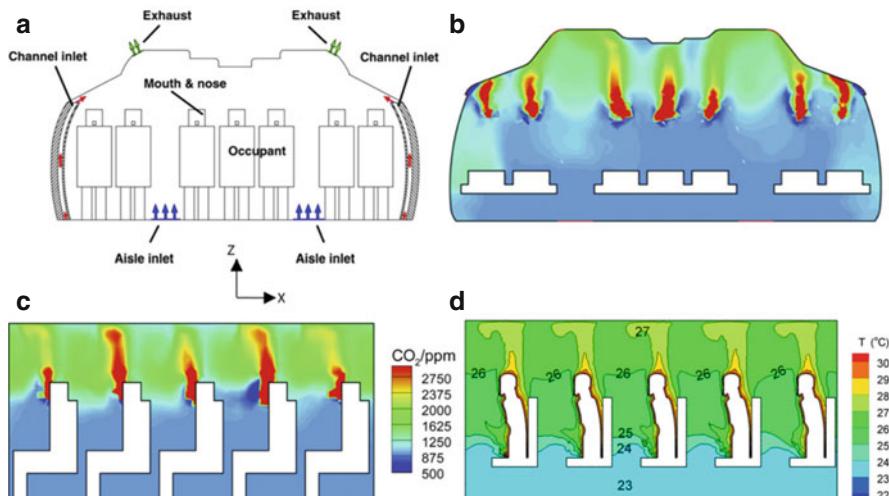

Fig. 25 Improved displacement ventilation for aircraft cabin: (a) schematics of ventilation schemes; (b) CO₂ concentration in a cross section; (c) CO₂ concentration in the midlongitudinal section; and (d) air temperature in the midlongitudinal section (Zhang et al. 2010a, b)

complaints. The acceptable air temperature gradient according to the ASHRAE standard 161 (2007) is less than 2 °C/m.

Pros and Cons of Displacement Ventilation

The displacement ventilation mode generally maintains the uprising flow, so it helps minimize air mixing and cross-transmission of airborne diseases. Compared with the mixing ventilation, the displacement ventilation has a higher ventilation efficiency, pertinently for expired airborne pollutants.

However, due to weak airflow in displacement ventilation, the human motion may occasionally destroy the uprising flow. The high concentration region is still very close to the inhalation zone. Moreover, the displacement ventilation leads to temperature stratification, in which the temperature gradients must be carefully controlled to prevent draft risk.

Personalized Ventilation

Personalized ventilation has been employed in various forms to shield away contaminants entering into the inhalation zone or protect from airborne infection. Most commercial airplanes are designed with overhead gaspers, i.e., the small, circular, and adjustable vents above passengers. When the gaspers are turned on, strong air jets are created toward the passenger's upper body. You et al. (2017) investigated the impacts of gasper ventilation on the airborne infection risk in a Boeing 767 aircraft cabin as shown in Fig. 26a. The mean airborne infection risk for the 49 passengers when they turned their gaspers on and off is shown in Fig. 26b. The horizontal axis indicates the mean infection risk when the gasper was off, while the vertical axis indicates the risk when the gasper was on. The solid line represents the diagonal,

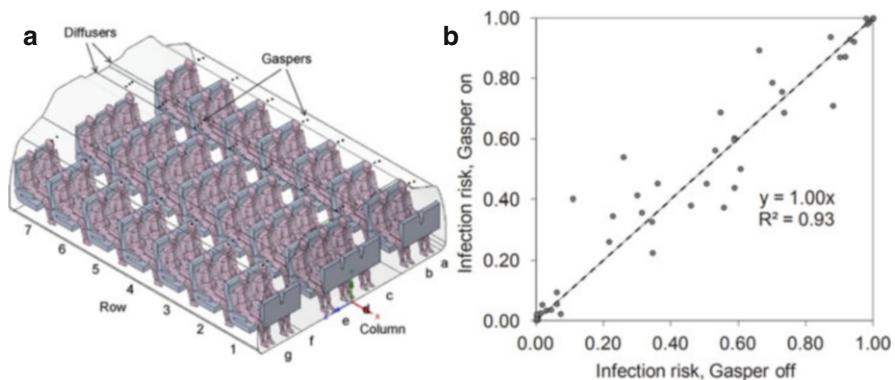

Fig. 26 Impact of overhead gasper ventilation on the calculated airborne infection risk: (a) schematic of a Boeing 767 aircraft cabin; (b) infection risk with and without gasper ventilation for each passenger with the index patient seated at 4E (You et al. 2017)

while the dashed line is the linear regression. Each point represents the case for a passenger. If a point is located exactly on the diagonal, it means that there was no difference in the mean airborne infection risk for that passenger between gasper on and off. If a point is above the diagonal, it means that the gasper ventilation increases the mean infection risk for that passenger, and vice versa. It can be seen that most of the points are close to the diagonal, which indicates that the overall impact of personalized gasper ventilation does not minimize the airborne infection risk. The reason is ascribed to the strong jets from the overhead gaspers, which entrains the surrounding air and promotes mixing of the cabin air. Because thermal plume goes up, strong jets at a typical speed of 15–20 m/s (Tang et al. 2017) are required to press the uprising flow to allow for the jets into the passenger. Such strong jets may probably cause draft risk complaints, especially for those who are sensitive to cool air motion.

To prevent strong jets, attempts were carried out to supply air adjacent to the breathing zone. One of the attempts is to supply fully conditioned outdoor air from the rectangular air terminal on the seatback in front of each passenger in a Boeing 767 aircraft cabin as shown in Fig. 27a (Zhang and Chen 2007). The supplied conditioned air was at 0.35 m/s and 19.5 °C, with a CO₂ concentration of 350 ppm. Figure 27b and c show that the CO₂ concentrations in the inhalation zone of two typical passengers with the personalized ventilation are much lower than those using the mixing ventilation and underaisle displacement ventilation. The reason is that the conditioned outdoor air was directly supplied into the breathing zone. Figure 27b and c also show that the displacement ventilation maintains the CO₂ concentration lower than the mixing ventilation. Note that the personalized ventilation in this research adopted the underaisle displacement ventilation as the background ventilation. Due to generally weak airflow in the background displacement ventilation, the low-moment air supply from the personalized air terminal is sufficient to deliver the conditioned air into the breathing

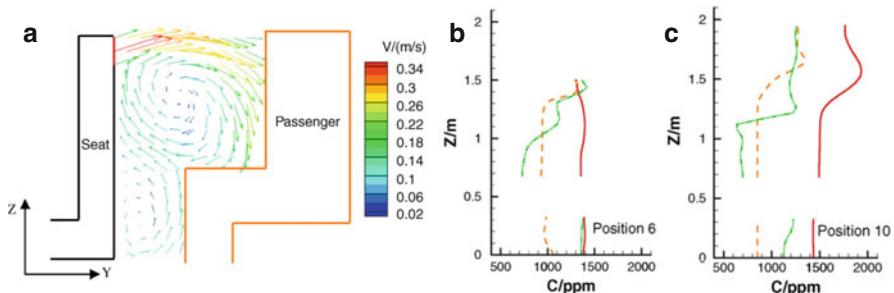

Fig. 27 Personalized ventilation with conditioned air supplied from the seatback air terminal in front of each passenger: (a) CFD-simulated airflow pattern; (b) CFD simulated CO₂ concentration profiles on a vertical pole in front of passenger 4A; and (c) CFD simulated CO₂ concentration profiles on a vertical pole in front of passenger 4D, where mixing ventilation is in red solid lines, displacement ventilation in orange dashed lines, and personalized ventilation in green dash-dot-dot lines (Zhang and Chen 2007)

zone. In general, the air speeds near the occupants are lower than 0.25 m/s, which would not cause much draft risk.

To further reduce draft risk around passengers, personalized ventilation with chair armrest air supply was proposed (Zhang et al. 2012a, b), and also using the underaisle displacement ventilation as the background system. This design delivers conditioned, warm, humid, outdoor air directly from the air terminal devices embedded within both chair armrests, as shown in Fig. 28a. To assure thermal comfort, the personal supply air is conditioned to about 25 °C, so the cabin is mainly cooled down by the air from the underaisle-perforated panels (around 22.5 °C). Figure 28b shows the flow pattern in one cross section across the personal air terminal devices. Although the air terminal devices supply air at medium momentum (around 0.65 m/s), on benefiting from the rising thermal plume near the human body, the supplied air is efficiently delivered into the inhalation zone. Figure 28c presents the CFD-simulated dimensionless tracer gas concentration for the pollutant released from the underaisle air supply. Note that the pollutant release from the underaisle air supply is the worst case of pollutant spreading for the background displacement ventilation. However, with the personal air supply, at least 40% of pollutants can be shielded off around the passenger. It is thus concluded that such personalized ventilation is robust to prevent the contaminants released at any height from imposing exposure to the passenger's breathing zone. Though there is temperature stratification in the aircraft cabin as shown in Fig. 28d, the system is acceptable in perspective of percent dissatisfied (PD) for draught risk as illustrated in Fig. 28e.

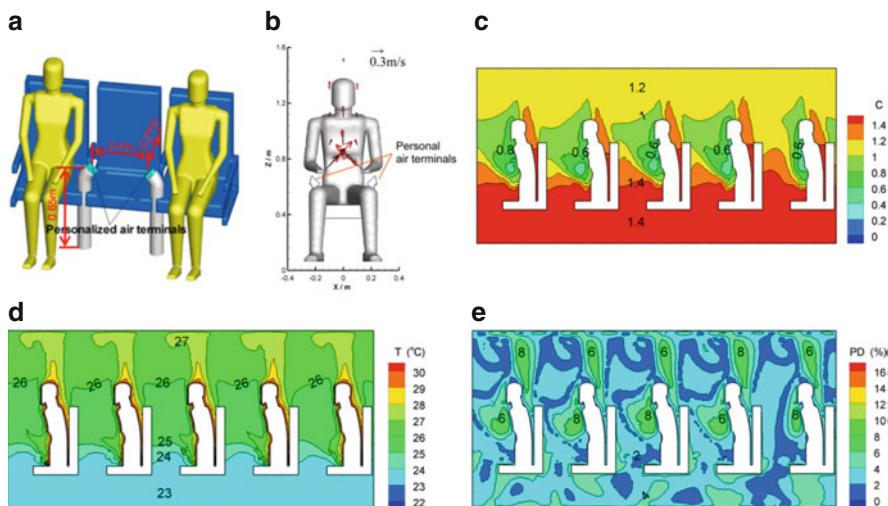

Fig. 28 Personalized ventilation with individual air terminals embedded in armrests: (a) schematics of the personalized ventilation; (b) measured (red arrows) and simulated (black arrows) flow pattern in one cross section; (c) CFD-simulated dimensionless concentration in the midlongitudinal section for pollutant released from the underaisle air supply; (d) temperature distribution; and (e) percentage of draft risk (Zhang et al. 2012a, b)

Personalized displacement ventilation is also proposed to be utilized in the aircraft cabin (You et al. 2019), as shown in Fig. 29a. Each passenger is provided with individual diffusers on the floor, just under the seats in front of the passengers, and the cabin air is extracted at the ceiling. The supplied air together with the uprising thermal plume carries exhaled contaminants from the passengers to the exhausts. Figure 29b-d compares airborne infection risk among the personal displacement ventilation, the mixing ventilation, and the conventional displacement ventilation with side-wall air supply, assuming the index passenger was seated in 4D. The computed average infection risks among all of the passengers were 0.23, 0.09, and 0.15, respectively, for the mixing ventilation, conventional displacement ventilation, and personalized displacement ventilation. From the perspective of average PD, personalized displacement ventilation prevails over conventional displacement ventilation. The highest PD among the passengers was 32%, 43%, and 31% for the mixing ventilation, conventional displacement ventilation, and personalized displacement ventilation, respectively. Though the above, the personal displacement ventilation also creates temperature stratification. If feet are adjacent to the personal displacement air terminals, one may complain about the possible draft feeling.

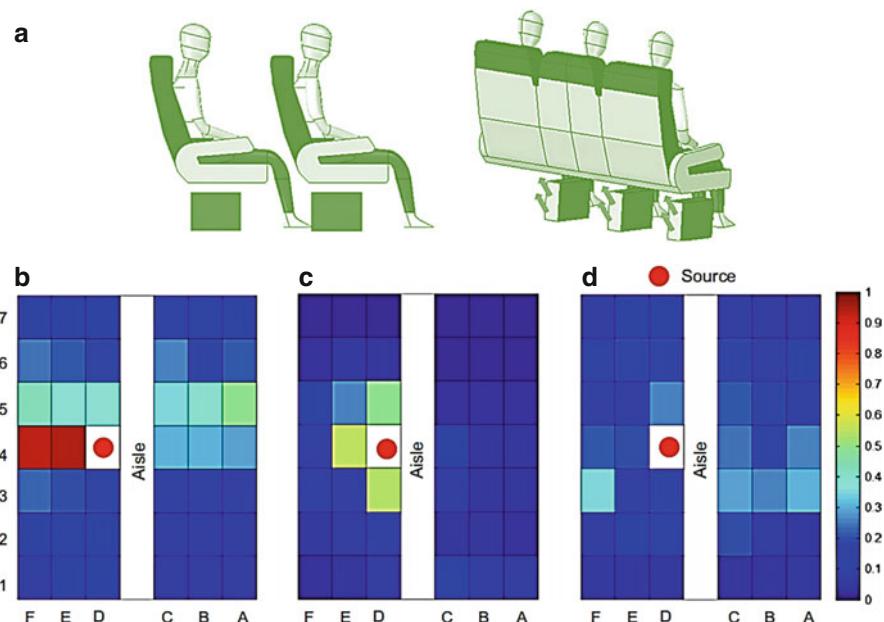

Fig. 29 Personalized displacement ventilation in a Boeing 737 aircraft cabin: (a) schematics of the personal underseat air supply; (b) CFD-simulated airborne infection risk in mixing ventilation for the index passenger at 4D; (c) airborne infection risk in conventional displacement ventilation; and (d) airborne infection risk in personalized displacement ventilation (modified from You et al. 2019)

Pros and Cons of Personalized Ventilation

The personalized air supply with displacement ventilation as the background system prevails substantially over the mixing ventilation and displacement ventilation in terms of lowering the inhaled pollutant concentration and minimizing airborne infection risk.

However, the high-speed gasper ventilation entrains the surrounding air and promotes air mixing and does not show favorable performance in improving cabin air quality and reducing airborne infection risk. In addition, the personalized ventilation with displacement ventilation as the background systems also creates temperature stratification, which must be carefully designed to prevent the draft risk. Besides, the personalized ventilation may have a higher initial investment expense than the remaining two systems because individual air terminals and connecting ducts are needed.

Conclusion

Natural ventilation is the most widely used in residential buildings in developing countries. Natural ventilation is simple, energy-saving, and affordable but may occasionally result in an insufficient ventilation rate. In situations with outdoor PM_{2.5} pollution, a combination of natural ventilation and portable demand-controlled particulate filtration has the lowest operating cost. The outdoor air supply and indoor particle filtration are suggested for decoupled, independent consideration. Among the mechanical ventilation modes, decentralized systems operating only during the occupied period have great potential to minimize utility costs. Mechanical ventilation in demand-controlled operation and its hybrid with natural ventilation can further reduce energy consumption.

In modern office buildings, mechanical ventilation is more preferred because of its robustness and continuity. Among the commonly used mechanical ventilation systems, mixing ventilation has a significant advantage in creating a relatively uniform indoor environment. However, the mixing ventilation may create cross-contamination and induce airborne infectious risk. In contrast, displacement ventilation, stratum ventilation, and personalized ventilation are showed to provide better indoor air quality than traditional mixing ventilation. However, temperature gradients or draft risks must be well controlled to prevent possible discomfort feeling.

For aircraft cabins, the currently used mixing ventilation mode creates an extensively mixed air environment, which has a lower ventilation efficiency than displacement ventilation mode. Personalized ventilation has been employed in various forms to create the preferred microenvironment for each passenger. Displacement ventilation combining with personalized ventilation can substantially improve cabin air quality and minimize airborne infection risk. However, temperature stratification and draft risks must be paid significant attention to when designing and running displacement ventilation and/or personalized ventilation.

Abstract

The evaluation of building ventilation performance is critical to understanding indoor contaminant transport dynamics and interpreting indoor contaminant measurements. However, ventilation performance involves many different issues and metrics that can make such evaluations challenging. Also, many indoor air quality research studies have not included adequate evaluation of building ventilation and its impacts on indoor contaminant concentrations. There are several reasons for this history of neglect; they include the complexity of ventilation, the

cost associated with the measurements, and the lack of guidance on how to conduct such evaluations. This chapter explains what is involved in evaluating and understanding ventilation performance in buildings, with a focus on the parameters involved, how building configuration and ventilation system type impact how such evaluations are conducted, and the connection between the reasons for ventilation evaluations and the strategies employed. Among the ventilation performance parameters that are covered are whole building outdoor air change rates, ventilation system outdoor air and supply air delivery rates, and envelope infiltration rates. Some of the key points stressed in this chapter include the following: actual ventilation performance often does not match design intent; ventilation rates vary significantly with weather and system operation and therefore a single value is not particularly useful without information on the conditions during the measurement; multiple repeated measurements under different conditions are required in order to fully understand ventilation in a building; and, while indoor carbon dioxide concentrations can be a useful tool in evaluating ventilation, its application is based on multiple assumptions that must be valid.

Keywords

Airflow · Building performance · Indoor air quality · Infiltration · Ventilation

Introduction

Building ventilation performance is important for several reasons, including impacts on indoor air quality (IAQ), energy use, thermal comfort, occupant health and safety, and degradation of building materials and furnishings. In some respects, the impacts are relatively straightforward. For example, the energy required for heating and cooling is based primarily on the amount of outdoor airflow into a building, the indoor-outdoor air temperature difference, and air properties such as specific heat and humidity ratio. However, the details of energy and other impacts are often more complex as they depend on the details of the relevant airflows, the heating, ventilating and air-conditioning (HVAC) equipment in the building, building and equipment operating strategies, and other factors.

Building ventilation performance cannot be characterized by a single metric but involves a range of performance issues and parameters. The next section of this chapter discusses ventilation performance in more detail, with a focus on ventilation systems and building characteristics. These performance issues include system status, envelope air leakage, ventilation system airflow rates, outdoor air change rates, interzone airflow, and air distribution. A key step in understanding the significance of ventilation performance is to understand how the system is intended to perform, sometimes referred to as the design intent. To that end, building and system design information is discussed after the section on performance issues. The next section covers measurement methods to quantify performance, accounting for building configuration and system design in making these measurements, as well as

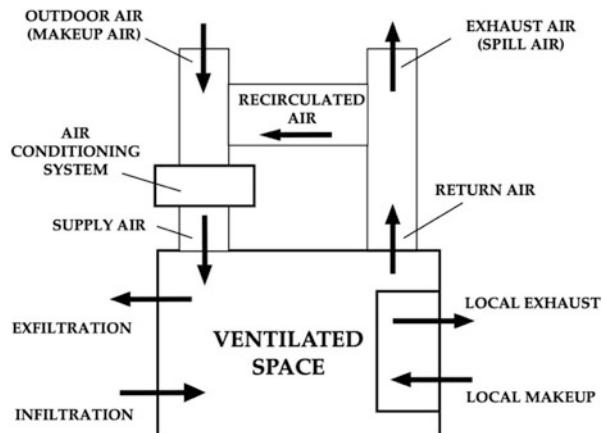

capturing variations in performance over time and as a function of weather. Comparison of measurement results to the system design, as well as to relevant standards and guidelines, is also discussed.

It is important to note that many IAQ studies of buildings have done a poor job of evaluating ventilation. This is demonstrated by an analysis of the ventilation characterization approaches in a key review of 26 peer-reviewed papers on the relationship of ventilation rates and occupant health outcomes (Sundell et al. 2011). A number of different techniques were used to assess ventilation rates in these papers, and there was a range of detail included in the description of these techniques. However, an analysis of the ventilation assessment approaches in these studies revealed that about half of them do not mention the instrumentation used to make the measurements and only four report a value for the measurement uncertainty (Persily and Levin 2011). More than 10% of the papers do not describe how the ventilation rates were determined, and about 75% do not describe the time scale over which the measurements were made. Other common problems with the treatment of ventilation in IAQ studies is a lack of sufficient description of how the building is intended to be ventilated, information on the HVAC equipment in the building including design ventilation rates, or data on weather and equipment operation during the ventilation measurements. This chapter describes how to evaluate ventilation in buildings with different ventilation system types, and what information needs to be provided with ventilation measurement results to support their interpretation and use.

Terminology

While this chapter discusses ventilation performance parameters in some detail, it is important to note that the relevant terms are not always used consistently by researchers, practitioners, and others. Figure 1 shows a mechanically ventilated building with a ventilation approach that is typical of many commercial buildings in the USA, with several key terms displayed. Note that many of these terms are defined in ASHRAE Standard 62.1 (ASHRAE 2019a). (While a US commercial building perspective exists for much of the discussion in this chapter, much of this material also applies to residential buildings and non-US buildings.) Sometimes outdoor air is referred to as makeup air, often when it is needed for combustion or exhaust ventilation equipment. In many systems, outdoor air is mixed with recirculated air that flows from the ventilated space as return air. In general, a portion of the return air leaves the building as exhaust air or spill air. Some ventilation systems, sometimes referred to as 100% dedicated outdoor air systems (DOAS), do not recirculate any air. The mixture of outdoor air and recirculated air flows through an air conditioning system where it is heated/cooled, humidified/dehumidified, and filtered. The air then flows to the space as supply air, where it serves the needs of that space for outdoor air ventilation and in many cases also provides thermal conditioning. The figure does not show local mixing boxes such as variable-air-volume (VAV) boxes that are sometimes used to mix supply air (sometimes referred to primary air in

Fig. 1 Schematic of ventilated building

such systems) with room air drawn to meet local thermal requirements. Figure 1 also shows local exhaust airflow, which is often used to remove locally generated contaminants before they mix with air in the rest of the building. Local makeup air is sometimes provided rather than drawing air from elsewhere in the building.

It is important to note that some individuals consider ventilation to be outdoor air and others consider it to be supply air; the term "air change rate" also does not specify the type of air. To avoid confusion, it is important to clarify the air source as outdoor or supply air when discussing ventilation. ASHRAE Standard 62.1 defines ventilation as follows: the process of supplying air to or removing air from a space for the purpose of controlling air contaminant levels, humidity, or temperature within the space. This definition does not mention outdoor air but focuses on air treatment (e.g., heating, cooling, and filtration), delivery, and exhaust. In this chapter, when the term ventilation appears without a qualifier, it is being used in this general sense to cover outdoor and supply air delivery, air treatment, and exhaust air removal.

One issue that is often not fully appreciated in considering the impacts of ventilation is the distinction between infiltration and outdoor air ventilation. Infiltration refers to uncontrolled entry of outdoor air through unintentional openings in the building envelope, i.e., leakage. Infiltration is driven by indoor-outdoor air pressure differences due to weather (wind and temperature) and the operation of building systems (e.g., exhaust fans and vented combustion equipment). Exfiltration refers to airflow from the building interior to the outdoors, again through unintentional leaks. The term infiltration is often used to describe the combined processes of infiltration and exfiltration. It is important to note that infiltration rates are not controlled, nor is the distribution of infiltration air within a building. Additionally, infiltration can have negative impacts on IAQ (since infiltration air is unfiltered), indoor moisture management, and material durability. Outdoor air ventilation refers to outdoor airflow into a building through intentional openings such as intakes, vents, and open windows. Mechanical ventilation is outdoor air ventilation induced by powered equipment, i.e., fans, while natural

ventilation is driven by weather. Ventilation systems, mechanical or natural, that are well designed, installed, operated, and maintained are preferable to infiltration for meeting building ventilation requirements since they can provide the desired ventilation rate where it is needed, avoiding both under- and overventilation. Ventilation systems also provide opportunities to reduce energy impacts, such as by recovering heat or moisture from the outgoing air.

Reasons for Evaluating Ventilation

When conducting any measurement, it is essential to consider why it is being done and what will be done with the results. When deciding what to measure as part of a building ventilation evaluation, one must start with the reason for the evaluation, as well as the configuration of the building and the ventilation system design. Building and system issues are discussed later in the chapter, but the reason for the ventilation evaluation is critical. There are multiple reasons that one might evaluate ventilation in a building or a space within a building, and the reasons will impact the approach that is used including the timing of the evaluation and the financial resources and expertise required. Reasons for evaluating ventilation include: a research study of ventilation or IAQ, an effort to understand the reasons for an IAQ problem, and a commissioning effort to ensure the building and system are operating as intended. Research can range from an intense, long-term study of a single building to a survey of dozens to hundreds of buildings involving short-term (hours to days) measurements. Long-term ventilation studies of a building may be designed to characterize ventilation and infiltration rates and other performance parameters as a function of weather conditions, system operation, and occupant activities, and therefore require many real-time measurements over days, weeks, and perhaps seasons. To facilitate long-term, real-time measurements, automated measurement and data acquisition systems are very helpful if not essential, perhaps involving a temporarily installed tracer gas measurement system or anemometers in HVAC ductwork. Long-term research studies of indoor contaminant levels would involve similar (long-term, real-time) ventilation measurements, though they may focus on a limited number of ventilation performance parameters. At a minimum, the interpretation of long-term indoor contaminant measurements requires outdoor air change rates to understand variations in contaminant concentrations, often employing mass balance analysis.

For short-term IAQ research studies, which may involve only a single or a small number of indoor contaminant concentration measurements, it generally does not make sense to install instrumentation and data acquisition systems that may be justified in a longer term study. However, air change rates and perhaps other ventilation performance parameters still need to be quantified to interpret indoor contaminant concentration measurements. Such analyses may also need system supply airflows to account for contaminant removal by filtration and air cleaning equipment and infiltration rates to account for outdoor contaminant penetration (i.e., the removal of outdoor contaminants as they flow through building envelope leaks). A special case of short-term IAQ studies are building surveys, in which

dozens of buildings or more are studied to capture a range of performance parameters including the concentrations of different contaminants, thermal comfort conditions, nonthermal indoor environmental parameters (e.g., lighting and acoustics), and occupant symptoms and perceptions of the indoor environment. Several IAQ surveys have been conducted over the years, most of which have included some measurements of ventilation performance (EPA 2006; Bluyssen et al. 1996; Offermann 2009; Bennett et al. 2011, 2012). In these studies, the cost of the measurements is critical and difficult choices often have to be made about which parameters will be measured and the level of sophistication for the various measurements. But given the first-order relationship of ventilation and IAQ, these studies need to include reliable ventilation measurements to be useful.

Short-term IAQ studies are also conducted to understand the cause(s) of occupant IAQ complaints or health problems. Such forensic investigations generally include an assessment of the potential role of the ventilation system and how its performance may be contributing to the problem being studied. Most of these studies are done using approaches determined by the investigator, but there is an ASTM standard for investigating residential IAQ issues that includes some aspects of ventilation performance (ASTM 2014). The specific parameters included in IAQ investigations and the manner in which they are assessed are generally a function of the building and its HVAC systems, the nature of the IAQ problem being investigated, and the contaminant sources that could be causing the problems. These investigations may require measurement of outdoor air change rates, supply airflow rates, and infiltration rates. They may also merit assessment of interzone airflows that can transport contaminants from zones where key sources are located to the zones where the occupants are experiencing symptoms. This chapter does not cover the measurement of interzone airflows in detail, but it does discuss their measurement and describes some qualitative tools that can be useful.

Another reason for evaluating building ventilation is as part of a commissioning effort to ensure the system is operating as intended. Commissioning is becoming increasingly common and is in fact required by high-performance building standards and rating systems (ASHRAE 2020). HVAC system commissioning has been part of normal practice for decades, where it is referred to as testing and balancing (TAB) (ASHRAE 2008). As noted in the foreword to ASHRAE Standard 111, “Field test results are considered essential to designers, manufacturers, and installers to better enable them to evaluate the results of their design, equipment performance, and installation techniques under actual operating conditions.” TAB is typically done for new buildings and systems, but there is value in recommissioning systems at various points in the life of a building to ensure that it is still performing as intended given the likelihood that control sensors and hardware may have degraded over time or building space use has changed.

Building and System Impacts on Ventilation Evaluation

In addition to the reasons for conducting an evaluation, the building configuration and the ventilation system design and layout are key to how a ventilation evaluation

is conducted, specifically what is measured and how. Buildings and systems are extremely variable, and these variations must be considered when planning and conducting ventilation evaluations. Key building configuration parameters include building size, how the building is divided into zones, how zones are connected in terms of airflow (e.g., doorways, common hallways), and ventilation approach (es) employed. In describing the size of a building, one needs to include the building height, the number of stories, and floor area and height of each story. Zoning covers how the building is laid out into different sections or sometimes wings, which portions are handled by which ventilation systems, and how space use and occupancy vary among zones. These latter factors will determine how much outdoor air is required by ventilation standards and regulations. Other relevant building features that should be considered in the assessment include information on the climate of the building location, e.g., annual heating and cooling degree days, monthly average outdoor air temperature and wind speed, and wind exposure of the building.

The approach used to ventilate the building is key to planning a ventilation evaluation effort and involves the following questions: Is there a mechanical ventilation system that brings in outdoor air, or is the building ventilated only by infiltration and natural ventilation? Does the ventilation system provide space conditioning (heating and cooling) only with no outdoor air intake? Does the system provide 100% outdoor air with no recirculation? Are there local exhausts in kitchens and toilet rooms? If natural ventilation is used to ventilate the building, is it a designed system (e.g., thermal stacks and designed air inlets), or simply operable windows? If mechanically ventilated, does the building contain a central, ducted system that serves multiple rooms or zones? Or do the systems serve single zones, e.g., using through-the-wall fan coil units. When are these systems intended to operate, i.e., is operation based on time of day, controlled by a thermostat or manual? If the system provides outdoor air intake, is that intake rate varied based on weather conditions, indoor contaminant concentrations (e.g., CO₂ demand control ventilation), time of day, or some other approach? These questions must be answered in order to understand how the building is intended to be ventilated, which ventilation performance parameters are relevant, and how they should be measured.

This chapter is organized into three primary sections. The following section describes performance issues that need to be covered in conducting ventilation assessments, as well as the specific parameters used to characterize each issue. That section is followed by a description of the system design information that needs to be collected as part of ventilation assessments to support interpretation of the results. The third section focuses on the measurement methods used to determine the performance parameters described previously. The chapter concludes with some key points regarding building ventilation assessment. Note that this chapter is not a detailed guide on how to conduct such assessments, including how to make the often-challenging decisions on exactly what to measure in a specific building and how to do so. It might be considered as a heavily annotated menu rather than a how-to cookbook. The author is planning to expand this material into a much longer guidance document (the cookbook) that will contain those operational details. The reader can access a great deal of useful information on building ventilation and its measurement via the AIVC (Air Infiltration and Ventilation Centre) bibliographic

database Airbase, which contains 22,000 references and 16,000 documents, at <https://www.aivc.org/resources/airbase>.

Performance Issues and Parameters

This section describes the performance issues that are relevant to ventilation evaluations and specific parameters under each. As noted above, the parameters that are assessed as part of a building ventilation evaluation and the manner in which they are assessed depend on the purpose of the evaluation and the details of the building and its ventilation systems. Table 1 lists key ventilation performance issues and parameters, with methods for their measurement or assessment covered later in this chapter.

The first performance issue in Table 1 is system status, which is fairly broad and mostly qualitative but extremely important. It includes whether the system is operating and the condition of the system and its components, including cleanliness and moisture damage, whether there are clearly dysfunctional or broken components (e.g., dampers) and filter condition. Another important aspect of system status is maintenance, including the intended system maintenance schedule and records of maintenance activities. Since maintenance is critical for keeping systems performing as intended, this information is key to evaluating ventilation systems. The last

Table 1 Ventilation performance issues and parameters

Performance issue	Relevant parameters
System status	Operation Condition Maintenance Design documentation
Envelope air leakage	Envelope airtightness Building infiltration rate Indoor-outdoor pressure difference
Ventilation system airflow	Outdoor air intake rate Percent outdoor air Supply airflow rate (system and space level) Return airflow rate (system and space level) Exhaust airflow rate (system and space level) Operating status and mode of operation
Outdoor air change rate	Whole building Room or other building zone
Interzone airflow	Airflow rates ^a Interzone partition airtightness Interzone pressure differences
Air distribution	Ventilation efficiency or effectiveness ^a

^aMeasurement methods not described in this chapter

parameter under system status in Table 1 is the existence of system design documentation, the specifics of which are described in more detail in the next section of this chapter. It is unfortunate, but in many buildings, such design documentation is nonexistent or at least not current. For example in the EPA BASE study of 100 randomly selected office spaces in the USA, design values of minimum outdoor air intake rates were not available for roughly half of the buildings studied (Persily and Gorfain 2008).

The second performance issue in Table 1, envelope air leakage, is important because infiltration is the only outdoor air ventilation mechanism in many buildings, particularly residential buildings and some older commercial and institutional buildings. In fact, infiltration is generally a significant portion of the total outdoor air change rate in all buildings, even buildings with relatively tight envelopes (Ng et al. 2015). Infiltration impacts heating and cooling energy use and provides a path for outdoor contaminants to enter a building. As noted earlier, infiltration is not a good way to ventilate a building since the rates and air distribution are not controlled, the incoming air is not filtered, and infiltrating air can lead to indoor moisture problems and material degradation. Envelope airtightness, measured with a fan pressurization test, is a key parameter for understanding the potential for infiltration. It is usually expressed as a volumetric airflow rate or effective leakage area at a reference indoor-outdoor pressure differential and is typically normalized by the building volume or the envelope surface or floor area. Airtightness measurements can be completed relatively quickly (compared with infiltration rate measurements) and provide a single parameter that is useful for comparing buildings and for predicting airflows using computer models and other calculation tools (Dols and Polidoro 2020; ASHRAE 2021; Breen et al. 2014). There is a significant body of work on field studies of building airtightness in residential and commercial buildings that can be useful for comparing test results (Chan et al. 2012a, b; Emmerich and Persily 2014). However, envelope airtightness measurements are conducted under imposed indoor-outdoor pressure differences to override pressures due to weather effects. Infiltration rates, on the other hand, are the rate of outdoor air entry through leaks in the envelope due to normal weather effects and the operation of local exhaust fans and vented building equipment (e.g., combustion appliances), and therefore provide a measure of the airflows that are actually occurring in the building. Infiltration rates are therefore more relevant to real-time performance, but the values still vary with weather and equipment operation and only indicate the rates for the conditions during the measurement.

Infiltration rates are typically expressed in air changes per hour or h^{-1} , which is the volumetric airflow rate of the infiltrating air divided by the building volume. These units are commonly used for air change rates, whether they are outdoor, supply or some other airflow. Some people use ACH, ACPH, or other nonstandard units, or refer to these airflows as air exchange rates. The author of this chapter objects to using invented units like ACH, noting that the pure SI unit for air change rate is actually s^{-1} . The term “air exchange rate” is also flawed because it implies that air is simply exchanged between the outdoors and indoors when, in fact, airflow into and out of buildings often takes very indirect and circuitous routes involving

intermediary spaces such as crawl spaces, attics, wall cavities, and plenums. Air change rate is preferred as simply a unit, with the type of airflow described using modifiers such as outdoor air intake, supply air, or infiltration.

In discussing air change rates, including infiltration, it is important to note that if a space has an outdoor air ventilation rate of one air change per hour, it does not mean all of the air is replaced in 1 h. One air change per hour means that a volume of air equal to the space volume enters every hour, but that entering air mixes with the air already in the space such that the air leaving is a mixture of air that entered recently and air that has been in the space for a longer time. If there is a uniform contaminant concentration in the space, the concentration decays exponentially with a time constant equal to the inverse of the air change rate. Therefore, after one time constant (1 h for one air change per hour), the contaminant concentration is reduced to 63% of its initial value.

Measured indoor-outdoor air pressure differences across the building envelope can also be a useful indicator of envelope leakage, as their sign and magnitude provide information on where air may leak into and out of a building over its exterior surface. These pressures are not readily convertible to actual infiltration rates, but they can be helpful for understanding the direction of infiltration airflows, particularly at key locations such as entrances and areas where there are strong outdoor sources, e.g., loading docks. Indoor-outdoor pressure differences vary with location and time, and therefore they should be measured under a range of conditions to better understand the airflow dynamics. In some cases, pressurization testing or infiltration rate measurements may not be feasible, and indoor-outdoor air pressure measurements can be quick and useful even though they provide less information.

The next performance issue listed in Table 1 is ventilation system airflow, along with the parameters that can be used to characterize these airflows. Note that many of these are displayed in Fig. 1. These parameters include: outdoor air intake rate – how much outdoor air is brought in by the system; supply air flow rate – how much air the system delivers to the occupied portion of building or to a specific room or zone; percent outdoor air intake of the system – the ratio of the outdoor air intake to the supply airflow rate; return airflow rate – how much air the system removes from the occupied portion of building or from a specific room or zone; and exhaust airflow rate – the amount of air exhausted by a central system or local exhaust. Not all of these parameters apply to all ventilation systems, e.g., some systems do not have any return airflow but rather supply only outdoor air to occupied spaces, and some systems do not have any outdoor air intake. The latter is the case for most space conditioning systems in US homes, although that is changing in newer housing. The last listed parameter for ventilation system airflow (operating status and mode of operation) is actually a number of different parameters using the overarching term operating status (e.g., is the system on or off?) and what mode of operation is currently in effect. For instance, many systems in commercial buildings have several modes of operation including minimum outdoor air intake and economizer operation.

The outdoor air change rate performance issue in Table 1 refers to the sum of the airflow rate due to infiltration and the outdoor air intake, i.e., the total rate at which

outdoor air enters a building. This is the outdoor airflow rate relevant to heating and cooling loads as well as contaminant mass balance analysis. When considering contaminants with nonzero outdoor concentrations, the total outdoor air change will generally need to be considered separately for the outdoor air intake by the system and for the infiltration through the envelope. Outdoor contaminants entering via the system intake may need to account for removal due to filtration and air cleaning, and contaminant entry via infiltration may need to account for penetration losses. Infiltration is sometimes assumed to be negligible, relative to outdoor air intake rates, but in the absence of measurements or sound calculations, this assumption cannot be supported and may lead to the neglect of important air and contaminant entry into a building. Building outdoor air change rates include all of the outdoor airflows at all infiltration entry points on the envelope and the system intakes for all systems. If there are many systems, it can be challenging to measure at all of the intakes, but conceptually, whole building outdoor air change rates are clearly defined. Outdoor air change rates can be expressed as volumetric airflow rates or air changes per hour, which is the volumetric rate divided by the interior volume of the building being considered. In many cases, it can be challenging to define the interior volume given that many buildings are divided into conditioned spaces, unconditioned spaces (e.g., attached garages), and semi-conditioned spaces (e.g., attics and basements), which often have significant airflows to and from the occupied and conditioned spaces. The interactions of these volumes can also complicate tracer gas measurements of air change rates as discussed below.

In many cases, researchers and practitioners are interested in outdoor air change rates for individual rooms. However, rooms in buildings exist as part of multizone building airflow systems, with airflows between rooms, and therefore room outdoor air change rates are not straightforward to define and less so to measure. The outdoor air change rate for a room would include outdoor air infiltration directly into the room and outdoor air delivered to the room by a ventilation system. The influence of airflow from other rooms on contaminant concentrations are more complex, and their measurement involves multizone tracer gas techniques. These techniques are mentioned in the section “[Measurement Methods](#)” but are not described in detail. In some studies, CO₂ concentrations in individual rooms, often bedrooms, are used to estimate outdoor ventilation rates to the rooms. However, as discussed in the section “[Measurement Methods](#),” these techniques generally neglect interzone transport of CO₂ from other rooms, resulting in uncertainties that are difficult to characterize. Note that CO₂ concentrations are not listed as a metric of ventilation in Table 1, despite their common use. As explained below and in more detail elsewhere (ASTM 2018b), CO₂ concentrations are not direct measures of ventilation. Under some circumstances they can be used to estimate per person ventilation rates using well-established tracer gas methods, but this application requires the validity and verification of several key assumptions.

The next performance issue in Table 1, interzone airflow, is important for contaminant mass balance analyses, particularly when building zones are at different concentrations, and for achieving an overall understanding of the airflow dynamics in a building. They are difficult to measure as they require the use of multizone tracer

gas techniques, which are not typically employed except in research studies. In lieu of measuring interzone airflows directly, one can measure the airtightness of the partitions and the pressure differences between zones. Airtightness of interzone partitions can be assessed using fan pressurization methods and have been conducted to quantify the air leakage between attached garages and the living spaces of residences (Offermann 2009; Nirvan et al. 2012) and between rooms in low-energy homes (Guyot et al. 2016; Ng et al. 2018). Interzone pressure differences can be helpful in understanding the direction of these airflows. As in the case of indoor-outdoor pressure differences, interzone pressure differences are not easily converted to actual airflow rates, but they can be helpful for understanding the potential for contaminant transport from zones containing sources of interest to other zones. Interzone pressures vary with location and time, and therefore need to be repeated under a range of conditions to understand airflow dynamics.

The last performance issue listed in Table 1 is air distribution, which refers to the manner and uniformity with which ventilation air is delivered to a space. Some air distribution systems, for example in many US office buildings, are designed to mix the supply air with air in the occupied space and are often referred to as mixing systems. Other air distribution systems are designed to ventilate a space in a manner resembling plug flow, e.g., operating rooms, in which air enters and “sweeps” through the space in an approximately one-dimensional airflow pattern. Air distribution can be quantified using various measures of ventilation effectiveness, such as age of air, which are described briefly in the section “[Measurement Methods](#).”

Building and System Design Information

As noted earlier, a key factor in determining how to assess building ventilation is the design of the building and its ventilation system(s), including how the building is configured, how ventilation is intended to occur, system design airflows, and the assumptions on which the design is based. Gathering system design information is an essential part of assessing ventilation in a building, as such information is critically important as a basis for comparing the results of ventilation measurements. Field studies have shown that building ventilation performance is too often inconsistent with design intent (Persily 2016; Persily and Gorfain 2008), and such discrepancies can increase energy use and degrade IAQ. Examples of performance not matching design intent are noted later in this chapter, but the important message is that one should never assume a building is performing as intended. Measured data are essential to determining what is actually occurring regarding ventilation and airflow. It is interesting to note that many building and IAQ surveys contain entries for an HVAC description that are only a line or two. Ventilation systems are more complex than can be captured in a small amount of space and require some detail in order to document important design information. Several previous survey studies of multiple buildings have collected system design information. The EPA BASE study is of particular note, as it had detailed protocols and checklists for collecting information on the building, the portion of the building being studied, and the

system serving that space (EPA 2003). A modified version of the BASE protocol was employed in a study of 37 small and medium commercial buildings in California (Bennett et al. 2011). A number of other studies of large numbers of buildings have collected building and system information (Derbez et al. 2018; Ramalho et al. 2013; Offermann 2009; Pigg et al. 2014; Weisel et al. 2005). However, standardized protocols for collecting building and system design information have not been developed, but they could be quite useful in future studies.

Table 2 contains information needed to describe a ventilation system. The items in bold font might be considered the most critical, but all of them are important. The first entry to Table 2 relates to the system status, which in the context of design involves determining whether the design documentation exists and is up-to-date. Building use and applicable standards and regulations change over time, and the design should be updated to reflect these changes, but that does not always happen. System maintenance schedules are also an important aspect of system design given the importance of maintenance in keeping systems performing as intended.

The next aspect of system design that needs to be captured is the approach used to ventilate the building of interest. Is the building ventilated by unintentional infiltration only? Or is there a designed mechanical or natural ventilation system? Designed natural ventilation systems are those that include elements that are arranged and sized based on engineering principles, e.g., thermal stacks and inlet vents, which are described elsewhere (CIBSE 2005; Dols et al. 2012). The term hybrid or mixed-mode ventilation is used when a building uses both mechanical and natural ventilation. Local exhaust systems are typically located in buildings zones, such as kitchens and bathrooms, with high contaminant generation rates (including moisture) in order to remove those substances before they have a chance to mix with the rest of the building air. Mechanically and naturally ventilated buildings may also have local exhausts, although they often have central exhaust systems with a single fan connected to a duct system that removes air from multiple spaces, such as toilet rooms throughout a building. Whether a building has operable windows, which would fall under natural ventilation but are typically not a designed natural ventilation system, is also part of a building's ventilation approach.

The next section of Table 2 lists information that describes mechanical ventilation systems, the first being the type of system: supply or exhaust only, 100% outdoor air, or having the ability to recirculate return air. There are many terms used to describe ventilation systems in terms of how they perform heating and cooling and how they distribute air to spaces, such as variable-air-volume, dual-duct and others, but those details are not covered here. Rigorous system taxonomies do not yet exist to capture this information, although EPA (2003) contains a comprehensive approach to HVAC system description that merits updating. For each air handling unit (AHU) in the mechanical ventilation system, the design will typically include fan specifications with the design supply airflow rate, the minimum outdoor air intake rate, and in some cases a maximum outdoor air intake rate that would apply when the system is operating under economizer mode. (Economizer operation refers to increased outdoor air intake to cool a building rather than using mechanical cooling equipment, i.e., chillers, as an energy efficiency option.) However, economizer operation is only

Table 2 Ventilation system design information (with most essential information in bold font)

System category	Design information
System status	Design documentation Maintenance schedule
Ventilation approach	Infiltration only
	Mechanical ventilation
	Natural ventilation
	Hybrid ventilation
	Local or central exhaust
	Operable windows
Mechanical ventilation	Type: supply or exhaust only, 100% outdoor air, recirculation
	Supply airflow rate
	Minimum and maximum outdoor air intake rate
	Basis for minimum outdoor air intake rate (which standard or building regulation; calculations and assumptions employed)
	Particular filter locations and efficiencies
	Exhaust airflow rate: system and space level
	Space-level air distribution, e.g., use of mixing boxes and description of their controls.
	Sequence of operations
	System maintenance schedules by component
Natural ventilation	Operable windows (location, size of openable area)
	Purpose-provided vents (location, size)
	Engineered system, description of major elements and intended airflow patterns , primarily where air is intended to enter and leave the building and the occupied spaces, <i>and assumed operating conditions</i>
	Controls: occupant-based, automated (describe)
	Estimated ventilation rates and method of estimation
Hybrid or mixed-mode ventilation	Design concept: when would mechanical system operate (e.g., based on season, time of day, weather)
	Above information for both mechanical and natural

feasible if the outdoor air is cool and dry enough and if elevated outdoor pollutants can be effectively removed by filtration or air cleaning. Outdoor air ventilation rates are specified during building design to comply with building regulations and standards that contain requirements for minimum ventilation rates, typically on a per occupant and per-unit floor area basis. For example, ASHRAE Standard 62.1 contains such requirements for commercial and institutional buildings, while ASHRAE Standard 62.2 contains requirements for residential buildings (ASHRAE 2019a, b). Ventilation standards exist around the world, based on the priorities and expectations of the country or region in which they are developed (CEN 2007; Limb 2001). Fan specifications or other design documentation should include the basis for the minimum outdoor air intake rates including the standard or building regulation used to determine these rates, key assumptions (e.g., floor areas and design

occupancies of the spaces, occupancy category), and a record of the calculations of the minimum intake rate. However, the existence of these details is more common in commercial buildings than in residential. ASHRAE Standard 62.1 actually requires that this information be provided in writing; the standard also contains an informative appendix (not an official part of the standard) with sample tables for preparing design documentation (ASHRAE 2019a).

Other information needed to describe mechanical ventilation systems listed in Table 2 include the location of particulate filters and their removal efficiencies, e.g., MERV ratings. Exhaust airflow rates for central exhaust systems and exhaust vents in spaces feeding these central systems, and airflow rates for local exhaust systems are also listed. Information on space level air distribution is next, which can be quite detailed but at a minimum the existence of mixing and VAV boxes should be noted, along with a description of how they are controlled. The latter information is often contained in the so-called sequence of operations for a system, which explains how the system is intended to operate, how it will respond to outdoor weather and internal thermal loads, and other aspects of system control (The ASHRAE Terminology Glossary (www.ashrae.org/ashraeterms) definition of sequence of operations includes the following: an organized narration specifying how the integrated functions of a device, system, or facility will perform. It should incorporate energy efficiency and environmental concerns with detailed, comprehensive control strategies, i.e., how each individual piece of equipment will be controlled and what information and adjustment will be available to the user. These may be provided in a combination of narratives, diagrams, and point lists for every unique type of equipment and for each system.). The sequence of operation is critical to understanding how a system is intended to operate and then to determining whether it is operating as intended. The final entry under mechanical ventilation is system maintenance, which includes schedules for visual inspection of different components, filter changing, and sensor calibration. ASHRAE Standard 62.1 contains a table of minimum ventilation system equipment maintenance activities that is useful in identifying items to record under this category.

Describing natural ventilation systems involves identifying the locations and sizes of operable windows and any purpose-provided inlet and outlet vents. If the system is engineered, rather than just providing these openings and assuming the resulting ventilation is adequate and well-distributed, the system description should include information on the major elements of the system, (e.g., inlet vents, thermal stacks) and the intended airflow patterns (e.g., where air is intended to enter and leave the building, and how it is expected to move through the building). The latter should be provided under different weather conditions, such as cold and windy, warm and mild, or other prevalent weather patterns for the climate. The manner in which the components of the natural ventilation system are controlled is also key to its design. Specifically, are the vents controlled based on occupant preferences and actions? If the system is automated based on weather conditions, indoor air temperatures, indoor contaminant concentrations, or other parameters, the manner in which these controls are intended to operate needs to be described. Finally, if the design has an estimate of the expected ventilation rates in the building or in individual spaces,

these rates, including the assumed weather conditions on which the estimate is based and the method used for their estimation, should be noted.

For hybrid or mixed-mode ventilation systems, in addition to the previously described information for mechanical and natural ventilation systems, the system description should include the design concept: When would the mechanical system operate? Is that based on season, time of day, weather conditions, or some other approach? Is there an interlock that prevents the mechanical ventilation system from operating when windows or vents are opened?

While the information in Table 2 may appear to be very detailed, understanding the ventilation system design is key to building ventilation assessment. Measured ventilation rates or other performance parameters are extremely difficult to interpret without such design information.

Measurement Methods

Building ventilation performance assessment methods have been available for decades and have been reviewed previously. The AIVC bibliographic database Airbase, mentioned earlier, is a helpful resource for identifying previous reviews and other relevant material. McWilliams (2002) provides a thorough bibliography of publications covering multiple measurement techniques. Nazaroff (2021) discusses several means of characterizing residential air change rates in a review of available measurement results. There is not space in this chapter for a detailed description of available assessment methods; instead, this section reviews methods of assessing the performance parameters listed in Table 1, providing references (particularly standard methods of test where available) and highlighting some key issues in their application. This section also discusses other important issues including variations in ventilation rates and deviations from design intent. As noted earlier, buildings and systems are extremely variable, and the specific features of each must be considered when planning and conducting ventilation measurements. Also, the interpretation of measurement results requires that they be compared with a baseline value, which would typically be based on the design information discussed in the previous section and results from similar buildings, as well as relevant standards and regulations.

System Status

There is no standard approach to assessing system status, although the BASE protocols mentioned earlier thoroughly cover system condition, operation, and maintenance (EPA 2003). These protocols contain detailed checklists for documenting system condition and maintenance schedules. The inspection checklist (C-12) covers the operation and condition of many system components including fans, filters, drain pans, controls, and terminal units. The information covered under operation includes simple matters such as whether the fan is on or off and if air is moving in the intended direction through the outdoor air intake. The system condition questions cover the presence of dirt and moisture, and the state of dampers, linkages, and sensors.

Assessing system operation and condition is primarily conducted by visual inspection of the system and its components using these checklists or other resources, as well as accessing information available from building automation system (BAS) interfaces. However, as useful as BAS information can be, visual inspection is essential to confirm BAS indications of system operation and to assess the condition of the system and its components, as BAS systems do not necessarily monitor cleanliness, moisture damage, dysfunctional or broken components, and filter condition. The BASE protocol maintenance checklist (C-11) is useful for recording information on system maintenance procedures and schedules. The maintenance information covered by this checklist includes the frequency of air handler inspections, filter replacement, control system inspection and sensor calibration, ventilation system testing and balancing, and the inspection, cleaning, and treatment of a range of specific system components. Whether one uses these detailed checklists or some other approach, system condition and maintenance are extremely important to understanding ventilation in a building. Information on maintenance practices can be obtained through discussions with building managers and operators as well as examining manuals on system operation that should be provided with the design documentation. Note that in larger buildings, the operations staff can vary in their familiarity with these procedures, and it is important to identify knowledgeable staff members.

A key aspect of assessing system status is locating the design documentation, determining if it is up-to-date, and identifying any key gaps or updates required to reflect current building use and compliance with current standards and regulations. Similarly, maintenance schedules and logs need to be identified, either hard copies or electronic. These records should be evaluated as to whether they are current and for thoroughness in covering all the building systems and components. As noted earlier, in some buildings, design and maintenance records can be hard to find and may not exist at all, although this should be less common as building and system information is increasingly in digital form. The EPA BASE protocol contains checklists (C-1 through C-10) for documenting HVAC system design information including air handlers, perimeter units, unitary systems, and exhaust fans. Among these system design descriptions, minimum outdoor air intake rates are one of the most important for assessing ventilation system performance. Along with this value, the design should also describe how this minimum rate was determined, which standard or building regulation was used, the activities assumed to be taking place in the spaces served by the system, the design occupancy, and the floor area served. These assumptions are key to determining if the design outdoor air rate is still applicable to the space as it is currently being used and if a more recent ventilation standard or regulation is relevant. The previous section of this section, “[Building and System Design Information](#),” discussed system design information in more detail, with reference to Table 2.

Envelope Air Leakage

As discussed earlier, infiltration is the only ventilation mechanism in many buildings, and even in tight buildings, infiltration rates are comparable to mechanical ventilation rates. Characterization of air leakage involves three parameters: envelope

airtightness, building infiltration rates, and indoor-outdoor pressure differences. Envelope airtightness is measured with a fan pressurization test, which involves using a fan (either brought to the building or the existing air handling equipment) to temporarily impose a uniform indoor-outdoor pressure difference across the envelope and then measuring the airflow required to induce this pressure difference. Often a series of pressure differences are induced to generate an airflow versus pressure curve, which can reduce the uncertainty in the reported test result. Fan pressurization testing has been employed for about 50 years, and several standards exist that describe the equipment and instrumentation, test protocols, data reduction, and reporting. There are three ASTM fan pressurization standards, with E779 (ASTM 2019) being the most general. E1827 (ASTM 2017) describes the use of an orifice blower door to conduct the test, and E3158 (ASTM 2018a) is specific to larger buildings. ISO 9972 (ISO 2015) is also a fairly general test method, while CGSB 149.15 (CGSB 1995) discusses the use a building's air handling equipment to conduct the test. Using existing air handlers has advantages over bringing a fan to the building, assuming one is able to accurately measure the airflow supplied by the system using the ventilation system airflow methods described below. Envelope airtightness is typically expressed as a volumetric airflow rate, e.g., m^3/s , at a reference indoor-outdoor pressure differential that is typically normalized by the building volume or the envelope surface area, or as an effective leakage area, which may be normalized by the building envelope or floor area (ASHRAE 2021).

In conducting whole building fan pressurization tests, it is important that all points on the exterior envelope of the building are subject to the same indoor-outdoor pressure difference. This condition can be facilitated by opening all interior doors and running tests when outdoor temperatures are mild and wind speeds are calm. The impact of indoor-outdoor air temperature differences becomes more critical as buildings get taller, since stack- or buoyancy-induced pressures increase with building height. The referenced test methods have criteria for weather conditions and pressure difference uniformity and describe the management of interior doors and other partitions to support achieving uniform pressure difference. Another important issue in fan pressurization testing is the need to clearly define the pressure boundary of the building that is being tested. In buildings with attics, basements, and other unconditioned or partially conditioned spaces, the definition of the pressure boundary can be complex. Some of these spaces are not well-connected with either the outdoors or the building interior, leading to significant pressure differences to the outdoors or interior, interfering with the goal of a uniform indoor-outdoor pressure difference. These standards describe how to deal with such spaces, but tests in these buildings can be more complex than in simpler single zone buildings. Multizone buildings, in which the interior spaces are not well-connected in terms of airflow, may require more than one fan pressurization device in the different zones to meet the pressure uniformity test requirement. Another important issue in conducting fan pressurization tests is the position of vents and dampers in the exterior envelope, which is covered by the standards referenced above. If all such vents and dampers are closed and sealed, the test results provide a measure of the envelope construction quality in terms of airtightness. If those vents and dampers are open, the results are a

more useful measure of the airtightness in determining infiltration rates under normal conditions of weather and building operation.

Infiltration rates, in units of air changes per hour or h^{-1} , quantify the amount of outdoor air that enters a building through unintentional openings in the building envelope. In buildings that are ventilated only by infiltration (no mechanical ventilation or open windows or doors), the tracer gas methods for measuring outdoor air change rate described below can be used to measure these rates. Given the strong dependence of infiltration rates on indoor-outdoor temperature difference, wind speed and direction, and the operation of building equipment (e.g., vented combustion appliances), multiple measurements under a range of these variables are required to characterize infiltration in a building. (Examples of such detailed measurements are shown below.) At a minimum, a reported infiltration rate must be accompanied by information on weather conditions and building equipment operation to be meaningful. In large buildings, particularly those with large horizontal footprints or otherwise divided into sections of different ages and envelope construction, different portions of the building may have different envelope leakage values and different indoor-outdoor pressure differences due to variations in wind exposure and other factors. These differences can result in different infiltration rates in these various sections of the building, which can be difficult to measure with standard tracer gas techniques but which can have significant effects on energy use, thermal conditions, and indoor contaminant levels.

In buildings with outdoor air mechanical ventilation, infiltration rates can be estimated by subtraction; one measures the whole building outdoor air change rate using a tracer gas dilution method and subtracts the system outdoor air intake rate measured using the system airflow rate measurement techniques described below. This approach is not common, but was applied in a commercial building by Persily and Norford (1987), who studied the variation in infiltration and intake rates as a function of weather and ventilation system control mode. However, ventilation system operation can induce indoor-outdoor pressure differences that will impact the infiltration rate. Even if the ventilation system is balanced, i.e., the system outdoor air intake and exhaust rates are equal, operating the system can induce local pressure effects that will impact infiltration rates. Infiltration rates in mechanically ventilated buildings can also be measured by conducting a tracer gas test with the system off, as was done in a very, tight residential building by Ng et al. (2015). However, conducting tracer gas tests with the system off can interfere with achieving uniform tracer concentrations, which are required for accurate measurements as discussed below.

As noted earlier, measuring indoor-outdoor air pressure differences across the building envelope can be useful in understanding envelope leakage. There are no standards that describe how to make these measurements and interpret the results, although there have been some useful articles in building industry trade publications. Standards exist that describe air pressure measurements and instrumentation in detail (ASHRAE 2014, 1988). Indoor-outdoor pressure differences can be measured at key locations over the building envelope, either one-time or periodically with a handheld device or automatically over an extended period of time to capture inevitable

variations in these pressure differences. Since these pressures will vary with location and time, they should be measured under a range of weather and system operation conditions to understand the airflow dynamics of the building being studied. Consistent pressure difference values over the entire building envelope or locally can be an indication that a specific building or system operating mode is inducing higher infiltration rates than others, or that there is an airflow imbalance between the supply and exhaust airflows for a space. The latter conclusion should be confirmed by measuring those system flows and comparing them to their design values.

Ventilation System Airflow

Depending on the type and configuration of a ventilation system, it will be associated with several different airflows as described in Table 1 and shown in Fig. 1: outdoor air intake, supply, return, and exhaust. For systems serving multiple spaces, the latter three are relevant at both the system level and in individual rooms or ventilated spaces. As noted earlier, not all of these parameters apply to all ventilation systems, e.g., some have no return airflow and some have no outdoor air intake. The rate at which outdoor air is brought into the ventilation system can also be characterized by the percent outdoor air or outdoor air fraction, which is the outdoor air intake rate divided by the supply airflow rate. Percent outdoor air values vary from 0% (no intake) to 100% (no return air being recirculated). Exhaust airflow rates, both at the system and space level, are relevant to systems whose sole function is to draw air from single or multiple spaces, e.g., toilet rooms, and exhaust that air to the outdoors. As noted earlier, system airflow rates depend on the system operating status and mode of operation, which need to be considered in planning these measurements and included with reported measurement results.

System airflow rates can be measured in ducts or at outdoor air intakes using standard air speed traverse methods employing pitot tubes or hot-wire anemometers (ASHRAE 2008; NEBB 2005; SMACNA 2002). Traverse measurements involve multiple air speed measurements across a cross section of a duct, with the number of measurement points depending on the duct size. The average air speed is then multiplied by the cross-sectional area of the duct to yield the volumetric airflow rate in units of L/s or cfm. Accurate traverse measurements require uniform velocity profiles in the ducts, and the referenced standards and guides contain criteria for evaluating whether the profile is acceptable. These documents typically claim a measurement accuracy of $\pm 10\%$ under good conditions, but the basis of these accuracy estimates is not provided. In order to meet the requirements for a uniform velocity profile, there needs to be a sufficient number of lengths of ductwork downstream of transitions (as a multiple of duct diameter) upstream of the measurement plane. However, in many system configurations, such lengths do not exist, making these measurements less accurate. This is especially true at outdoor air intakes, where there may be very few duct diameters before the outdoor airstream mixes with the return air (Fisk et al. 2002). Some ventilation systems have permanently installed airflow monitoring stations, which include an array of thermal

anemometers or other sensors to provide a continuous airflow rate measurement, which is often accessible via the BAS. While these systems can be fairly accurate under ideal conditions, they should be calibrated as installed as every system installation is unique and may affect the measurements. Technologies exist to measure outdoor air intake rates by incorporating air speed or pressure sensors into outdoor air intake louvers. Studies into the performance of such devices show promise, with potential measurement errors from 10% to 30%, but each louver and sensor configuration needs to be tested to verify its accuracy, which tends to degrade at lower airflow rates (Fisk et al. 2004, 2008).

Outdoor air intake rates can be determined by separately measuring the supply airflow rate (using a duct traverse) and multiplying it by the percent outdoor air intake rate. Percent outdoor air can be estimated based on measurements of the air temperature in the return, supply, and outdoor airstreams of the air handler (ASHRAE 2008). Accurate measurements using this approach requires that the three air temperatures are sufficiently different relative to the air temperature measurement uncertainty and that there is no heating or cooling of the air between these temperature measurement locations. Alternately, one can estimate the percent outdoor air based on the CO₂ concentration in these three airstreams, which is discussed in ASTM Standard D6245 (ASTM 2018b). This method also requires that the three CO₂ concentrations are sufficiently different relative to the concentration measurement uncertainty, with the referenced standard describing how to estimate the associated measurement error.

Airflow rates in ducts can also be measured with tracer gas methods as described in ASTM E2029 (ASTM 2011a). This method involves injecting tracer gas into a duct at a constant rate and measuring the concentration upstream and downstream of the injection point. The airflow rate is equal to the tracer gas injection rate divided by the increase in tracer gas concentration from upstream of the injection to the downstream location. As described in the referenced standard, care must be exercised in injecting the tracer gas to facilitate good mixing with the duct airstream, and the downstream concentration measurements must provide a good estimate of the average downstream concentration.

Supply airflow rates into, and return and exhaust airflow rates out of, individual ventilated spaces can be measured using flow hoods. These devices use a conical or other shaped hood to collect all of the air from a supply vent and guide it over an airflow measuring device that employs vane anemometers or pressure difference based gauges (ASHRAE 2008; SMACNA 2002; NEBB 2005). Flow hoods can also be used in reverse at return and exhaust vents. The referenced standard and manufacturers' literature provide limits on air speeds, calibration requirements, cautions on directional effects related to supply air discharge patterns, and potential impacts of pressure drops associated with the flow measurement device itself.

Ventilation system operating status and mode of operation needs to be checked and recorded whenever measuring system airflow rates. This involves more than just whether the system is on or off but also the outdoor air intake mode, e.g., morning warm up during the heating season when outdoor air fractions will be reduced or even zero, or economizer operation when outdoor air intake is maximized for

cooling the building without using mechanical cooling equipment. Modern ventilation systems in commercial building typically have multiple modes of operation, and describing their operating status requires an understanding of the system design and sequence of operation as described earlier.

Ventilation system airflow measurements must be planned based on the building layout, the number of systems and an understanding of which portions of the building are served by each. Part of this planning relates to logistics, scheduling, and instrumentation deployment, as these systems can be located at significant distances from each other in different mechanical rooms throughout a large building. If system airflow rate measurements are going to be related to airflow measurements at supply, return, or exhaust vents in the occupied space, the spaces served by the system must be identified prior to making the measurements through the examination of the building mechanical drawings and floor plans. Situations in which this can be useful include comparisons of the supply airflow rate at the system to the sum of all the supply airflow rates at the individual vents, which can help to verify the supply airflow rate value and perhaps also to provide an indication of duct leakage between the air handler and the vents. Another example is multiplying the percent outdoor air fraction at the air handler by local supply airflow rate measurements to estimate the outdoor air delivery to the ventilated space.

When evaluating buildings with multiple air handling systems, ventilation measurements in the different systems need to be coordinated to ensure that they are conducted under sufficiently similar weather, occupancy, and operation conditions such that the results can be combined in a meaningful way to yield total supply and outdoor air intake rates for the building. For example, measuring outdoor air intake in some systems during the cool part of a morning when outdoor air intake fractions are high, and other systems during warmer periods in the afternoon when outdoor air intake are more likely to be at minimum values, will not allow a meaningful determination of the total outdoor air intake of the building.

Outdoor Air Change Rate

Outdoor air change rates, envelope infiltration plus outdoor air intake, impact the amount of energy required for heating and cooling a building and indoor contaminant concentrations. Infiltration is often assumed to be negligible, but in the absence of measurements or physics-based analysis, this assumption cannot be supported. Also, as noted earlier, infiltration is the only means of outdoor air ventilation in many buildings.

Total outdoor air change rates can be measured using tracer gas dilution methods as described in ASTM Standard E741 and ISO 12569 (ASTM 2011b; ISO 2017). In fact, tracer gas methods are the only way to measure building outdoor air change rates except in the unusual case in which a building is so extremely tight that all of the airflows into and out of the building are known to take place via the ventilation system ductwork. In these cases, the system airflows can be measured using duct airflow measurement techniques described above. Both referenced tracer gas standards are single-zone techniques, which means the tracer gas concentration

throughout the building being tested can be characterized by a single value. Some discussions refer to this as perfect mixing, but the key issue is actually tracer gas concentration uniformity. The referenced ASTM standard requires that concentrations in the test space differ by less than 10% of the average concentration to achieve a test precision and bias of 10%. There are three tracer gas dilution methods: decay, constant concentration, and constant injection. In the decay method, a quantity of tracer gas is released directly into the test space or supplied via the ventilation system and allowed to mix with the interior air until the concentration is sufficiently uniform. Sometimes portable mixing fans are installed in the space to enhance mixing, but these should not be relied on to mix the air and tracer between rooms in a building. Air handling systems can be used to enhance distribution and mixing of the tracer gas between rooms. However, if these systems are left on during the actual decay, they can create indoor-outdoor pressure differences across the building envelope that impact the infiltration rates. Once the tracer gas concentration is sufficiently uniform, the concentration decay over time is monitored and used to estimate the air change rate, with ASTM E741 providing detail on sampling, analysis, and reporting. Some tracer gas decay studies have been conducted by monitoring the decay rate in a single room, such as a bedroom, and referring to that as the air change rate of that room. However, this approach ignores air and tracer transport from adjoining spaces, and unless there is explicitly accounting for interzone transport in the tracer gas mass balance analysis, single-room decay rates in multizone buildings should not be referred to as outdoor air change rates. They can be informative but should only be referred to as room decay rates as they generally do not provide accurate outdoor air change rates for a test space or the whole building.

Another tracer gas dilution approach, also described in ASTM E741, is the constant concentration tracer technique, which involves varying the tracer gas injection rate to maintain a constant indoor tracer gas concentration using automated feedback control. This approach can be advantageous in multizone buildings where zones have different outdoor air change rates, in which a decay test would not be able to maintain a uniform tracer gas concentration throughout the building. However, this approach requires more complex instrumentation than the decay method and is not used often except in research studies (Takaki et al. 2005).

The third single-zone tracer gas dilution method is the constant injection method, which involves injecting tracer gas at a constant rate into the space being tested and monitoring the concentration response. Assuming the outdoor concentration is zero and the injection rate is constant, the single-zone mass balance can be integrated to yield an expression for the outdoor air change rate that requires the average of the inverse of the tracer gas concentration. If the airflow rate is constant, the tracer gas concentration will eventually reach steady state, at which point the outdoor airflow rate equals the tracer gas injection rate divided by the steady-state tracer gas concentration. The constant injection approach can be useful for measuring airflow rates in ducts per ASTM E2029 as discussed earlier, and the steady-state formulation serves as the basis for the use of peak CO₂ concentrations for estimating ventilation rates, which is discussed below.

The constant injection tracer approach is the basis of the so-called perfluorocarbon tracer (PFT) method, in which a PFT is injected using passive devices, typically over measurement periods of days to weeks or longer. Passive samplers are then deployed throughout the building being tested to determine the average tracer gas concentration during the sampling period. This approach has the advantage of being relatively inexpensive since the samplers are analyzed in a laboratory facility after the field test, and it has been used in a number of residential field surveys (Offermann 2009; Yamamoto et al. 2010). This technique employs a transient tracer gas mass balance, since the air change rate cannot be assumed to be constant over typical sampling periods given variations in weather, equipment operation, and occupant activities. The fact that the sampling technique determines the average concentration, not the average of the inverse concentration, introduces bias into the measurement results. Specifically, there is a tendency to overestimate the average air change rate, which has been shown to be as high as 15–35% for seasonal average air change rates (Sherman 1989). In tight buildings with very low infiltration rates and fairly constant mechanical ventilation rates, this bias is less of a concern. In those cases, a short-term tracer gas measurement may suffice.

The peak CO₂ approach has been used for decades, purportedly as an inexpensive and simple means of estimating outdoor air change rates in buildings and sometimes spaces within buildings. However, it has been misapplied in many cases due to a lack of recognition that it is fundamentally a single-zone, constant injection steady-state tracer technique and thus must abide by several key assumptions to yield valid air change rates. These assumptions include: the CO₂ generation rate is known, constant, and uniform throughout the building being tested; the CO₂ concentration is uniform throughout the building and has achieved steady state; the outdoor CO₂ concentration is known and constant; and the outdoor air ventilation rate is constant (ASTM 2018b). Also, because it is a single-zone approach, it can only be used to determine the air change rate of an entire building with a uniform CO₂ concentration. If the CO₂ concentration varies among rooms, the single-zone mass balance is no longer valid and one must employ a multizone mass balance of CO₂ that accounts for the airflows between zones. The assumption that the CO₂ generation rate is known, constant, and uniform throughout the building translates to the occupancy level also being known, constant, and uniform. It also requires that the occupant levels of physical activity are relatively constant as physical activity impacts CO₂ generation rates (Persily and de Jonge 2017). The requirement for the CO₂ concentration to be at steady state translates to conditions being constant for long enough that a steady-state concentration is achieved. As described in ASTM D6245 (ASTM 2018b), the time required to achieve steady state depends on the air change rate of the building. For a given air change rate, the concentration will be within 95% of steady state after three time constants, where the time constant is the inverse of the air change rate. For an air change rate of 1 h⁻¹, it will therefore take 3 h to reach 95% of the steady-state concentration. For an air change rate of 0.5 h⁻¹, it will take 6 h. During this time, the ventilation rate, occupancy, and outdoor CO₂ concentration must all be constant, which will not be the case in some buildings. Using a CO₂ concentration before

steady state has been achieved will overestimate the air change rate, in some cases by significant amounts.

As noted above in the discussion of the tracer gas decay technique, the peak CO₂ approach has also been applied in single rooms, such as bedrooms, with the result being referred to as the air change rate of that room. However, the tracer gas methods on which this approach is based apply only to single zones. Using peak CO₂ in bedrooms ignores interzone air and CO₂ transport from other indoor spaces such as adjoining rooms and hallways. The impacts of such transport on the measurement results are difficult to characterize unless interzone transport is explicitly accounted for in the tracer gas mass balance analysis. Only then can CO₂ concentrations in a bedroom be used to calculate outdoor air change rates. Several studies have converted peak CO₂ concentrations in bedrooms to outdoor air change rates without speaking to the issue of interzone transport and the inaccuracies in this approach. Maximum CO₂ concentrations in bedrooms and other spaces in multizone buildings can be informative, but they are not outdoor air change rates.

It needs to be noted that single-zone, tracer gas dilution methods for measuring outdoor air change rates are challenging in naturally ventilated buildings. Specifically, when there are large openings, e.g., open windows, the large and localized airflows into the building at zero outdoor tracer gas concentrations will interfere with the tracer gas concentration uniformity requirements of these test protocols (Jones and Kirby 2010; Nikolopoulos et al. 2012). Some studies have measured air speeds in ventilation openings, but these approaches have not been well studied nor will they capture infiltration through unintentional leaks.

The tracer gas dilution methods discussed so far are for measuring building outdoor air change rates. In some circumstances, one is also interested in airflow rates between zones, commonly referred to as interzone airflows. Also, as noted earlier, larger buildings with sections that are different in terms of construction, wind exposure, or ventilation system design or operation can have different air change rates. The single-zone tracer decay and constant injection methods are not able to quantify differences between building sections and may be challenging to implement given the lack of tracer gas concentration uniformity that is likely to exist. Measuring airflows in such situations requires multizone tracer techniques that are discussed briefly below.

Interzone Airflow

Interzone airflows are an important aspect of ventilation assessment in many applications, particularly when one needs to perform a contaminant mass balance analysis for building zones at different contaminant concentrations or to understand the overall airflow dynamics in a building. Interzone airflows, as well as differences in airflows to and from outdoors in different sections of a building, become more important as buildings are larger and configured such that different portions of the building vary in their construction and ventilation systems. The constant concentration

method discussed above can be used to determine the outdoor airflow rate into individual zones but not interzone airflow rates. Multizone tracer gas methods exist for estimating interzone airflows, but they are complex and have typically only been used in research studies going back four decades (T'Anson et al. 1982). More recent applications of multizone tracer techniques (Dodson et al. 2007; Du et al. 2012, 2015; Bekö et al. 2016) are discussed by Nazaroff (2021). These references involve studies to estimate airflows to and from basement zones or garages to the living space, or bedrooms to and from the rest of the building. Interzone airflow measurements are scarce in commercial buildings, with one study conducted by the author almost 30 years ago (Persily and Axley 1990). In contrast to the single-zone tracer gas techniques discussed above, multizone tracer gas techniques have not been standardized, are more complex and costly, and are subject to potentially large uncertainties, which are some of the reasons they have not been widely applied.

As alternatives to tracer gas measurements of interzone airflows, the airtightness of partitions between zones and pressure differences between zones can be measured more easily. The former can be measured using fan pressurization methods, while the latter can be measured with differential pressure gauges, but neither approach has been standardized and general guidance on their application is lacking. Measurement of the airtightness of interzone partitions can be useful for understanding the potential for interzone airflows, but without values of the pressure difference across the partitions, they cannot be related to actual airflow rates. However, these interzone airtightness values can be used for airflow modeling.

As noted above in the discussion of indoor-outdoor pressure differences, standards exist that describe air pressure measurements and instrumentation (ASHRAE 1988, 2014). Again, the concept is to measure interzone pressure differences at locations of interest in the building to better understand the direction of these airflows, and more specifically the pressure relationships between zones. The measurement locations should relate to the goals of the building study being carried out, which might include concerns regarding airflows to and from zones with elevated contaminant concentrations (e.g., toilet rooms and attached garages) or stack-driven pressures within a building via stairwells and other vertical stacks. These pressures can be measured one-time with a handheld device or automatically over an extended period of time to capture variations. They should be measured under a range of weather and system operation conditions as they will vary with location and time.

Air Distribution

Air distribution refers to the manner and uniformity with which ventilation air is delivered to a space, specifically the portions of the space where occupants are located. A variety of metrics and definitions have been employed over the years to quantify air distribution including age of air, pollutant removal efficiency, ventilation effectiveness, and ventilation efficiency. The specific terms and definitions are not always used consistently, but published experimental and simulations studies are

generally clear on what is being measured or calculated. Most air distribution measurements involve tracer gas methods, though some are based on air speed, temperature, and contaminant levels (Fisk et al. 2005; Rim and Novoselac 2010; Karimipanah et al. 2007; Zhai 2005; Faulkner et al. 2004; Chao and Wan 2004). The air diffusion performance index (ADPI) is used to characterize the performance of air diffusers in spaces based on air speed and temperature distribution in the context of thermal comfort and depends on the geometry and cooling load of the space, but it does not characterize outdoor air distribution (ASHRAE 2013). An ASHRAE standard for measuring air change effectiveness using a tracer gas to quantify the effectiveness of outdoor air distribution was approved in 1997, and reaffirmed in 2002, but has not been updated since (ASHRAE 1997).

Other Considerations

Variation in Ventilation

As noted earlier, many of the performance parameters listed in Table 1 vary with weather, system operation, and occupant activities. The existence and extent of these variations in ventilation performance have been seen in multiple building studies of infiltration rates, mechanical ventilation system airflows, and total outdoor air change rates (Persily 2016). Given these variations, one needs to understand the building and its system before planning a ventilation measurement effort, and multiple measurements under a range of conditions are needed to characterize ventilation in a building. Even if one is only interested in the outdoor air change during a specific period of time, for example in conjunction with indoor contaminant measurements, it is critical to report weather, system status, and other factors along with the outdoor air change rate measurement. Space does not permit an extensive discussion of the many studies showing these variations, but three examples are highlighted here.

One example is a study involving multiple measurements of outdoor air change rates in a three-bedroom manufactured house used for IAQ research, before and after an airtightening retrofit (Nabinger and Persily 2011). The retrofits included sealing of ducts and floor penetrations over a vented crawlspace and installation of a house wrap under the exterior siding, resulting in an overall reduction of 24% in the envelope airtightness based on whole building pressurization tests. Figures 2 and 3 are plots of the air change rate versus indoor-outdoor temperature difference with the forced-air heating and cooling fan off and on, respectively. Each plot distinguishes between the measurements before and after the airtightening retrofit. Note in Fig. 2 that the air change rate varies over a range of about 5 to 1 based on temperature difference with the fan off; the range of variation with wind speed is similar in magnitude. Also, the dependence on temperature difference has an entirely different form with the fan on in Fig. 3, and this dependence changes dramatically after the retrofit. These data highlight the importance of accounting for weather, system operation, and building status when measuring and reporting air change rates.

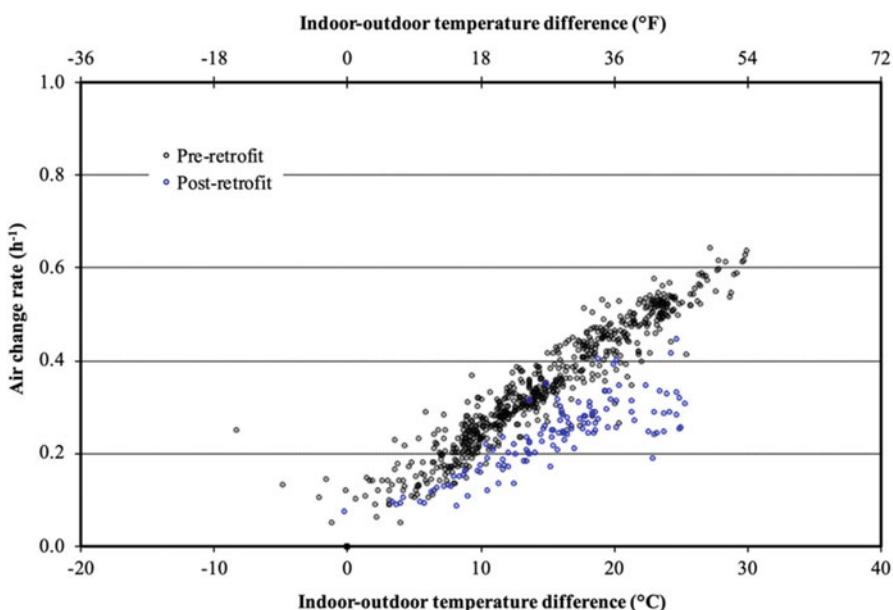

Fig. 2 Air change rates versus indoor–outdoor temperature in manufactured house, forced-air system off

An earlier, year-long study of air change rates in an occupied townhouse also shows variations with weather and occupant actions, specifically exhaust and attic fan operation and window opening (Wallace et al. 2001). About 4500 hourly average air change rates were measured, with a mean air change rate of 0.65 h^{-1} and a standard deviation of 0.56 h^{-1} . Figure 4 is a frequency distribution of the measured rates, revealing a lognormal distribution, which is typical for air change rates in single buildings and collections of buildings. Once again, we see a roughly 5 to 1 variation in air change rates. Window opening had a strong influence on the air change rates, with operation of an attic fan having a smaller influence. The indoor–outdoor air temperature difference impacted the air change rates, but wind speed had very little effect on this house due in part due to its location in a wooded area.

Another example is a long-term study of 14 mechanically ventilated office buildings in the USA (Persily 1989). These studies involved automated tracer gas decay measurements over multiple seasons of the year to get a fairly complete picture of air change rate variations with weather and system operation in each building. Figure 5 shows whole building air change rates for one of those buildings with the mechanical ventilation system operating over a wide range of outdoor air temperatures (Persily et al. 1992). These data exhibit the economizer cycle common in US commercial buildings, in which the system operates at minimum outdoor air intake during warm weather (about 20°C and higher) when mechanical cooling is required. At cooler temperatures, the outdoor air intake rate is increased dramatically to use outdoor air to cool the building rather than the mechanical cooling equipment

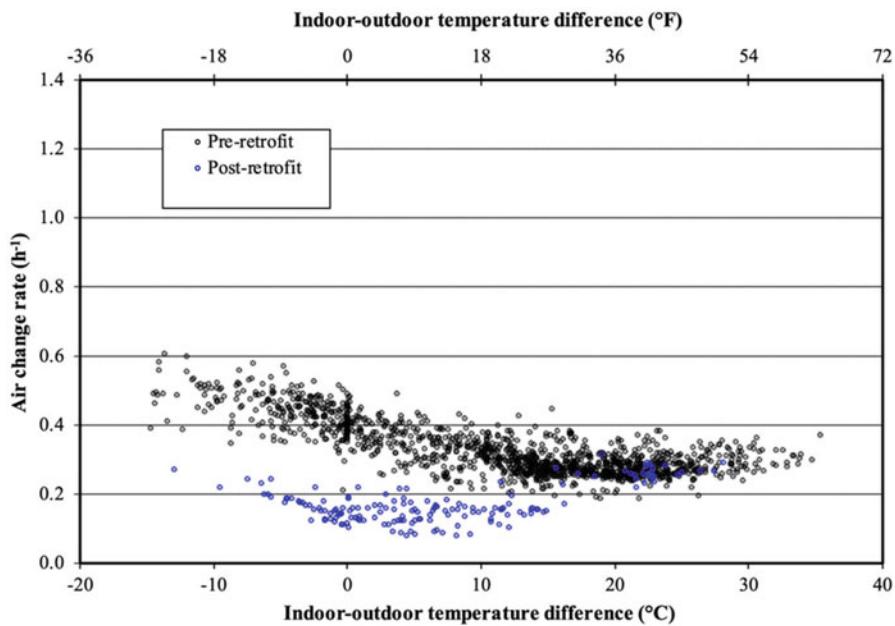

Fig. 3 Air change rates versus indoor–outdoor temperature in manufactured house, forced-air system on

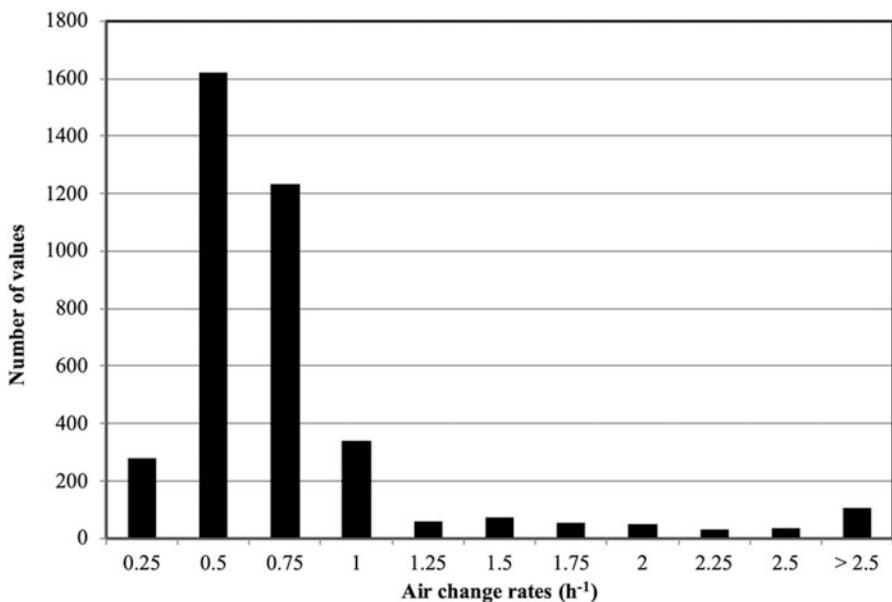

Fig. 4 Distribution of air change rates over 1 year in an occupied town house

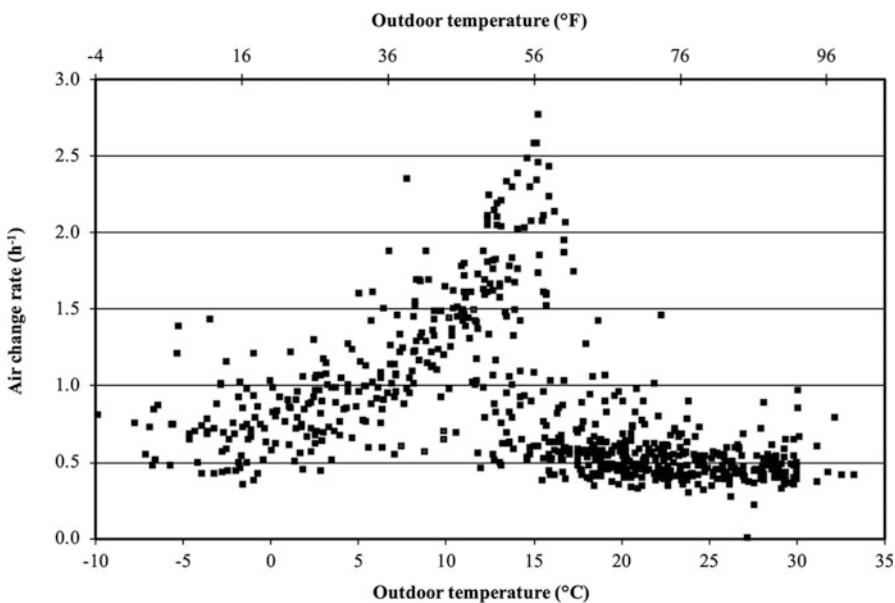

Fig. 5 Air change rates versus indoor–outdoor temperature in an office building (Persily et al. 1992)

as an energy efficiency measure. At lower outdoor air temperatures, the HVAC control system reduces the outdoor air fraction as less outdoor air is needed to cool the building. The outdoor air rate varies over a range of 5 to 1 based on the control system function, with a range of about 2 to 1 at a single outdoor temperature, presumably due to wind effects, measurement error, and other factors.

Figure 6 is a frequency distribution of outdoor air change rate measurements in 14 US office buildings (Persily 1989). This plot shows more than 3000 individual measurements, each corresponding to a tracer gas decay test lasting an hour or two, conducted over a wide range of weather and system operating conditions. The air change rates vary over a range of 10 to 1, with the rates in the individual buildings typically covering a narrower range depending on the weather during each building's tests and its individual characteristics such as airtightness. It is important to note that about 40% of the measured values were below the outdoor air ventilation requirement of 10 L/s per person for office buildings in ASHRAE Standard 62-1989, which was in effect at the time. Also, about 50% of the measurements were below the minimum outdoor air intake specification in the respective building's design documentation. This deviation from design is more notable since these air change rates include infiltration through envelope leakage, while the requirements in the standard and the design value are only for intentional intake. Presumably, if the system outdoor air intake rates were measured separately, even a higher fraction would be below the design value.

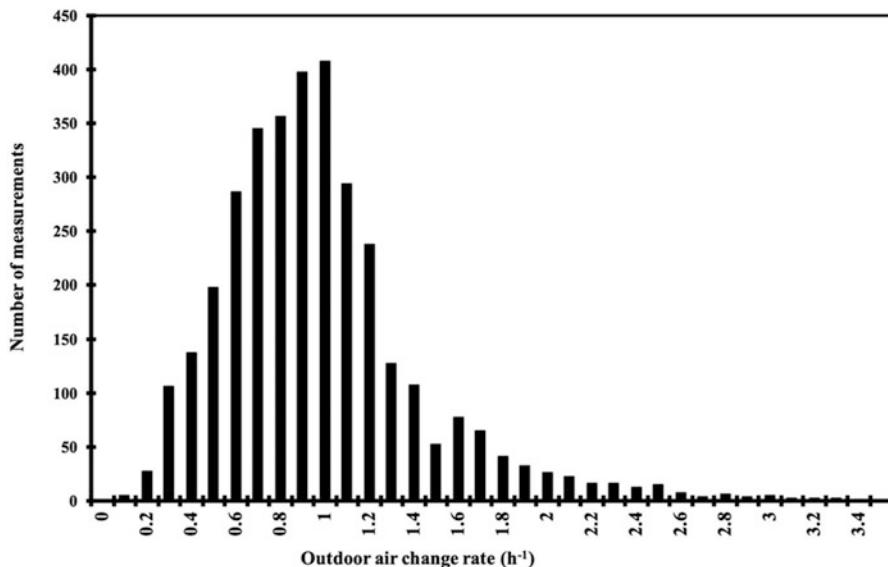

Fig. 6 Frequency distribution of outdoor air change rates in 14 US office buildings (Persily 1989)

Deviations from Design Intent

As noted above, actual ventilation performance can be significantly different from design intent. Such deviations in ventilation performance have been seen in studies of mechanical ventilation system airflows and total outdoor air change rates (Persily 2016). One example of that deviation is from the EPA BASE study of 100 US office buildings mentioned earlier. That study included ventilation measurements during a 1-week study period in each building (Persily and Gorfain 2008). The mean measured outdoor air ventilation rate was 49 L/s per person based on volumetric airflow measurements at the air handlers and measured occupant densities, which is high relative to the minimum outdoor air requirements in almost all ventilation standards. However, these high air change rates were due in part to frequent operation in economizer mode and the actual space occupancies being on average 80% of the design occupancy. Nevertheless, about 17% of the ventilation measurements were still below the 10 L/s per person requirement in ASHRAE Standard 62-1999, the version of the standard that was in effect at the time of the analysis (ASHRAE 1999). Considering only measurements made under minimum outdoor air intake and accounting for the actual occupancy levels, the mean ventilation rate was roughly 11 L/s per person and about one-half of the values were below the minimum requirement in Standard 62-1999. These results demonstrate the need to consider building occupancy and system operation when interpreting ventilation measurement results, as well as the deviation of measured ventilation rates from expectations based on design values or standard requirements.

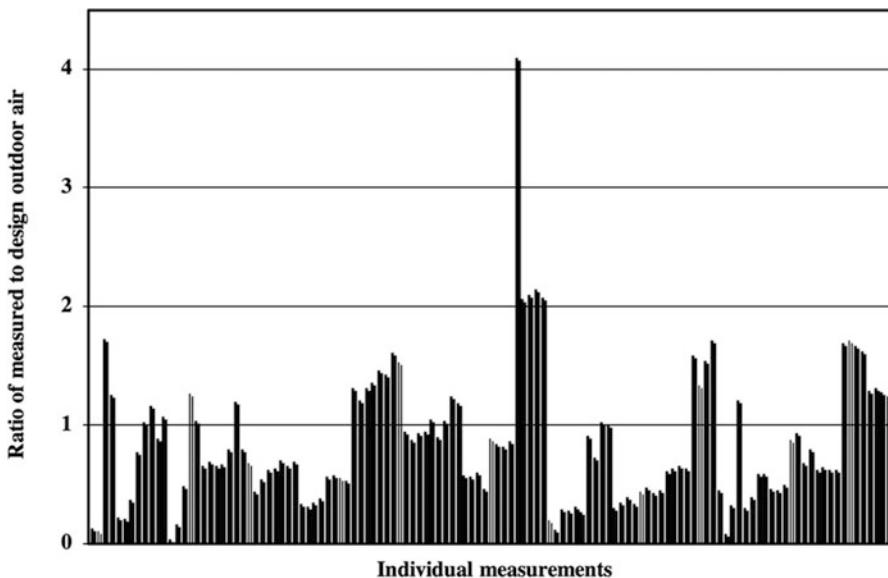

Fig. 7 Ratio of measured minimum outdoor air intake to design value (Persily 2016)

Another finding of the BASE ventilation study, highlighted in Fig. 7, is the deviation of the measured outdoor air intake rate from the corresponding design value, shown here exclusively for measurements conducted when systems were running at minimum outdoor air intake. The horizontal axis is simply the individual measurement result, and the vertical axis is the ratio of the measured value to the design value. If the systems were operating as designed, the ratios would all equal 1.0, subject to some variation due to measurement error. However, many values are less than one, reflecting systems operating with less outdoor air intake than intended, which can have a negative impact on IAQ. There are also many values greater than one, indicating higher outdoor air intake rates than intended, which leads to unplanned energy cost and potentially other problems, e.g., excessive indoor moisture.

Another field study in 108 new, single-family homes in California included measurements of air change rates using the steady-state PFT approach and outdoor air intake measurements using flow hoods or hot wire anemometers (Offermann 2009). This study evaluated the performance of ducted outdoor air ventilation systems, which typically operated intermittently in conjunction with the forced air space conditioning system fan, and of heat recovery ventilators that typically ran 24 h per day. Sixty-four percent of the ducted outdoor air systems failed to meet the California Energy Commission's 2008 Building Energy Efficiency Standards, which was attributed to a combination of low airflow rates and short operating times. All of the heat recovery ventilator systems met the 2008 standards. The median 24-h outdoor air change rate was 0.26 h^{-1} , with a range of $0.09\text{--}5.3 \text{ h}^{-1}$, and 67% of the homes had outdoor air change rates below the minimum California Building

Code requirement of 0.35 h^{-1} . The report attributed the lower air change rates to relatively tight envelope construction and limited window use by the building occupants. This study again highlights the impacts of system operation and occupant action, as well as the deviation of performance from design standards.

Conclusions

Assessing building ventilation performance, including the measurement of ventilation rates, is essential for interpreting indoor contaminant concentrations, accounting for the impacts of outdoor air entry on energy use, and understanding building airflow dynamics. This chapter has stressed that building ventilation assessment is not about a single quantity but covers several parameters, some of which are qualitative but still important. The quantitative parameters include but are not limited to outdoor air intake rates, system supply and exhaust airflow rates, envelope infiltration rates, and indoor-outdoor and interzone pressure differences, while the qualitative features include building design information, operational status and condition, and maintenance schedules. While ventilation assessment is important in field studies of IAQ and other building performance issues, it is not always obvious how to best characterize ventilation performance in any given building. Ultimately, the approaches employed will depend on the reasons for the measurements, the characteristics of the building and its system(s), the available time and resources, the required level of accuracy, and how the measurement results will be used. Buildings and systems are extremely variable, and these variations must be considered when planning and conducting ventilation assessments. Examples of important building characteristics affecting ventilation assessment include building size, how the building is divided into zones, how zones are connected in terms of airflow, the ventilation approach(es) employed in the building, and the ventilation system design. While this summary does not repeat all of the discussion of ventilation performance parameters and measurement methods, the critical points are that they be measured, that the measurement methods be well-described, and that the measurements be repeated to establish uncertainty of the results and to capture temporal and seasonal changes.

This chapter makes several important points about ventilation performance assessment, which are reiterated here:

- Ventilation rates vary significantly with weather and system operation, with weather effects easily leading to variations on the order of 5 to 1 for an individual building. Therefore a single value is not particularly informative without additional information on the conditions during the measurement. In order to fully understand ventilation in a building, multiple repeated measurements under different conditions are required. Also, a single value will be subject to unknown measurement errors unless the measurements are repeated, or otherwise planned and conducted to provide a sound uncertainty estimate. Extrapolating ventilation measurements from one set of conditions to another is potentially associated with

significant uncertainty, but can be performed with reasonable accuracy using models, especially if the model predictions have been validated using other measured data.

- Ventilation performance often does not match design intent due to the realities of building construction, system installation, operation, and maintenance. Interpretation of measurement results requires an understanding of how the system is intended to perform, e.g., when it is supposed to be operating and design outdoor air intake rates. Rather than reporting a measured ventilation rate as low or high, it is much more informative to say it is below the design value or the outdoor air requirements in a specific ventilation standard.
- Many of the measurement methods described in this chapter can be challenging to apply in the field given the complexities of real buildings and systems. Therefore, it can be helpful to use more than one measurement method to increase one's confidence in the results, i.e., air speed traverse in a supply duct combined with measurements of supply airflow rates out of individual diffusers. While indoor CO₂ concentrations can be a useful tool in evaluating ventilation, using peak CO₂ (which is in essence a steady-state, constant injection tracer gas method) to estimate per person outdoor air ventilation rates must be done with a full understanding of the assumptions involved.

The discussion in this chapter leads to suggestions for the development of standards and guidance. One such need is a standardized approach to describing buildings and systems. As described in this chapter, the EPA BASE protocol is the only such approach that currently exists, but it is quite detailed and bears updating given that it was developed more than 25 years ago (EPA 2003). Another area where additional guidance, or even standardization is needed, is the measurement and interpretation of indoor-outdoor and interzone pressure differences. Also, while tracer gas and building pressurization measurement standards include reporting requirements, standards or guidance for reporting the results of a ventilation assessment would be helpful. The following list includes some suggestions on what should be reported when documenting the results of ventilation assessments and measurements:

- *Building*: Age, height, measured envelope airtightness, activities in building and occupancy levels, geographical location
- *System*: Type(s), ventilation approach(es), availability of design documentation, design outdoor air ventilation rate, design exhaust airflow rate (with the latter two at both the system and space level)
- *Space*: Floor area and ceiling height, activity and occupancy levels, system (s) serving it
- *Assessments performed*: Quantities measured, measurement method(s), instrumentation employed including its measurement uncertainty, number of measurements, conditions during measurement (e.g., weather, system operating status)
- *Results*: Values including the test conditions and their overall measurement uncertainty

A standard or guideline on reporting ventilation assessments might present different levels of detail from the minimum essential in all cases to more comprehensive.

Building ventilation performance is important, and while it can be difficult to measure, that is not a valid reason not to perform these assessments or not to do them properly. IAQ researchers and others need to do a better job characterizing ventilation of the buildings and spaces they are studying to understand their measurement results and to report them thoroughly enough to allow comparability between studies and enable others to interpret their results. This chapter has described just a portion of the large amount of knowledge available on building ventilation assessment that has been generated over the years. As the building community strives for improved understanding of IAQ in buildings and overall better building performance, the role of ventilation must be addressed through the use of sound approaches to ventilation assessment.

Abstract

The control of airborne particulate matter (PM) in indoor air is important for improving the health and well-being of the building inhabitants. Indoor PM arises from both infiltration of ambient particulate pollution and from multiple indoor sources. Given the large amount of time people spend indoors, reducing exposure

Filtration · Clean air delivery rate · Efficiency · Pressure drop

Introduction

Removal of airborne particles from indoor air is an important way to improve indoor air quality and protect the health and well-being of the occupants. As described elsewhere in this handbook, particles in indoor air arise from multiple sources including infiltration of the ambient aerosols (Chen and Zhao 2022), indoor sources of particles (e.g., ► [Chap. 14, “Cooking Aerosol”](#)), and the formation of particles through reactions of hydrocarbons and oxidants such as ozone. The resulting particulate matter (PM) can produce adverse health effects (Samet et al. 2022) and damage or soil materials such as furniture, draperies, and artwork (Grau-Bové and Strlič 2013). The indoor atmosphere is a dynamic environment such that particles are constantly infiltrating, depositing, resuspending, being emitted from indoor sources, and/or forming from indoor chemistry. A wide variety of air cleaning and filtration technologies designed to remove particles from indoor environments are available for use (ASHRAE 2018; US EPA 2018). Thus, it is important to understand their mechanisms of action, their impacts on indoor particle removal rates, and ultimately their impacts on reducing indoor particle concentrations.

The most common approach to PM reduction is through filtration. Fibrous media filters are what most people envisage when they think of a filter. The filter is composed of a woven or nonwoven mat of fibers. In most filters used to control indoor air quality, the fibers are derived from wood (paper), glass, or synthetic polymer fibers. These may be held together with a binder material that may be as high as 10% of the filter material. Fibers of a wide range of diameters are used (ranging from less than 1 μm to over 100 μm) – often in the same filter. Figure 1 presents scanning electron micrographs of typical paper and glass fiber filters.

Depending on the nature of the structure and the volume of air to be cleaned, different approaches to filtration are employed ranging from room air cleaners to filters within central forced air heating/air conditioning systems to filtration of large volumes of air in heating, ventilating, and air-conditioning (HVAC) systems for large buildings (offices, schools, etc.). This chapter will begin with an introduction to the theory of air filtration and then examine filter use for different application scales.

Filtration Theory

Particle sizes of interest in indoor air quality extend from nanometers to tens of micrometers. Sizes above 100 μm have sufficiently high gravitational settling velocities that they do not remain airborne for very long given that a unit density spherical particle with a diameter of 100 μm has a settling velocity of 25 cm/s. A critical aspect of air filtration is that the fluid supporting the particles is a gas having much lower viscosity than particles suspended in a liquid. Because of this, air filtration does not depend on a sieving mechanism where the hole through which the fluid flows is smaller than the particle. Rather, air filters utilize an arrangement of fibers designed to allow air to flow through them while capturing a portion of the particles suspended in the air stream using a variety of mechanisms.

Single Fiber Collection Efficiency

The theoretical efficiency of a fibrous filter may be approached starting with the collection efficiency of a single fiber (Davies 1973). As an aerosol particle moves in the vicinity of a filter fiber, multiple mechanisms control its fate, depending on the particle size and fiber characteristics. Primary mechanisms include inertial impaction, interception, and diffusion, as depicted in Fig. 2. Other mechanisms, including gravitational settling and electrostatic attraction, may also contribute to single fiber collection efficiency.

In addition, there is an interaction term that accounts for the interception of diffusing particles.

The total single fiber collection efficiency, η_T , is then the sum of the collection by impaction (η_I), interception (η_R), diffusion (η_D), and diffusional interception (η_{DR}) (Hinds and Zhu 2022).

$$\eta_T \approx \eta_I + \eta_R + \eta_D + \eta_{DR} \quad (1)$$

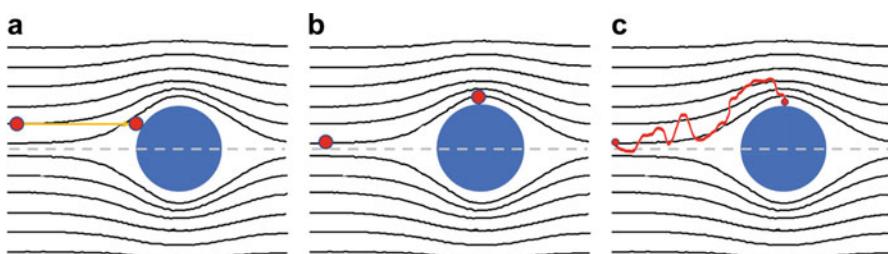

Fig. 2 Illustration of the mechanisms of particle collection by a single cylindrical fiber-oriented perpendicular to the flow through the filter

$$\eta_T = (2\kappa)^{-2} I * Stk + \frac{(1 - \alpha)R^2}{\kappa(1 + R)} + 2Pe^{-\frac{2}{5}} + 1.24 * R^{\frac{2}{5}}(\kappa * Pe)^{-1/2} \quad (2)$$

where

α = solid volume fraction of the filter = (fiber volume)/(total volume) = 1 - porosity.
 a = fiber radius.

a_p = particle radius.

$$I = (29.6 - 28\alpha^{0.62})R^2 - 27.5R^{2.8} \text{ for } R < 0.4$$

$$\kappa = -\frac{\ln \alpha}{2} - \frac{3}{4} + \alpha - \frac{\alpha^2}{4}$$

$$R = a_p/a; Pe = 2aU_0/D; Stk = \frac{\rho_p d_p^2 C U_0}{18 \xi d_f}$$

U_0 = face velocity = volumetric flow rate through the filter/filter area.

D = particle diffusion coefficient.

ϵ = kinematic viscosity.

d_f = $2a$ = fiber diameter.

d_p = $2a_p$ = particle diameter.

Under some circumstances would require inclusion of gravitational settling and electrostatic attraction for charged filter fibers. Details are provided in Hinds and Zhu (2022).

Overall Filter Efficiency

The efficiency of the filter is defined by how many particles of a given size penetrate the filter relative to the initial upstream concentration. Assuming that all fibers have the same diameter, the total length of fibers in a filter is given by:

$$L = \frac{4\alpha}{\pi d_f^2} \quad (3)$$

The number of particles collected from a unit volume of air passing through a unit cross-sectional area of the filter which have a thickness of dt (dN) is given by:

$$n_c = N\eta_T d_f L dt = N\gamma dt \quad (4)$$

where

$$\gamma = \frac{4\alpha\eta_T}{\pi d_f^2}$$

$$dN = -N\gamma dt \quad (5)$$

$$\int_{N_{in}}^{N_{out}} \frac{dN}{N} = \int_0^t -\gamma dt \quad (6)$$

$$\ln \frac{N_{out}}{N_{in}} = -\gamma t \quad (7)$$

The ratio of N_{out}/N_{in} represents the penetration (P) of particles through the filter. Thus,

$$P = e^{-\gamma t} = \exp \left(-\frac{4\alpha\eta_T}{\pi d_f} \right) \quad (8)$$

The efficiency of a filter is then the fraction of particles retained in the filter ($E = 1 - P$). The qualitative plot of filter efficiency based on single fiber collection efficiency compares well to real filters (Fig. 3). ***Thus, the efficiency depends only on diffusion and inertia, and NOT the size of the holes in the filter.*** Large particles are collected by inertial deposition and interception, and the collection efficiency decreases with decreasing size. However, for small, diffusional particles ($d_p < 0.1 \mu\text{m}$), the filter efficiency increases with decreasing size. Therefore, filter efficiency characterizations should include the particle diameter that will represent the highest penetration (typically around $0.3 \mu\text{m}$), since the collection efficiency will increase as particle size either increases or decreases. This size range with the lowest removal efficiency is commonly referred to as the most penetrating particle size (MPPS).

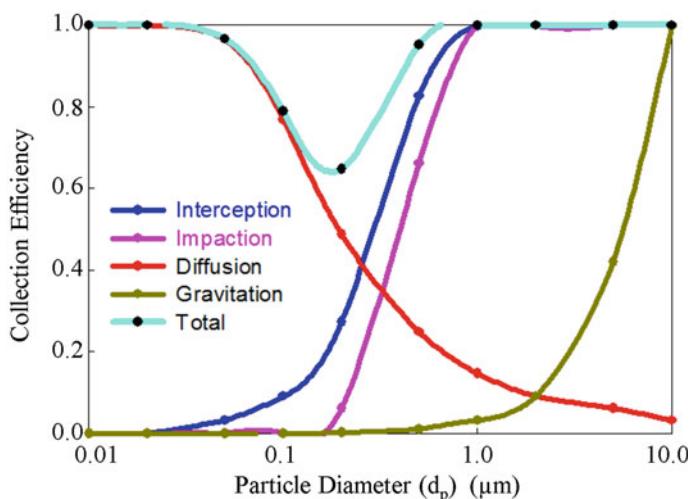

Fig. 3 Filter efficiency as a function of particle diameter showing the effects of the various deposition mechanisms

Selecting Filters: Test Methods and Rating Systems

Filters are tested for their size-resolved particle removal efficiency and other performance characteristics, including pressure drop and dust-loading capacity in test ducts following industry consensus test standards, such as ASHRAE Standard 52.2 (ASHRAE 2017) and/or ISO 16890 (ISO 2016). In all filter-testing approaches, the single-pass removal efficiency of a filter is a fractional measure of its ability to reduce the concentration of particles in air that passes through it:

$$\text{Efficiency} = \left(1 - \frac{C_{\text{downstream}}}{C_{\text{upstream}}} \right) \times 100\% \quad (9)$$

In ASHRAE Standard 52.2, the removal efficiency of particles 0.3 to 10 µm in diameter is measured under a range of dust-loading conditions and reported as a minimum efficiency-reporting value (MERV). MERV ranges from 1 to 20 based on the average removal efficiency across three particle size ranges (0.3–1 µm, 1–3 µm, and 3–10 µm), although MERV 17 to 20 are not commonly used in standard building applications but rather in clean room and surgical room environments. In general, higher MERV values represent higher filtration efficiency for most particle sizes, although it should be noted that the test standard does not characterize the removal efficiency of particles smaller than 0.3 µm that make up the vast majority of particles in any indoor or outdoor environment by number (Azimi et al. 2014; Fazli et al. 2019). The MERV ratings and particle efficiency are presented in Table 1.

Table 1 ASHRAE Standard 52.2 MERV table

MERV	Composite average particle size efficiency 0.3–1 µm	Composite average particle size efficiency 1–3 µm	Composite average particle size efficiency 3–10 µm	Types of particles captured
1	—	—	Less than 20%	Pollen, dust mites, standing dust, spray paint dust, and carpet fibers
2	—	—	Less than 20%	
3	—	—	Less than 20%	
4	—	—	Less than 20%	
5	—	—	20% or better	Mold spores, hair spray, fabric protector, and cement dust
6	—	—	35% or better	
7	—	—	50% or better	
8	—	20% or better	70% or better	
9	—	35% or better	75% or better	Humidifier dust, lead dust, auto emissions, and milled flour
10	—	50% or better	80% or better	
11	20% or better	65% or better	85% or better	
12	35% or better	80% or better	90% or better	
13	50% or better	85% or better	90% or better	Bacteria, most tobacco smoke, and droplet nuclei (sneeze)
14	75% or better	90% or better	95% or better	
15	85% or better	90% or better	95% or better	
16	95% or better	95% or better	95% or better	

The ISO 16890 standard similarly characterizes size-resolved removal efficiency of filters and also estimates removal efficiency for mass-based metrics of ePM₁, ePM_{2.5}, and ePM₁₀ for the mass of particles less than 1 μm , 2.5 μm , and 10 μm in diameter, respectively. Estimates of ePM are made using assumptions for ambient (outdoor) particle size distributions, making them most directly relevant for understanding filtration efficiency for particles of outdoor origin (such as those entering the HVAC system via the outdoor air intake).

Other common test metrics for filters also include the proprietary MPR (Micro-particle Performance Rating) and FPR (Filter Performance Rating) systems. There is less publicly available information on these proprietary test standards because they are used by commercial manufacturers and distributors of filters, but they are increasing in use, especially for residential and light-commercial applications. Last, for critical particle cleaning applications, as well as for many stand-alone in-room devices, the highest efficiency filters available can achieve “**high efficiency particulate air [filter]**” (HEPA) designation. HEPA filters remove at least 99.97% of dust, pollen, mold, bacteria, and any 0.3 μm airborne particles. Thus, they should also remove any larger or smaller particle with at least this efficiency. More details on testing and rating of filters are provided by ASHRAE (2020).

Filter Applications in Buildings

There are two main approaches to implementing filtration systems in buildings: 1) portable or room-level air-cleaning devices and 2) in-duct filters mounted inside HVAC systems.

Portable and Room-Level Systems

To reduce particle concentrations within a space via filtration, it is possible to use a room air cleaner. These systems include an air moving system (fan) and a filter coupled together such that the air passing through the fan must pass through the filter. There are many commercially available systems that are commonly sized based on the room square footage, determined by a combination of the flow rate through the system and the removal efficiency of the filter used within the system.

Clean Air Delivery Rate

Room air cleaners are commonly characterized in terms of the **clean air delivery rate (CADR)** or the **effective cleaning rate (ECR)** (Offermann et al. 1985). Although both terms are used interchangeably in the scientific literature, CADR is most commonly used on product labeling, as both a CADR test standard and the resulting test metric are maintained by the Association of Home Appliance Manufacturers (AHAM). The CADR represents the volume flow (cubic feet per minute, CFM) of air that has all given sized particles filtered from it. In other words: It is a measure of an air cleaner’s delivery of relatively clean air. There are separate CADR

values for particles of different sizes generated by tobacco smoke ($0.09\text{--}1\ \mu\text{m}$), dust ($0.5\text{--}3\ \mu\text{m}$), and pollen ($5\text{--}11\ \mu\text{m}$). The higher the CADR for a given particle size, the faster the unit filters the air; the faster the unit filters the air, the lower the resulting concentration will be in the space.

While the CADR can be measured as the product of flow rate times removal efficiency, it is actually measured by comparing loss rates in a test chamber with and without the air cleaner operating. In the ANSI/AHAM AC-1-2006 (ANSI 2006) test standard, the CADR is defined as “the rate of contaminant reduction in the test chamber when the unit is turned on, minus the rate of natural decay when the unit is not running, multiplied by the volume of the test chamber as measured in cubic feet” (Eq. 10).

$$\text{CADR} = V(L_{\text{on}} - L_{\text{off}}) \quad (10)$$

Where L_{on} and L_{off} are the first-order particle loss rates measured in a test chamber with an air cleaner on and off, respectively (min^{-1}), and V is the volume of the test chamber (ft^3). The standard is based on a $1008\ \text{ft}^3$ test chamber used to compare among different air cleaners in a uniform manner. The rating is for the combination of a new filter in a specific air cleaner design used in a 20-minute test.

AHAM provides a database of air cleaners that have registered results from CADR testing (<https://www.ahamdir.com/room-air-cleaners>). In general, reported CADRs for the three particle size ranges tested are within about 10% of each other, depending on the device. CADRs of in-room or portable devices – which are most commonly tested and reported at an in-room air cleaner’s highest fan speed setting – commonly range from less than 50 CFM to over 450 CFM, with most products falling between about approximately 100 and 250 CFM. Lower fan speed settings will typically reduce the CADR. AHAM recommends that filters should be chosen such that the CADR for smoke is equal to or greater than two-third of the room area for rooms with ceiling heights $<8\ \text{ft}$. CADR is now widely used to characterize in-room air cleaners.

Practical Considerations for Portable and Room-Level Filtration Systems

There are several practical factors to consider in portable or room-level filtration system applications. These include power demands, noise and comfort, and operation and maintenance, all of which affect trade-offs between flow rates and filter efficiency.

Pressure Drop and Power Demands There are trade-offs between filter efficiency and the ability of air to flow through the filter. As the solid volume fraction, α , increases, there are more fibers in the path of the flow. Thus, using an HEPA filter results in a higher differential in pressure between the inlet and outlet of the filter to yield the same flow rate as a lower efficiency, lower pressure drop filter. The pressure drop through a filter (ΔP) is given by (Davies 1973):

$$\Delta P = \frac{\epsilon t U_0 f(\alpha)}{d_f^2} \quad (11)$$

where:

$$f(\alpha) = 64\alpha^{1.5}(1 + 56\alpha^3) \text{ for } 0.006 < \alpha < 0.3$$

With higher pressure drop, it takes a more powerful fan (or, if using a variable speed fan, a higher fan speed) to draw the air through the filter to maintain the same flow rate. There are three “fan” laws that cover flow, pressure differential, and power use. Fan Law 1 relates the change in air flow rate of a fan to the change in speed of the propeller. If the propeller speed is increased by 10%, the air flow rate will also increase by 10%. Fan Law 2 tells us that the change in total static pressure across the filter will increase by the square of the change in propeller speed of the fan. If the propeller speed is increased by 10%, the total static pressure increases by 21%. Fan Law 3 tells us that the change in horsepower required by the fan to turn the propeller will increase by the cube of the change in propeller speed of the fan. If the propeller speed is increased by 10%, the horsepower required to turn the propeller will increase by 33.1%. Thus, filter systems with higher efficiency filters with higher resistance to airflow will often require a higher fan speed (and thus higher fan power, meaning more electricity usage) to produce the same flow rate through the system, and thus the unit will be more costly to operate.

Noise and Comfort There are often trade-offs between air cleaning rates and livability in the space. If the fan speed is too high, then the excess air velocity in the room might make it uncomfortable to use. Moreover, the CADR of an in-room air cleaner is usually highest at the highest airflow rate, which is also usually the loudest setting. If an in-room air cleaner is too loud, occupants might choose to switch off the unit or operate it at a lower fan speed setting (with a lower CADR). Unfortunately, noise is not routinely quantified or reported on consumer packaging, so it can be difficult to compare one device to another based on noise ratings. One can look for noise ratings provided voluntarily on product packaging or alternative sources of noise ratings such as consumer test reports websites.

Operation and Maintenance A given room with an air cleaner will be exchanging air with other spaces. If there is an exterior wall, there can be infiltration of ambient aerosol particles. Open doors or passageways allow movement of air from other locations where particles could be generated such as a kitchen. Forced air heating/cooling will move air with their particle concentrations around the dwelling and bring particles to the room with the cleaner. Thus, sealing around windows or outside doors and closing interior doors will make the room air cleaner more effective for the given space in which it resides. It may be obvious, but it is worth noting that in-room air cleaners only filter air when they are operating. Therefore, air cleaners should run frequently, even continuously, to deliver maximum effect. Running air cleaners continuously come with added costs including electricity costs to run the device and costs to replace filters as they become loaded. In considering selection of portable and in-room air cleaners, it is useful to conduct a life cycle cost assessment that factors in upfront costs, ongoing energy costs for operation, and filter

replacement costs for maintenance. New innovations in portable and in-room air cleaners include those that are using low-cost particle sensors to determine the fan speed to use to achieve a given particle concentration. Units now may also include pressure-differential sensors to monitor filter clogging and provide a warning that it is time to change the filter. As these technologies continue to decline in cost, more of these “smart” air cleaners will become available.

Trade-Offs: Flow Rates, Filter Efficiency, and Effectiveness These combined factors of pressure drop, power demands, noise, comfort, and operation and maintenance issues combine to result in sometime counterintuitive trade-offs between flow rates and filter efficiency. For example, a compromise between filter efficiency (which affects the replacement cost of the filter and the cost of the electricity to operate) and flow rate (which affects air speeds in the space and also the electricity costs to operate) can be found to maximum occupant comfort, subject to the level of contamination, size of the room, and tolerance of the occupants to air movement and noise.

As an example, it may be more practical to use a 95% efficient filter with lower pressure drop compared to an HEPA (99.97%) to meet particle removal goals in the space. Figures 4 and 5 show the results of an unpublished study conducted in a rectangular ($2.24\text{ m W} \times 3.91\text{ m L} \times 2.44\text{ m H}$) experimental chamber built using typical residential construction materials with an air-cleaning unit operating with two

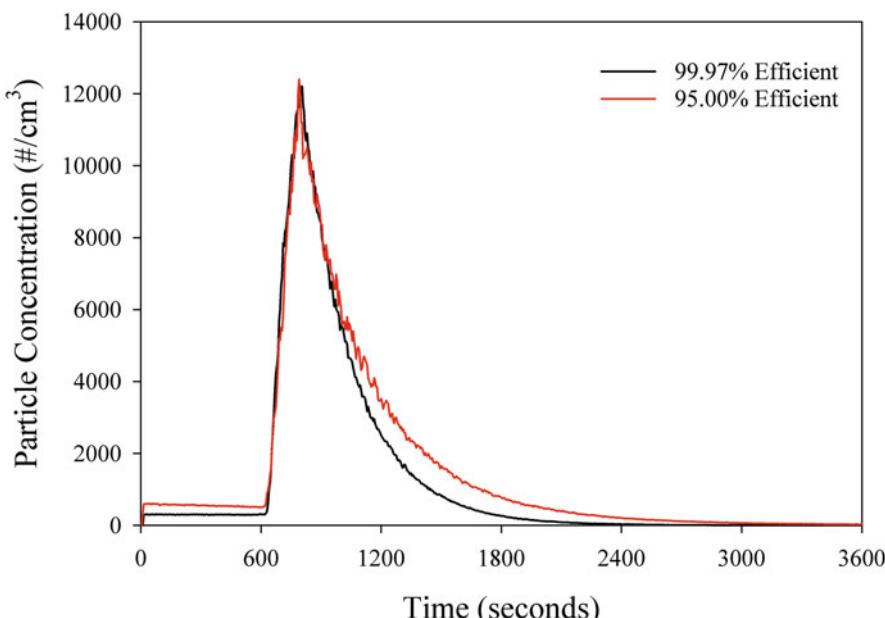

Fig. 4 Particle concentration decay for the 99.97% and 95% efficient filters on high fan speed

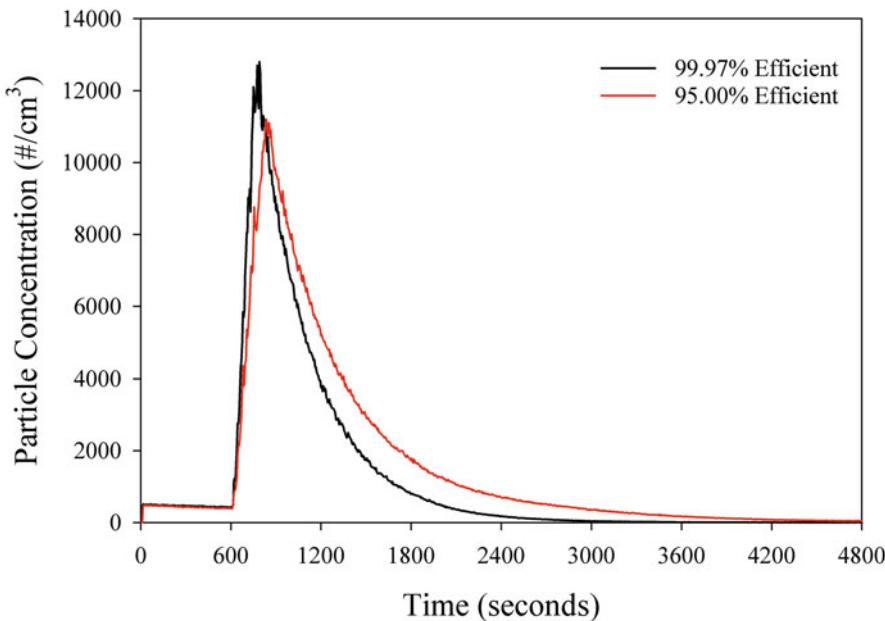

Fig. 5 Particle concentration decay for the 99.97% and 95% efficient filters on low fan speed

possible fan speeds. The airflows were: 207 cfm and 142 cfm for a 95% efficient filter installed with the fan operating on high speed and low speed, respectively, and 171 cfm and 119 cfm for a 99.97% efficient filter installed with the fan operating on high and low speed, respectively. It can be seen that the performance difference is relatively small, as the product of flow rate and efficiency (i.e., calculated CADR, Eq. 12) is similar between the two devices, but there can be substantial savings in energy when using the 95% filter due to lower power draw requirements for moving air through the lower resistance filter.

$$CADR = \dot{V} \times \eta \quad (12)$$

Where \dot{V} is the flow rate through the filter (CFM) and η is the removal efficiency of the filter.

Considerations of trade-offs between flow rates and efficiency, as well as concerns for upfront costs of many portable air-cleaning devices, have led to the development of do-it-yourself solutions for in-room air cleaning. A prime example is the Corsi-Rosenthal box fan filter, which combines low-cost box fans with relatively low-cost MERV 13 filters (or higher, but not as high as HEPA) to yield a cost-effective high-CADR in-room air-cleaning solution, without needing HEPA filters and controlled manufacturing. While the minimum average removal efficiency of a MERV 13 filter is only 50% or higher for particles in the most penetration particle size (MPPS) range (0.3–1 μm) in the 52.2 test, the flow rate through box fans

can be as high as 2500 CFM (unobstructed). Installing five MERV 13 filters in a cube with the sixth side being a box fan could result in a CADR of as high as 1000 CFM, assuming flow is reduced to 2000 CFM and the removal efficiency of the filters is 50% (i.e., $2000 \text{ CFM} \times 0.5 = 1000 \text{ CFM}$).

In-Duct Filters

For residential, commercial, and institutional buildings with dedicated forced-air heating, cooling, and/or ventilating (HVAC) systems, in-duct filters are widely used, originally to protect equipment (e.g., heat exchangers and fans) from large particles, but now increasingly to protect people from exposure to airborne particulate matter. In all cases, filters are placed such that the air flow within the HVAC system passes through to capture particles. There are some important practical differences in filtration between smaller residential systems and larger commercial and institutional systems that influence what types of filters can be installed, what the energy and airflow consequences of higher efficiency filtration might be, and how effective filters are in reducing particle concentrations. As such, two scales of in-duct HVAC filtration applications are considered here: residential and nonresidential (i.e., commercial and institutional).

Residential In-Duct Air Filters

In homes with forced air heating and/or cooling systems, a filter is placed such that the flow from the house to the air handler (often referred to as a furnace in heating-dominated climates) passes through the filter (Fig. 6). The filtered air then passes through the heat exchanger, and the conditioned and filtered air is distributed to the house through central ductwork. Filters are often located in a filter slot on the upstream side of the furnace or may be located at return grille(s) farther from the air handler.

Most existing homes typically use MERV 8 or lower in-duct air filters (El Orch et al. 2014), and even newer homes built to ASHRAE Standard 62.2, “Ventilation and Acceptable Indoor Air Quality in Residential Buildings,” which is not universally adopted across the USA but is required in some jurisdictions, which are required to have only a minimum of MERV 6 air filters in their forced air mechanical systems (ASHRAE 2019). From Table 1, it can be seen that MERV 8 and lower filters have limited effectiveness in removing many of the particle types and sizes that are important for occupant health. Among higher efficiency residential filters that are readily available, homeowners commonly upgrade to MERV 11 or MERV 13 but rarely venture beyond MERV 13 (Stephens 2019). Conversely, the US EPA recommends using filters with an MERV 13 or higher to capture at least 50% of the smallest particles that contribute most to indoor fine particulate matter ($\text{PM}_{2.5}$) concentrations (US EPA 2018). There remain many opportunities to improve residential filtration, as well as practical challenges.

Historically, the use of higher efficiency (i.e., higher MERV or equivalent) filters in residences has been limited by the prevailing conception that they have higher

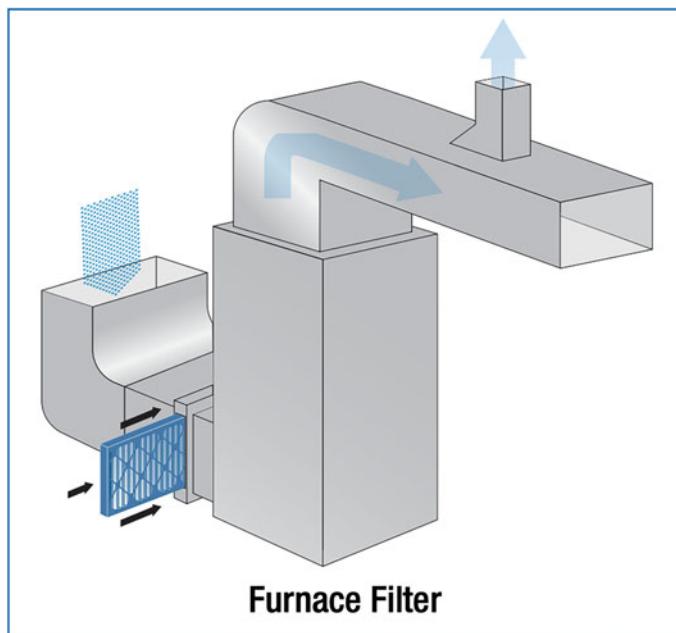

Fig. 6 Schematic of a home-forced air furnace showing the location of the air filter. Figure taken from https://www.epa.gov/sites/default/files/2018-07/documents/residential_air_cleaners_-_a_technical_summary_3rd_edition.pdf

pressure drops and thus higher resistance to airflow, which makes heating and cooling systems “work harder” to overcome the pressure drop, using more fan energy (Figure 7). However, most residential forced air heating and cooling systems in existing homes utilize permanent split capacitor (PSC) blower motors, which do not adjust speeds to compensate for additional airflow resistance but rather respond to a higher pressure drop by moving less air (and often drawing less power). Therefore, in most existing homes, the concern for higher efficiency (and higher pressure drop) filters is: How much will they reduce airflow, and how will the reduced airflow impact system performance and energy use (e.g., runtime and heating/cooling capacity)? To date, most research suggests that the impacts on these performance metrics are relatively small (Fazli et al. 2015; Stephens et al. 2010a, b; Walker et al. 2012), except for systems that have not been properly designed or maintained and may already be on the verge of failure; in these systems, the additional pressure drop of higher efficiency filters could decrease airflow to the point where system performance issues such as frozen cooling coils can arise. It is also worth noting that many newer forced air heating and cooling systems utilize electronically commutated motors (ECMs) that will adjust fan speeds to overcome additional resistance encountered in the system. In these systems, adding a higher pressure drop filter will tend to lead to increased fan power draws to overcome the

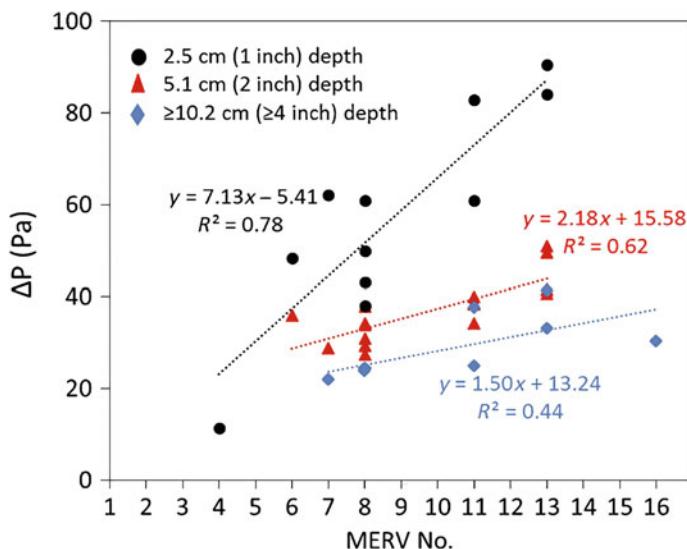

Fig. 7 Initial pressure drop for new filters as a function of the manufacturer's reported MERV ratings. (Figure taken from Fazli et al. 2019)

added resistance and maintain a relatively constant airflow rate, but with no other meaningful impacts.

Given these issues with pressure drop, some strategies that manufacturers use to enable higher efficiency filtration in residential forced air systems are increasing filter thickness and utilizing electrostatically charged (sometimes called electret) filter media (Wang and Hofacre 2008; Liu et al. 2017). The use of electrostatically charged media allows for higher initial particle removal efficiency than relying on mechanical capture mechanisms alone, although it should be noted that as the filter loads with particles over time, the electrostatic charge will diminish and reduce removal efficiency (Lehtimäki et al. 2002; Owen et al. 2013). Conversely, dust loading can increase the removal efficiency of lower MERV mechanical media filters. The use of extended depth filters allows for spreading the filter media out over a larger surface area and reduces the filter pressure drop; research shows that there are now 2-inch and 4-inch depth MERV 13 and MERV 16 filters available with initial pressure drops that are below MERV 6–8 1-inch filters (Fazli et al. 2019). One challenge of deeper filters is that modifications to existing HVAC systems are often required to accommodate their wider thickness.

It is also worth noting that while there are commercially available options for improving residential air filtration in central forced air systems, there are fewer options for high efficiency filtration in mechanical ventilation systems that intentionally bring in outdoor air (e.g., energy and heat recovery ventilators) and for heating and cooling systems that do not utilize centralized ductwork for air distribution (e.g., mini-split heat pump systems).

Commercial and Institutional In-Duct Air Filters

Larger commercial and institutional buildings utilize heating, ventilation, and air conditioning (HVAC) systems to provide occupant comfort and meet ventilation needs for occupied spaces. Ventilation is described in detail elsewhere in this handbook (Lv et al. 2022; Persily 2022).

Figure 8 shows a schematic view of a typical central HVAC system. Outdoor air and return air are mixed – at variable fractions ranging from 100% outdoor air to the code minimum amount of outdoor air, depending on factors such as occupancy and climate conditions – and then filtered, conditioned, and supplied to the occupied space. Whether ambient or returned indoor air, particulate matter will be introduced into the system either as part of the ambient makeup air or from indoor sources (or both). These particles need to be removed, and filters are commonly employed so that the design problem is similar to residential in-duct filter issues, but on a much larger scale. The design problem is how much filtration is needed to provide air quality sufficient for the purposes of utilizing the occupied space. There is again the trade-off between filtration efficiency and pressure drop/energy use, as many commercial and institutional systems utilize fans that adjust speed to maintain airflow rates in the fact of added resistance from a higher pressure drop filter (Azimi and Stephens 2013; Bekö et al. 2008; Montgomery et al. 2012). Thus, in many cases,

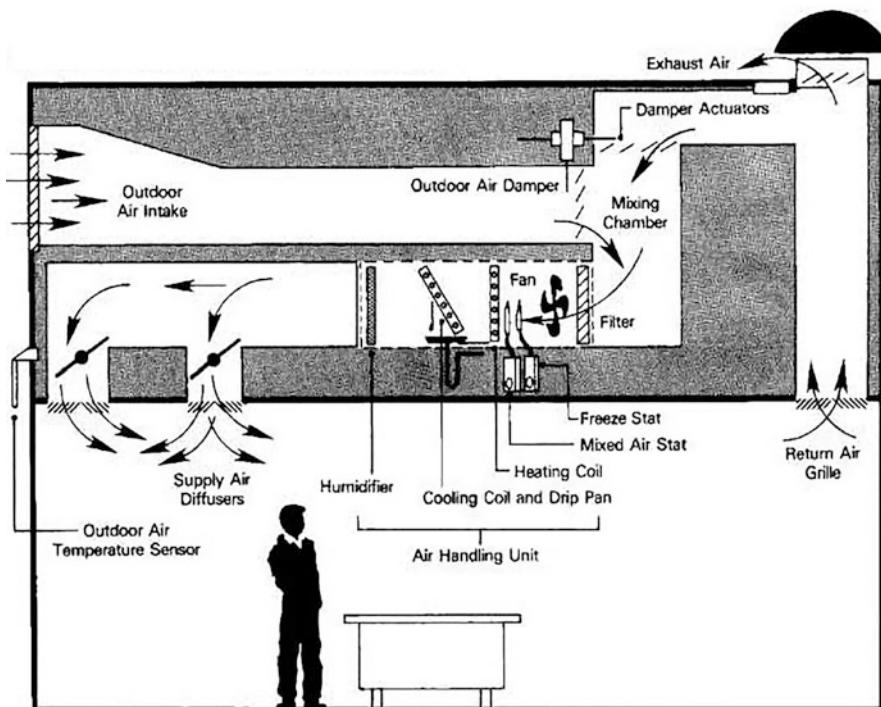

Fig. 8 Diagram of the components of a typical HVAC system. (Figure taken from USEPA 1991)

Fig. 9 Actual installation using MERV 8 box filters (left) and MERV 13 bag filters (right) to provide high-filtration efficiency at a lower total pressure drop

lower-efficiency (MERV 8) filters were often used to remove large particle dust, but not significant amounts of fine particles. In fact, ASHRAE Standard 62.1 “Ventilation for Acceptable Air Quality,” which is widely adopted in building codes across the USA, requires a minimum of MERV 8 filters in all buildings except those located in an area where the national standard for PM_{2.5} is exceeded (these buildings should improve to MERV 11 filters).

However, during the COVID-19 pandemic beginning in 2020, many buildings were upgraded to MERV 13 filtration, led by the convening of an ASHRAE Epidemic Task Force, which adopted core recommendations for reducing airborne infectious aerosol exposure, including using combinations of filters and air cleaners that achieve MERV 13 or better levels of performance for air recirculated by HVAC systems. Commercial and institutional systems also differ from residential systems in that they can also use larger bag filters, as well as prefilters. Prefilters are lower efficiency (and lower cost) that are installed upstream of a higher efficiency (higher cost) filter, extending the lifetime of the higher-efficiency filter and lowering filter replacement costs. Figure 9 shows this type of configuration with MERV 8 box filters (left) that are placed in front of MERV 13 bag filters. The bag filters provide significantly more surface area than would be possible in a box filter and, thus, lower pressure drop for the same filtration performance (Fig. 9).

Impacts of Filters in Real Buildings

Regardless of the type of building (i.e., residential or commercial), filter installation (i.e., in-duct or in-room), or filter type (i.e., MERV 2 through HEPA), there exist useful performance metrics that can be used to evaluate (through measurements) or predict (through models) the impacts of filters on indoor particulate matter in

buildings. There are also several practical factors that affect how a filtration system performs in a real building.

The effectiveness of an air filtration device or system is a dimensionless measure of its ability to remove pollutants from the spaces it serves in real-world situations (Miller-Leiden et al. 1996; Zhang et al. 2020). It is simply a comparison of pollutant concentrations in a space with and without an air filtration device/system operating, assuming other parameters like emission rates, ventilation/infiltration rates, deposition rates, and any other source and loss mechanisms are held constant (Eq. 13).

$$\text{Effectiveness} = 1 - \frac{C_{\text{on}}}{C_{\text{off}}} \quad (13)$$

where C_{on} and C_{off} are the contaminant concentrations in a space with the filtration device/system on and off, respectively (#/m³ or equivalent). The terms C_{on} and C_{off} can be expanded to include common loss terms of ventilation, deposition, and CADR, assuming other factors such as source strengths are held constant (Waring et al. 2008):

$$\text{Effectiveness} = 1 - \frac{\text{ACH} + k_{\text{dep}}}{\text{ACH} + k_{\text{dep}} + \text{CADR}/V} \quad (14)$$

where ACH is the air change rate in the space (h⁻¹), k_{dep} is the deposition loss rate constant in the space (h⁻¹), and CADR/V (ft³/min) is the CADR divided by the volume of the space (ft³) and multiplied by a conversion factor of 60 mins per hour. For stand-alone in-room air cleaner applications, the effectiveness can be measured easily (Eq. 13) or readily calculated using the CADR of the unit (Eq. 14). For in-duct devices that operate continuously, as long as the removal efficiency of the filter and the flow rate through the filter is known, an effective CADR can be calculated (Eq. 12) and incorporated into estimates of effectiveness (Eq. 14). For both in-duct and in-room devices that operate intermittently, such as portable air cleaners that are switched on and off by occupants and residential in-duct filters in heating and cooling systems that operate only intermittently to meet heating and cooling loads, a fractional runtime term (f) can be introduced into Eq. 15 to predict effectiveness:

$$\text{Effectiveness} = 1 - \frac{\text{ACH} + k_{\text{dep}}}{\text{ACH} + k_{\text{dep}} + f \text{CADR}/V} \quad (15)$$

It is also worth noting that it is possible to measure the effective CADR of both in-room and in-duct filtration systems operating in real spaces (MacIntosh et al. 2008; Stephens and Siegel 2012). The procedure is similar to the AHAM CADR test procedure described previously, except that it takes place in a real building operating under relatively tightly controlled conditions (e.g., minimal occupancy or at least constant occupancy, consistent or at least measured ventilation rates, etc.). Particles are injected and allowed to decay to background levels while monitoring, repeated with and without an air filtration device/system operating. The data are used to

estimate loss rate constants under each condition, which can be used to estimate an in situ CADR (Eq. 10). Particle concentration measurements can also be conducted within HVAC systems to measure the in situ removal efficiency of in-duct filtration systems (ASHRAE 2008; Ben-David et al. 2018), although this is generally easier to accomplish in large commercial systems than in smaller residential systems (Li and Siegel 2020).

Finally, several practical factors also impact how a filtration system performs in a real building. The runtime fraction, or the fraction of time a filtration system operates, has a large impact on the effectiveness of filtration systems. Typical residential heating and cooling systems operate less than 25% of the time in most locations, which limits how effective even the best in-duct filter can be (Touchie and Siegel 2018). Systems can instead be run in continuous fan-only mode, but there are energy penalties for doing so, as well as comfort and maintenance considerations. Studies of portable air cleaner use have also noted that occupants frequently turn off devices and/or turn them down to lower fan speed settings with lower CADR. Other factors that affect primarily in-duct systems include how the filter performs as installed (compared to lab-tested performance), including whether or not there is any bypass airflow around the filter, which can diminish performance by allowing essentially unfiltered air into the air stream (VerShaw et al. 2009; Ward and Siegel 2005). The timing and nature of indoor particle sources relative to when filtration systems operate also affects their effectiveness in real buildings. For example, if indoor emission sources occur at time when filtration systems are off, obviously the effect of filtration diminishes (Li and Siegel 2021). Occupants can also open windows in buildings with operable windows, which may introduce outdoor pollutants when ambient concentrations are elevated higher than indoors. There is also the issue of proximity effects, especially for in-duct systems, whereby point sources of indoor pollutants (such as cooking) may lead to occupant exposures for those in proximity to sources prior to pollutants being mixed in the space and encountering a central filter; locating in-room devices closer to known sources can help mitigate this effect.

Conclusions

Filtration is a well-developed and universally employed technique for removing particles from air that is forced to move through the filter. The efficiency of removal depends on filter design and particle size. The minimum efficiency typically occurs for particles with aerodynamic diameters around 0.3 μm . As particles increase in size, they become more inertial and can be more effectively collected by the filter. As particle size decreases, the particles become more diffusional and are more effectively collected. The flow through the filter depends on its efficiency of filtration and the pressure differential across the filter. Higher filtration efficiency filters require a higher pressure differential to drive the same flow rate and, thus, require more

energy. Choosing the appropriate filter for a given situation involves trade-offs between efficiency, flow rates, and energy use, and care is needed to ensure that the particle removal is sufficient to protect the inhabitants of the indoor spaces as well as the objects like furniture or art work onto which those particles might deposit.

Abstract

Indoor air cleaning has been proved to be an efficient way to reduce indoor harmful VOCs. Many advanced technologies have been studied for the quick and economical removal of VOCs from indoor air. This chapter introduced photo-catalytic oxidation (PCO) and room-temperature thermal catalytic oxidation (TCO). The principle of PCO was introduced, and then a general model was developed for analyzing the VOCs removal performance by PCO. The enhancement of PCO performance was analyzed based on the general model. The unwanted by-products during the PCO reaction process were observed online and qualitatively identified. We also introduce various kinetic models for TCO. The experimental results show that a kinetic model with a bimolecular Langmuir-Hinshelwood mechanism and temperature effect best fit the data. The activation energy of the TCO reaction for formaldehyde was then obtained. In summary, the great potential of the combination of PCO, TCO, and adsorption will advance indoor air cleaning in the future.

Introduction

Indoor air pollutants impact human health, comfort, and productivity. Volatile organic compounds (VOCs) are among the most abundant chemical pollutants in the indoor air that we breathe (USEPA 1990; WHO 1989). Some of these compounds are associated with sick building syndrome (SBS), including mucous membrane irritation, headache, and fatigue (Wang et al. 2007; Meininghaus et al. 1999; Kim et al. 2001; WHO 1989; USEPA 1990); others are known carcinogens (e.g., formaldehyde and acrolein [Oehha 2007]). Millions of people are currently suffering from the consequences of poor indoor air quality and billions of dollars are lost in the world each year due to poor indoor air quality (Fisk and Rosenfeld 1997).

Because indoor air quality is an important determinant of human health, comfort, and productivity, high-quality indoor air is desirable. Air cleaning technologies are of increasing importance, especially when building ventilation rates are being reduced to conserve energy. Commonly used technologies for indoor air purification include adsorption, catalytic oxidation, and photocatalytic oxidation (PCO) (Zhang et al. 2011; Gallego et al. 2013; Mo et al. 2009a).

Photocatalytic Oxidation**Principal**

As the pioneers in this field, Fujishima and Honda (1972) discovered the phenomenon of photoinduced water cleavage to TiO₂ electrodes. In the subsequent three decades, a wide range of potential applications of PCO to air purification has been reported.

The air purification technique of PCO commonly uses nano-semiconductor catalysts and ultraviolet (UV) light to convert organic compounds in indoor air into benign and odorless constituents – water vapor (H₂O) and carbon dioxide (CO₂) (Tompkins 2001). Most PCO reactors use nano-titania (TiO₂) as the catalyst that is activated by UV light. Figure 1 shows the schematic of the UV-PCO process of VOCs using TiO₂ as the catalyst. An electron in an electron-filled valence band (VB) is excited by photoirradiation to a vacant conduction band (CB), leaving a positive hole in the VB. These electrons and positive holes drive reduction and oxidation, respectively, of compounds adsorbed on the surface of a photocatalyst (Ohtani 2008).

The activation equation can be written as:

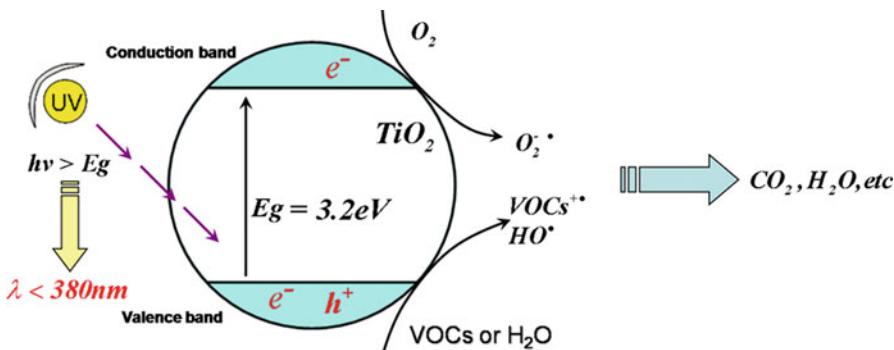

Fig. 1 Schematic of TiO_2 UV photocatalytic oxidation process of VOCs (Mo et al. 2009a)

In this reaction, h^+ and e^- are powerful oxidizing and reducing agents, respectively. The oxidation and reduction reactions can be expressed as:

When organic compounds are chemically transformed by a PCO device, the hydroxyl radical ($\text{OH}\cdot$), derived from the oxidation of adsorbed water or adsorbed OH^- , is the dominant strong oxidant. Its net reaction with a VOC can be expressed as:

The process of PCO has several advantages (Ollis 2000): (1) GRAS (generally recognized as safe): the common photocatalyst is anatase TiO_2 , an n-type semiconductor oxide which is also a component of some toothpaste and pharmaceutical suspensions; (2) mild oxidant: kinetic studies demonstrate that the ultimate source of oxygen during oxidation is molecular oxygen, a far milder oxidant than hydrogen peroxide or ozone, etc.; (3) ambient temperature: photocatalysis appears to be active at room temperature; and (4) general: while several mechanistic pathways for oxidation have been proposed, the dominant view is that the hydroxyl radical (or some other equally strong oxidant) is photogenerated on the titania surface; the potency of this oxidant is responsible for the titania's broad activity toward various contaminants (such as aromatics, alkanes, olefins, halogenated hydrocarbons, odor compounds, etc.).

Enhancement of the Removal Effectiveness

Much research has been performed on how different factors affect the PCO reactor performance (Obie and Brown 1995; Obie 1996; Obie and Hay 1997; Dreyer et al.

1996; Hall et al. 1998; Yoneyama and Torimoto 2000). It is difficult to know what influence the various factors have on the VOC removal performance of PCO reactors only through experiments. Modeling and simulation are powerful methods for determining the relationship between VOC removal performance and the influencing factors. Hossain et al. (1999) developed a three-dimensional convection-diffusion reaction model for analyzing the VOC removal performance of honeycomb PCO reactors under steady-state conditions, which fitted very well with the experiments. Chen and Zhang (Chen and Zhang 2008; Chen 2007) involved both a model and experimental investigation on the interference between multiple VOCs. It indicated that the interference effects among test VOCs were generally small in the 2-VOC and 3-VOC mixture tests performed on toluene, ethylbenzene, octane, decane, and dodecane with the initial concentration of approximately 1 mg/m^3 for each compound. However, there were still few studies on the interaction effects between PCO reactor structure and environmental factors.

Based on a few suitable assumptions, many physical models of PCO reactors were developed. Tronconi and Forzatti (1992) developed a lumped parameter model for a honeycomb structure reactor decomposing NO_x . They derived dimensionless numbers to express the reaction rate and convective mass transfer rate and demonstrated the application of the model to different geometries and boundary conditions. Hall et al. (1998) described a reduced-order model for photocatalytic honeycomb reactors and discussed mass transport and reaction rate limits. He found that the product of volumetric flow rate and conversion rate, which represent the overall rate of VOC removal, reaches an asymptote with the velocity increasing. Zhang et al. (2003) developed a PCO reactor model. They found that two parameters, the number of the mass transfer unit, NTU_m , and the fractional conversion, ε , were the main parameters influencing the photooxidation performance of a PCO reactor. In Zhang's model, it was assumed that the photocatalytic reaction was a first-order reaction with a constant reaction rate coefficient and a constant convective mass transfer coefficient along the flow direction. Yang et al. (2004) developed an improved model considering the variable apparent reaction rate coefficient, K , and the variable convective mass transfer coefficient, h_m , along the flow direction. Three new parameters, the ideal reaction number of mass transfer units, $\text{NTU}_{m,ir}$, the ideal reaction fractional conversion, ε_{ir} , and the reaction effectiveness, η , were defined. The latter is useful in evaluating the upper limit and the bottleneck of VOC removal performance of PCO reactors.

Mo et al. (2005) developed a general PCO reactor model that takes account of the variable apparent reaction rate coefficient and convective mass transfer coefficient on the reaction surface (not only in the axial but also in the perimetric direction). It provides a novel insight into the analysis of VOC removal performance of PCO reactors. In practical applications, three types of PCO reactors (plate, honeycomb, and light in tube) are often applied (Fig. 2). These reactors can be summarized as shown in Fig. 3b, which describes the mass transfer balance of a finite element in the cross-section.

Based on the general channel shown in Fig. 3, the following assumptions are made: (1) the cross-sectional shape remains the same along the airflow direction; (2) there is only one species of VOC in indoor air or the VOCs can be treated as one

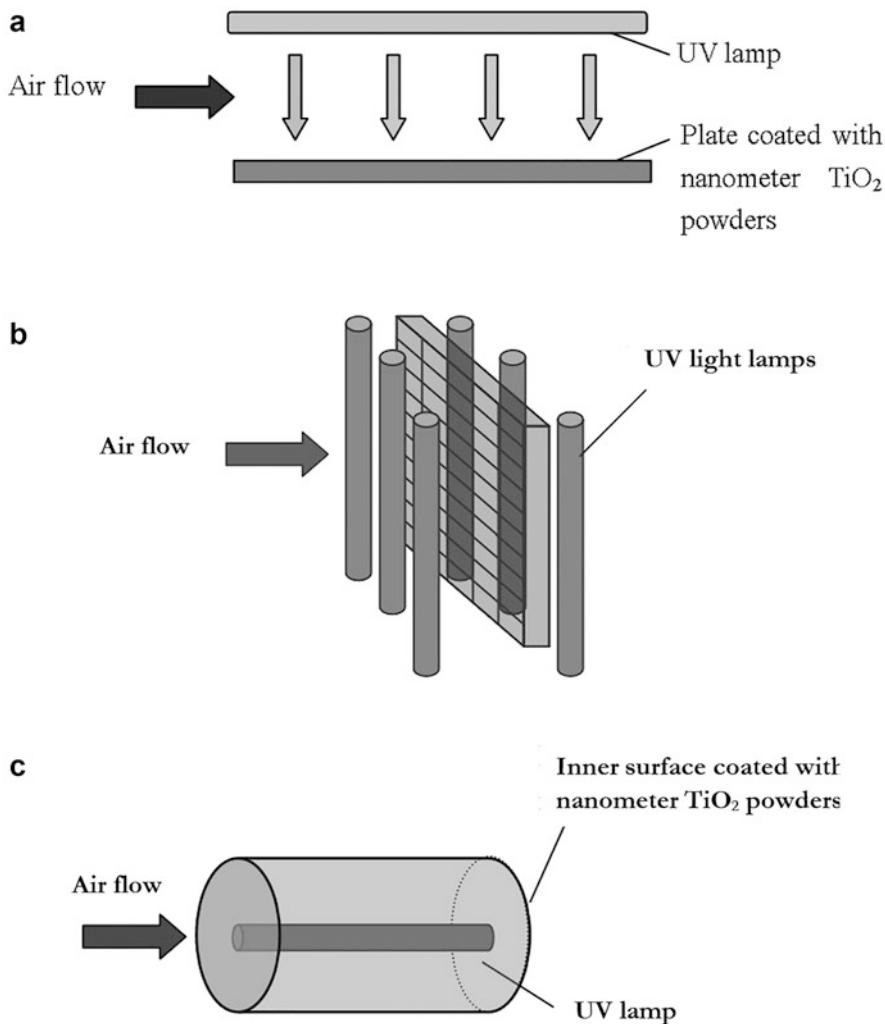

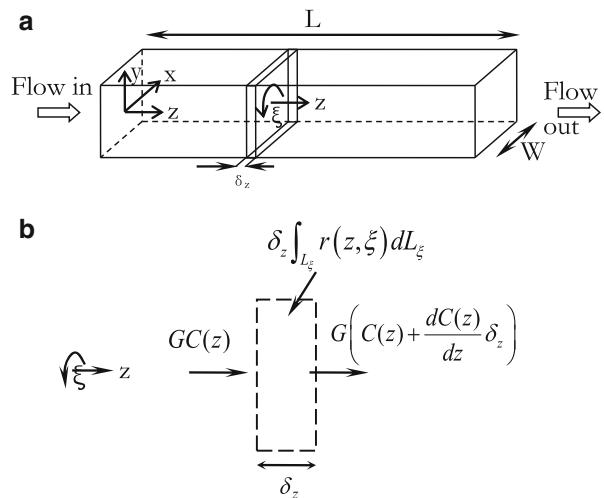

Fig. 2 Schematic of several PCO reactors. (a) Plate-type reactor; (b) honeycomb-type reactor; (c) light-in-tube reactor (Mo et al. 2005)

species. The photocatalytic reaction rate is expressed as the product of the VOC concentration adjacent to the reaction surface and the apparent reaction rate coefficient. Thus, for the PCO reactor shown in Fig. 3b, the mass conservation equation and boundary condition can be written as:

$$-G \frac{dC(z)}{dz} = \int_{L_\xi} r(z, \xi) d\xi \quad (5)$$

Fig. 3 Schematic of a channel of a monolith PCO reactor: (a) coordinates of the channel; (b) mass balance of the finite cross-sectional element (Mo et al. 2005)

$$r(z, \xi) = K(z, \xi)C_s(z, \xi) = h_m(z, \xi)(C(z) - C_s(z, \xi)) \quad (6)$$

$$z = 0, \quad C(z) = C_{in} \quad (7)$$

where z is the distance in the axial direction, m; ξ is the distance in the perimetric direction, m; L is the length of the channel, m; L_ξ is the perimeter of the cross-sectional area of the reaction surface path, m; G is the volumetric airflow rate, m^3s^{-1} ; $C(z)$ is the mass-rate-averaged VOC concentration on the cross-section at location z , that is:

$$C(z) = \frac{\int_{A_c} (u \cdot C) dA_c}{\int_{A_c} u dA_c} \quad (8)$$

where u is the velocity compound in z direction, A_c is the cross-sectional area, m^2 ; $C_s(z, \xi)$ is the local VOC concentration in the air adjacent to the air-solid interface at location (z, ξ) , mol m^{-3} ; C_{in} is the inlet VOC concentration, mol m^{-3} ; $r(z, \xi)$ is the local reaction rate at location (z, ξ) , $\text{mol m}^{-2} \text{s}^{-1}$; $K(z, \xi)$ is the local apparent reaction rate coefficient at location (z, ξ) , m s^{-1} , which is the function of intensity and wavelength of UV light, the physical properties of photocatalyst, and the humidity concentration and VOC concentration (based on the Langmuir-Hinshelwood kinetic rate formula in Obee (1996)); and $h_m(z, \xi)$ is the local convective mass transfer coefficient at location (z, ξ) , m s^{-1} .

Defining the local total VOC removal factor:

$$K_t(z, \xi) = \frac{1}{1/K(z, \xi) + 1/h_m(z, \xi)} \quad (9)$$

The solution of Eq. (5) gives:

$$\ln C_{out} - \ln C_{in} = -\frac{1}{G} \int_0^L \int_0^{L_\xi} K_t(z, \xi) d\xi dz \quad (10)$$

where C_{out} is the outlet VOC concentration, mol m⁻³.

Define the average total VOC removal factor K_t as follows:

$$K_t = \frac{\int_0^L \int_0^{L_\xi} K_t(z, \xi) d\xi dz}{\int_0^L \int_0^{L_\xi} d\xi dz} = \frac{\int_0^L \int_0^{L_\xi} K_t(z, \xi) d\xi dz}{A_r} \quad (11)$$

where A_r is the reaction surface area, m². Combining Eqs. (10) and (11) yields

$$C_{out} = C_{in} \cdot e^{-\frac{K_t A_r}{G}} \quad (12)$$

The number of the mass transfer unit, NTU_m, the fractional conversion, ε , and removal rate, \dot{m} , for a PCO reactor are expressed as follows:

$$NTU_m = \frac{K_t A_r}{G} \quad (13)$$

$$\varepsilon = \frac{C_{in} - C_{out}}{C_{in}} = 1 - e^{-NTU_m} \quad (14)$$

$$\dot{m} = G\varepsilon = G(1 - e^{-NTU_m}) \quad (15)$$

When $h_m(z, \xi)$ and $K(z, \xi)$ are independent of location ξ , this model can be simplified to the model of Yang et al. (2004); when independent of both z and ξ , this model can be simplified to the model of Zhang et al. (2003). The advantage of the present model is that it can be used to analyze the VOC removal performance of three-dimensional PCO reactors, in particular to those with inner extended surfaces and spatially dependent mass transfer rate coefficient and reaction rate coefficient.

From Eq. (13), the fractional conversion, ε , monotonically increases with increasing NTU_m. Thus, in order to improve the fractional conversion of a PCO reactor, it is very important to analyze how to increase NTU_m.

The Number of the Mass Transfer Unit, NTU_m

NTU_m can be rewritten as follows:

$$NTU_m = \frac{K_t A_r}{G} = \frac{K_t A_r}{u_a A_c} = \frac{1}{A_c} \int_0^L \int_0^{L_\xi} \frac{1/u_a}{1/K(z, \xi) + 1/h_m(z, \xi)} d\xi dz \quad (16)$$

where u_a is the average air velocity of the cross-sectional flow area, m s⁻¹.

Applying the Reynolds number, Re; Schmidt number, Sc; local Sherwood number, $Sh(z, \xi)$; and local Damkohler number (Tronconi and Forzatti 1992), $Da(z, \xi)$:

$$\begin{aligned}\text{Re} &= \frac{u_a d_e}{\nu}, \quad Sc = \frac{\nu}{D} \\ Sh(z, \xi) &= \frac{h_m(z, \xi) d_e}{D} \\ Da(z, \xi) &= \frac{K(z, \xi) d_e}{D}\end{aligned}\tag{17}$$

where d_e is the equivalent diameter of the airflow channel, m; ν is the kinematic viscosity, $\text{m}^2 \text{s}^{-1}$; and D is the diffusion coefficient of the VOC species in air, $\text{m}^2 \text{s}^{-1}$. Equation (16) can be rewritten as:

$$\text{NTU}_m = \frac{1}{A_c} \int_0^L \int_0^{L_\xi} \left(\frac{Sh(z, \xi)}{\text{Re} Sc} \cdot \frac{1}{Sh(z, \xi)/Da(z, \xi) + 1} \right) d\xi dz\tag{18}$$

Applying the local Stanton number of mass transfer:

$$St_m(z, \xi) = \frac{Sh(z, \xi)}{\text{Re} Sc}\tag{19}$$

and defining the local reaction effectiveness:

$$\eta(z, \xi) = \frac{1}{Sh(z, \xi)/Da(z, \xi) + 1}\tag{20}$$

Equation (18) can be rewritten as:

$$\text{NTU}_m = \frac{1}{A_c} \int_0^L \int_0^{L_\xi} St_m(z, \xi) \eta(z, \xi) d\xi dz\tag{21}$$

The average St_m and η for the whole reactor can be expressed as follows:

$$St_m = \frac{\int_0^L \int_0^{L_\xi} St_m(z, \xi) d\xi dz}{\int_0^L \int_0^{L_\xi} d\xi dz} = \frac{\int_0^L \int_0^{L_\xi} St_m(z, \xi) d\xi dz}{A_r}\tag{22}$$

$$\eta = \frac{\int_0^L \int_0^{L_\xi} (St_m(z, \xi) \eta(z, \xi)) d\xi dz}{\int_0^L \int_0^{L_\xi} St_m(z, \xi) d\xi dz} = \frac{\int_0^L \int_0^{L_\xi} (St_m(z, \xi) \eta(z, \xi)) d\xi dz}{A_r St_m}\tag{23}$$

Finally, the NTU_m is

$$\begin{aligned}\text{NTU}_m &= A^* \cdot St_m \cdot \eta, \\ A^* &= \frac{A_r}{A_c},\end{aligned}\tag{24}$$

where A^* is the area ratio of the reaction area to the cross-sectional area. NTU_m is the linear product of three parts, A^* , St_m , and η .

Applying the Taylor series yields

$$(1 - e^{-NTU_m}) = \sum_{n=1}^{\infty} (-1)^{n-1} \frac{(NTU_m)^n}{n!} = \sum_{n=1}^{\infty} (-1)^{n-1} \frac{(A^* \cdot St_m \cdot \eta)^n}{n!} \quad (25)$$

Thus, the VOC removal rate is expressed as:

$$\begin{aligned} \dot{m} &= G\varepsilon = u_a A_c \cdot \sum_{n=1}^{\infty} (-1)^{n-1} \frac{(A^* \cdot St_m \cdot \eta)^n}{n!} \\ &= A_r \cdot h_m \cdot \eta - \frac{(A_r \cdot h_m \cdot \eta)^2 (u_a A_c)^{-1}}{2!} + \frac{(A_r \cdot h_m \cdot \eta)^3 (u_a A_c)^{-2}}{3!} \dots \end{aligned} \quad (26)$$

If u_a is high enough,

$$\dot{m} \approx A_r \cdot h_m \cdot \eta \quad (27)$$

Therefore, when the averaged velocity, u_a , increases, at some point it reaches an asymptote, which is accordant with Hall's conclusion (Hall et al. 1998). Furthermore, the limit value of \dot{m} is a linear product of A_r , h_m , and η .

In summary, the VOC removal performance of PCO reactors improves with increasing values of the aforementioned dimensionless parameters. The influence of geometry and configuration, convective mass transfer rate, and PCO reaction rate on the VOC removal performance of a PCO reactor can be analyzed by applying the above model.

Discussion on A^*

A^* is a very useful parameter in optimizing a PCO reactor geometric configuration. Considering that $0 \leq \eta \leq 1$ and $0 \leq St_m \leq 1$, the maximal value of NTU_m is A^* , theoretically. If taking NTU_m as A^* , the fractional conversion is still not satisfactory, and it means that no matter how much the mass transfer and reaction rate are enhanced, the VOC removal performance cannot reach the desired level. For this case, the geometric configuration design or selection should not be accepted. Therefore, A^* can be regarded as a reactor geometric configuration evaluation parameter with which any unreasonable reactor geometric design or selection can easily be found.

Discussion on St_m

The mass transfer is the precondition of a PCO reaction. That is to say, it has to make sure that the mass transfer rate is high enough to guarantee a high reaction rate. If the value of A^* is high enough, the value of St_m will determine the VOC removal performance. Assuming η equal to 1, the maximal value of NTU_m is $(A^* St_m)$. Only when the value of $(A^* St_m)$ is high, the VOC removal performance of the reactor is promising. Otherwise, the reactor design is failed. Therefore, St_m can be regarded as the mass transfer evaluation parameter with which the mass transfer bottleneck of any unreasonable reactor can be found.

St_m shows the synergistic degree of fluid and mass flow fields. The field synergy between flow and heat transfer was analyzed by Guo et al. (Guo et al. 1998; Guo 2001), based on the parabolic fluid flow. Tao et al. (2002a, b) extended the concept to elliptic fluid flow and other heat transfer problems. This concept was well used in heat transfer enhancement but not in the mass transfer field. Similarly, from the analogy between heat transfer and mass transfer, the synergy of fluid and mass flow fields presents a new insight into the physical meaning of St_m . Based on Guo's concept, Mo et al. (2005) derived how to enhance the mass transfer in a PCO reactor.

For two-dimensional steady boundary flow, the mass balance equation is written as:

$$u \frac{\partial C}{\partial x} + v \frac{\partial C}{\partial y} = D \frac{\partial^2 C}{\partial y^2} \quad (28)$$

where x is the coordinate along with the flow, and y is normal to x ; u and v are the velocity components in x and y directions, respectively, m s^{-1} ; and C is mole concentration, mol m^{-3} .

Defining the vector:

$$\mathbf{U}_\infty = 0 \cdot \mathbf{i} - u_\infty \cdot \mathbf{j}, \quad (29)$$

and the following dimensionless variables,

$$\begin{aligned} \bar{\mathbf{U}} &= \frac{\mathbf{U}}{u_\infty}, \quad \bar{\mathbf{U}}_\infty = \frac{\mathbf{U}_\infty}{u_\infty}, \quad \bar{x} = \frac{x}{\delta_m(x)}, \quad \bar{y} = \frac{y}{\delta_m(x)}, \\ \bar{\nabla} \bar{C} &= \frac{\nabla C}{(C_s(x) - C_\infty)/\delta_m(x)}, \end{aligned} \quad (30)$$

where $\delta_m(x)$ is the mass boundary layer thickness at x location, m ; u_∞ is the velocity components in x in free-stream flow, m/s ; C_∞ is the VOC mole concentration in free-stream flow, mol m^{-3} ; and $C_s(x)$ is the VOC mole concentration in the air adjacent to the surface at y location, mol m^{-3} .

St_m is finally expressed as:

$$St_m(x) = \frac{Sh(x)}{Re Sc} = \frac{\int_0^1 (|\bar{\mathbf{U}}| |\nabla \bar{C}| \cos \beta) d\bar{y}}{\int_0^1 (|\nabla \bar{C}|) d\bar{y}} \quad (31)$$

where Sh , Re , and Sc represent the Sherwood number, the Reynolds number, and the Schmidt number, respectively. β is the intersection angle between $\bar{\mathbf{U}}$ and $\nabla \bar{C}$.

It is evident from Eq. (31) that: (1) St_m depends not only on the values of the velocity and concentration gradient of fluid flow, but also on the intersection angle between them; (2) $St_m \leq 1$, only when there is $|\bar{\mathbf{U}}| = 1$ and $\beta = 0$ everywhere, $St_m = 1$, that is, the vector $\bar{\mathbf{U}}$ has to be the same with $\bar{\mathbf{U}}_\infty$, not only the value but also the vector direction; obviously, when β equals to 0 everywhere, $|\bar{\mathbf{U}}|$ must be equal to

1; and (3) β plays an important role in describing the synergistic degree of fluid and mass flow fields.

β is in the range of 0 to π . If β is equal to $\pi/2$, the mass flux on the reaction surface is zero. Thus, the fractional conversion of the reactor is 0%. If β is equal to 0 (or π), $St_m = 1$, which means that $NTU_m = A^* \cdot 1 \cdot \eta$. Thus, in this case, the fractional conversion depends only on A^* and η . β is important to analyze the value of St_m . The average St_m is proportional to the cosine value of the average angle. For example, if the average angle reduces from 89 degree to 88 degree, the cosine value of the average angle increases about 100%.

From Eq. (19) and the definition of the convective mass transfer coefficient, it yields

$$St_m = \frac{h_m}{u_a} = -D \frac{\nabla C|_{wall}}{(C_m - C_s)} \frac{1}{u_a} \quad (32)$$

where $\nabla C|_{wall}$ is the concentration gradient on the reaction surface and C_m is the mass-rate-averaged concentration of the cross-sectional area. Thus, if the term $(\frac{\nabla C|_{wall}}{(C_m - C_s)})$ is not equal to constant (as is the case in most practical situations), St_m is the function of the concentration distribution. Tronconi and Forzatti (1992) found that the Sherwood number, Sh , varies with the value of the Damkohler number, Da . That is to say, St_m depends on η . Thus, it implies that η influences the concentration distribution and then affects St_m indirectly.

However, if the VOC concentration difference in the PCO reactor is not high, the influence of VOC concentration to St_m can be neglected, just as the situation of the influence of temperature to the heat transfer. Zhang et al. (2003) found that when the VOC concentration is low (lower than 2 ppmv), NTU_m remains almost constant in a series of experiments with various VOC concentrations. Therefore, it is justified to assume that St_m is independent of the VOC concentration if the concentration is low (as is the case in most practical situations).

Discussion on η

Equation (20) can be changed into:

$$\eta(z, \xi) = \frac{1}{h_m(z, \xi)/K(z, \xi) + 1} \quad (33)$$

If the mass transfer rate is much greater than the reaction rate, i.e., $h_m(z, \xi) \gg K(z, \xi)$, $\eta(z, \xi)$ approaches its minimum, 0. If the reaction rate is much greater than the mass transfer rate, i.e., $K(z, \xi) \gg h_m(z, \xi)$, $\eta(z, \xi)$ approaches its maximum, 1. Therefore, η , the averaged value of $\eta(z, \xi)$ for the whole reaction surface, can be regarded as a PCO reaction evaluation parameter. If η is near 0, it implies that the bottleneck of VOC removal by a PCO reactor is reaction rate. For this case, applying a high-performance photocatalyst or improving the reaction condition may obviously increase VOC removal performance.

Determination of A^* , St_m , η , and β_a for a Given PCO Reactor

A^* can be calculated by the geometric size of the PCO reactor. St_m can be calculated by using the computational fluid dynamic (CFD) method or by using suitable empirical correlations. NTU_m is calculated by using the measured fractional conversion, ε of a PCO reactor. When A^* , St_m , and NTU_m are known, η can be calculated by using Eq. (24). In addition, η also can be calculated by using Eq. (23) and CFD method.

Illustrative Examples: Honeycomb-Type Reactors

Hossain et al. (1999) developed a mathematical model to describe the VOC removal performance of a titania-coated honeycomb monolith PCO reactor for air purification (Fig. 2b). In the experiment, they employed two-monolith/one-UV-lamp-bank configuration. Monolith lengths were 0.5, 1.0, and 1.5 in. (12.7, 25.4 and 38.1 mm). Each monolith contained 64 cells per square inch (CPSI). The flow rate was 55 cubic feet per min (CFM), with mean UV intensities on the 12" \times 12" monolith face of 6.5 mW/cm². The inlet formaldehyde concentration was 2.1 ppm_v and the water concentration was 2700 ppmv. Applying Hossain's model, Mo et al. (2005) solved the conservation equations, including the convection, diffusion, and reaction for each component in the monolith, using Phoenics 3.3 (Commercial CFD software). Thus, NTU_m , A^* , St_m , η , and β were obtained by using Eqs. (22), (23), and (24). Table 1 lists the CFD-simulated and experimental results for the formaldehyde conversion tests. Compared with Hossain's experimental data, a statistical best-fit result was obtained, with a slope of 1.045 and R^2 of 0.972. Thus, the CFD method is capable of predicting the experimental results with a high level of confidence.

According to the discussion above, the VOC removal performance can be evaluated step by step. From Table 1, A^* values are always much greater than 1. Thus the geometry design for this type PCO reactor is satisfactory. In addition, the products ($A^* St_m$) are also greater than 2 except for Test 1. However, the final fractional conversions are less than 85% because of low η values. It implies that the bottleneck for honeycomb type PCO reactor is the reaction rate. From Hossain's paper (1999), it is known that the UV radiation intensity drops sharply with increasing distance into the channel. This is the main reason for a small value of η . From Table 1, it is also seen that St_m is much smaller than its maximum, 1. The intersection angle, β , is close to 90 degrees, resulting in low St_m values. Hence, for this typical PCO reactor, A^* offsets the low St_m values, which makes the product ($A^* St_m$) satisfactory.

Identification of PCO By-Products

The resultant of complete PCO for VOCs should be CO₂ and water. However, many reactants form partial oxidation products (Blanco et al. 1996; Augugliaro et al. 1999), which may be relatively more harmful to people's health. As one of the typical organic compounds indoors, toluene was used as the target pollutant in the

Table 1 The simulated and experimental results for formaldehyde removal (Mo et al. 2005)

Test	Lamp number/number of surface radiated	Monolith length (in.)	Measured ε (%)	Simulated ε (%)	Diff. (%)	$\dot{m} = G\varepsilon \times 10^{-3}$ m ³ /h	NTU _m ($\times 10^{-2}$)	A*	S _{Tm} ($\times 10^{-2}$)	η(%)	β (degree)

PCO studies. Gas Chromatograph-Flame Ionization Detector (GC-FID), GC-MS, High-Performance Liquid Chromatography (HPLC), Fourier-Transform Infrared spectroscopy (FTIR), Temperature-Programmed Oxidation (TPO), and Temperature-Programmed Hydrogenation (TPH) are often used to characterize the by-products of toluene PCO (Blanco et al. 1996; Luo and Ollis 1996; d'Hennezel et al. 1998; Augugliaro et al. 1999; Blount and Falconer 2001, 2002; Marci et al. 2003; Irokawa et al. 2006; Guo et al. 2008; Chen and Zhang 2008; Martra et al. 1999). It appears that no significant by-products of toluene were identified using GC-FID (Luo and Ollis 1996). Combined with GC/FID/MS, GC/MS/HPLC, GC/FTIR, or TPH and TPO, some by-products were found on the PCO reaction surface. However, the only gas-phase by-product found was CO. FTIR has been widely used to analyze the surface by-products of toluene. However, it seems that FTIR is only suited to situations where the toluene concentration is high, from 30 to 13,000 ppm in the published articles (Mendez-Roman and Cardona-Martinez 1998; Martra et al. 1999; Augugliaro et al. 1999; Maira et al. 2001). Benzaldehyde, benzyl alcohol, benzoic acid, and phenol were the main by-products (Maira et al. 2001; Blount and Falconer 2001, 2002; Blanco et al. 1996). Since the concentration of toluene in indoor air is ppb or sub-ppm levels, it is doubted whether the investigation conclusions from these high concentration experiments could be used in indoor air cases. However, very little research concerning low-concentration, gas-phase by-products is reported in the literature. Sleiman et al. (2008) found that benzaldehyde and benzene were the main gaseous by-products of toluene at indoor air levels. Proton transfer reaction mass spectrometer (PTR-MS) has been proved to be a powerful device for online detecting transient by-products (Wisthaler et al. 2007). Several studies used PTR-MS to study PCO gas-phase by-products of a continuous flow of toluene over TiO₂ (Mo et al. 2009b, 2013).

Mo et al. (2009b) used a stainless steel plate-type UV-PCO reactor (as shown in Fig. 4) to study the PCO by-products. The experiments were all performed at a typical indoor air conditioning level with temperatures of 24.0–26.0 °C, and relative humidity (RH) of 47–50%. Two photocatalyst-coated glass plates (76.0 × 25.0 × 1.0 mm³) were placed in the reactor. The photocatalyst powders (Degussa P25) were deposited on the glass plate as a film using the dip-coating method (Yang et al. 2007) with a net weight of 22 mg loading on the reaction side. Two UV-C lamps were used to irradiate the photocatalyst film from the top of the reactor through a quartz glass. The lamps (Philips Hg-Lamp, TUV 15 W G15T8 UV-C, made in Holland) with 98% of the UV lamp radiation emitted at 254 nm and the UV radiation intensities were in the range of 0.43–0.95 mW/cm² on the reaction surface. Compressed air from a gas cylinder was divided into two streams. One stream passed through a mass flow controller and the other passed through a bottle-wash humidifier to control the humidity concentration. Pure toluene gas was mixed with the compressed air and then was supplied to the plant-type PCO reactor. All the airflow rates were controlled by two mass flow controllers. The total airflow rate was kept at 0.55 l/min with a contact time of 0.2 s in the reactor.

In the PTR-MS measurement, mass-scan and mass-identification-detection (MID) modes were used during the research. MID was used to continuously trace

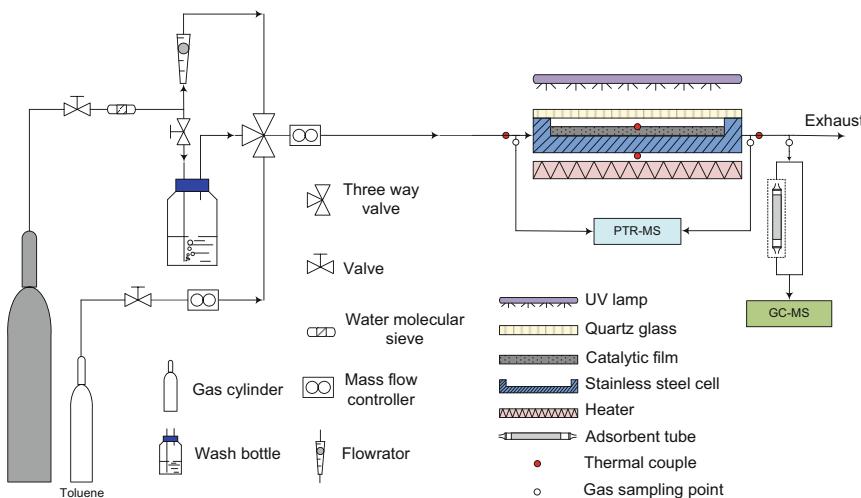

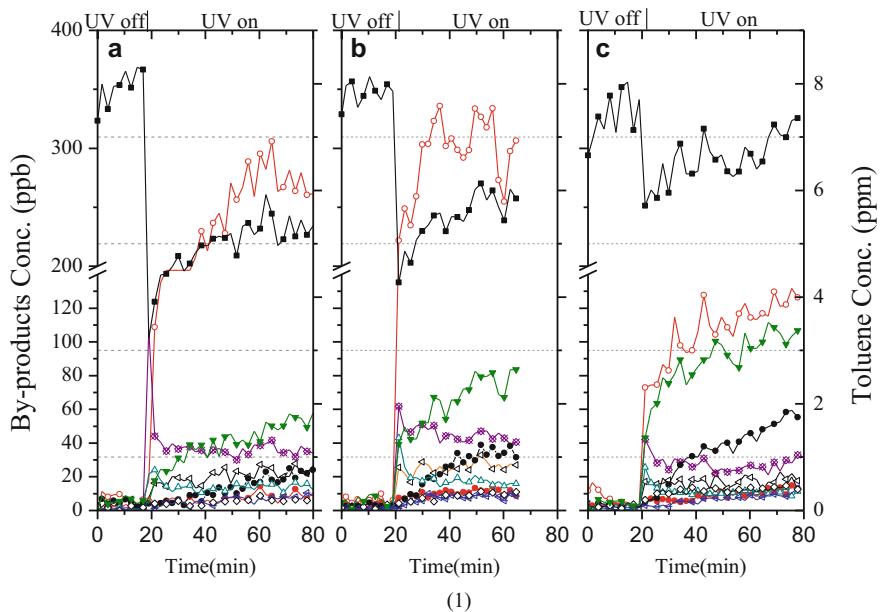

Fig. 4 Schematic of the experimental system, including the gas preparation part and UV-PCO reaction cell (Mo et al. 2009b)

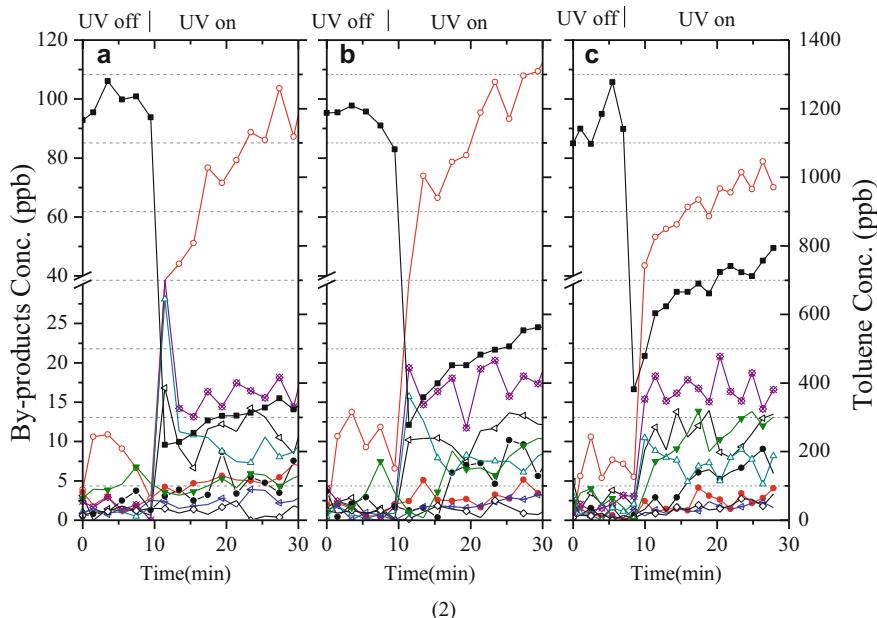

some specific compounds found from the mass-scan mode. In the experiments, the compounds with molecular mass 30, 32, 42, 44, 46, 58, 60, 78, and 106 were found to be the by-products. The concentrations of molecular mass 30, 32, 42, 44, 46, 58, and 60 always increased after UV irradiation. The concentrations of molecular mass 78 and 106 were only found to increase when inlet toluene concentrations of 1200 and 8000 ppb. The by-products with molecular mass 30, 32, 42, 44, and 58 have not previously been reported in the literature.

In order to observe the instant changes of by-products, the compounds identified in the mass scan process were traced continually in MID process. No adsorption effect of molecular mass 30, 32, 42, 44, 58, 60, 78, and 106 on the interior surface of the reactor cell was observed before and after the UV light irradiated on the blank glass without TiO₂ film. Figure 5 shows the conversions versus time before and after UV light irradiated on the glass with TiO₂ film at different inlet concentrations and UV intensities. Under the experimental condition, the concentrations of molecular mass 44 and 58 increased sharply at the beginning of UV-PCO reaction (UV on) and trended to be steady state. The concentration peaks of molecular mass 44 and 58 were much high under high inlet toluene levels and high UV intensity (Fig. 5a1, b1). Simultaneously, the compounds with molecular mass 32, 46, and 106 were generated, but the increases were slower compared with the compounds of molecular mass 44 and 58. Molecular mass 78 was only found to have slight and regular change when the inlet concentration of toluene was 8000 ppb (Fig. 5a).

Under the instant concentration pulse of water vapor, the by-products adsorbed on TiO₂ surface were replaced by water vapor due to their completed adsorption effect. These by-products were released into the gas phase. Figure 6 shows the

Fig. 5 (continued)

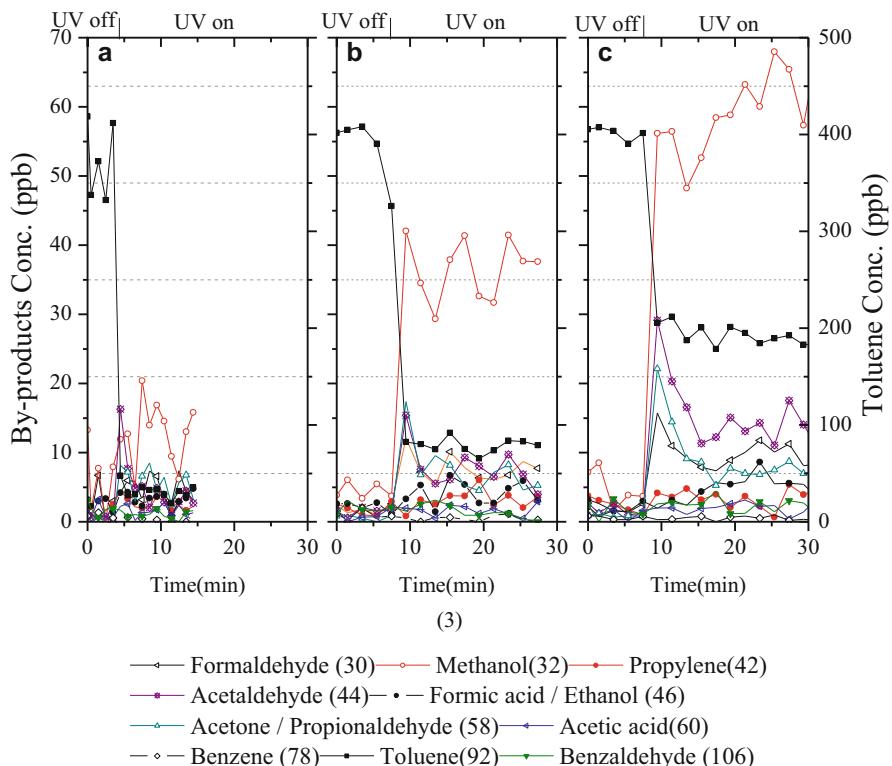

Fig. 5 Toluene and its by-products conversions vs. time with inlet toluene concentration of (a) 8 ppm, (b) 1200 ppb, and (c) 450 ppb; $T = 24\text{--}26\text{ }^{\circ}\text{C}$; RH = 47–50%; 254 nm: (1) UV intensity = 0.95 mW/cm^2 ; (2) UV intensity = 0.78 mW/cm^2 ; (3) UV intensity = 0.43 mW/cm^2 (The numbers in brackets are their molecular mass values.) (Mo et al. 2009b)

concentration changes of the by-products. Under UV irradiation and lack of water vapor (RH: 1.1%), the inlet and outlet concentrations of toluene were almost the same. It means that the PCO reaction of toluene was inhibited without water vapor. With the instant increase of water vapor and UV off, the concentration peaks (Fig. 6a) of molecular mass of 42, 46, 60, 78, and 106 were detected by PTR-MS. In addition, PTR-MS also detected some other gas-phase by-products with very low concentrations (less than 15 ppb) during the water vapor pulse (Fig. 6b). They were molecular mass 54, 56, 72, 86, and 122. It indicated that these by-products were generated under a lack of water vapor. They were strongly adsorbed on TiO_2 surface and made the deactivation of photocatalyst (Fig. 6). The by-products with molecular mass 32, 42, 44, 58, and 60 were generated if keeping UV on with abundant water vapor (RH: 84%). It shows that the adsorbed by-products on TiO_2 surface should be continuously decomposed into compounds with small molecular mass. The by-products with molecular mass 42 and 60 were both generated under high and low concentrations of water vapor.

(Mo et al. 2009b)

By-Products Detected via GC-MS

The gas phase by-products were concentrated from the outlet gas by an adsorption tube packed with Tenax TA. Due to the low concentration of by-products, the concentration process was performed to be over 10 h. The compounds with molecular mass 58, 60, 72, 78, 86, 106, and 122 were respectively identified to be acetone, acetic acid, butyraldehyde, benzene, pentanal, benzaldehyde, and benzoic acid. Some by-products found in Mo's study (2009b) agreed with the literature (Table 2). d'Hennezel et al. (1998) and Irokawa et al. (2006) reported that benzaldehyde was the main by-products on the reaction surface. Benzene (molecular mass 78) was identified on the solid surface by Blanco et al. (1996) and Martra et al. (1999) at very high inlet toluene concentrations after PCO process. In addition, acetic acid (molecular mass 60) and formic acid (molecular mass 46) were also found from PCO decomposition of toluene by d'Hennezel et al. (1998).

Possible PCO Pathways of Toluene

Most previous studies believed that the primary pathway in toluene photocatalytic oxidation is the hydrogen abstraction from the methyl group leading to a benzyl radical and then forming benzaldehyde, benzoic acid, and benzyl alcohol (d'Hennezel et al. 1998; Van Durme et al. 2007; Guo et al. 2008). d'Hennezel et al. (1998) gave a detailed photocatalytic oxidation pathway from toluene to benzoic acid. However, the further pathways of the aromatic ring were still not clear enough.

Frankcombe and Smith (2007) presented that the first step of toluene oxidation was the addition of an OH radical to the toluene ring followed by donation of the hydrogen atom of the added OH fragment to an O₂ molecule, which leaded to the corresponding hydroxylated isomers (phenol, -methyl-). Finally, the aromatic ring was opened and formed two carbonyl groups (O=C-R-C=O) at the attacked position, respectively. Based on this mechanism proposed by Frankcombe and Smith (2007), it is believed that toluene and its three initial by-products (benzaldehyde, benzoic acid, and benzyl alcohol) were attacked by a OH radical addition to the aromatic ring, which resulted in the opening of the aromatic ring. The compounds generated after ring opening contained several carbonyl bonds (C=O) and alkenyl bonds (C=C). In this study, the main by-products identified in the gas phase were all with small molecular mass, which indicated the carbonyl and alkenyl bonds were synchronously or continuously attacked by OH radical and adsorbed oxygen O₂. It implies that the toluene might react through the pathways: toluene → benzaldehyde → benzoic acids → ring broken → O=C-R-C=C-R'-C=O → shorter-carbon-chain aldehydes and alcohols. This results in the main photocatalytic oxidation pathways of toluene (Mo et al. 2009b). The compounds enclosed by full frame were identified in this study. In addition, the by-products: oxalic acid, pyruvic acid, propionic acid, isovaleric acid, and succinic acid reported in Mo's study (2009b) were also detected by Irokawa et al. (2006).

The concentration of water vapor has both active and inhibiting effects on the photocatalytic oxidation process (Mo et al. 2013). It has already been proved that the

photogenerated positive holes will drive the oxidation of compounds adsorbed on the surface of a photocatalyst (Ohtani 2008). But the holes will react with adsorbed water and generate hydroxyl radical (OH^\bullet), which is the dominant strong oxidant (Einaga

et al. 2002). Therefore, water plays a key positive role on PCO reaction. However, another function of water is the competitive adsorption effect with other compounds (Einaga et al. 2002; Raillard et al. 2004). When the concentration of water vapor is extremely high, competitive adsorption with water reduces the residence time of the by-products on the surface of the photocatalyst. Both low and high molecular weight by-products quickly release from the surface and are detected in the gas phase.

When the concentration of water vapor decreases, this competitive adsorption is inhibited. More and more toluene and its by-products are adsorbed on the photocatalytic surface, resulting in the higher toluene-decomposed efficiency and lower generation of by-products. There is a balance between the active and inhibiting effects of water. If the formation of HO[•] radicals is exactly consumed by adsorbed toluene and its by-products, a minimal quantity of by-products is obtained. If the OH[•] only matches the demand of toluene decomposition but not its by-products simultaneously, a maximum efficiency of toluene removal is obtained, but more by-products will release into the gas phase due to the lack of HO[•] radicals. Thus, the maximum efficiency and minimal by-product generation do not occur at the same water vapor concentration.

However, when the water vapor level approaches 0, the by-products accumulated on the reaction surface and blocked the photocatalyst (Mo et al. 2009b; Sleiman et al. 2009), resulting in a deactivation of the photocatalyst. In Mo's study (2013), acetaldehyde was the main by-product at low water vapor levels. This is consistent with the results of Sleiman et al. (2009), who found that some small aldehydes were produced in the gas phase at low water vapor concentrations. In addition, many high molecular weight by-products were adsorbed on the surface (Mo et al. 2009b). However, Sleiman et al. (2009) found there were fewer high molecular weight by-products, such as benzaldehyde at low water vapor concentration, compared with that at high water vapor concentration after 1 or 3 days reaction time. The reason may be that the photocatalyst deactivates very early at low water vapor concentration and does not generate any by-products later, thus the high molecular weight by-products adsorbed on the surface or in the gas phase were finally less than that found with high water vapor concentrations.

Figure 7 summarizes the photocatalytic oxidation efficiencies of toluene versus water vapor levels with the inlet toluene concentrations of 90, 145, 250, 400, 600, 700, and 800 ppb_v. It shows that the profiles of toluene oxidation efficiency varied significantly with water vapor concentrations. When the inlet toluene concentrations were lower than 250 ppb_v, the efficiencies always decreased with increasing humidity. When the inlet toluene concentrations were higher than 250 ppb_v, the oxidation efficiency increased first and then dropped down with the increase of water vapor levels. Maximum efficiency was obtained at optimal humidity.

Thermal Catalytic Oxidation

Recently, thermal catalytic oxidation (TCO) by specific catalysts was reported to remove formaldehyde efficiently. TCO does not require ultraviolet (UV) light or plasma, and the catalytic reaction occurs in the entire bulk of the catalyst rather than

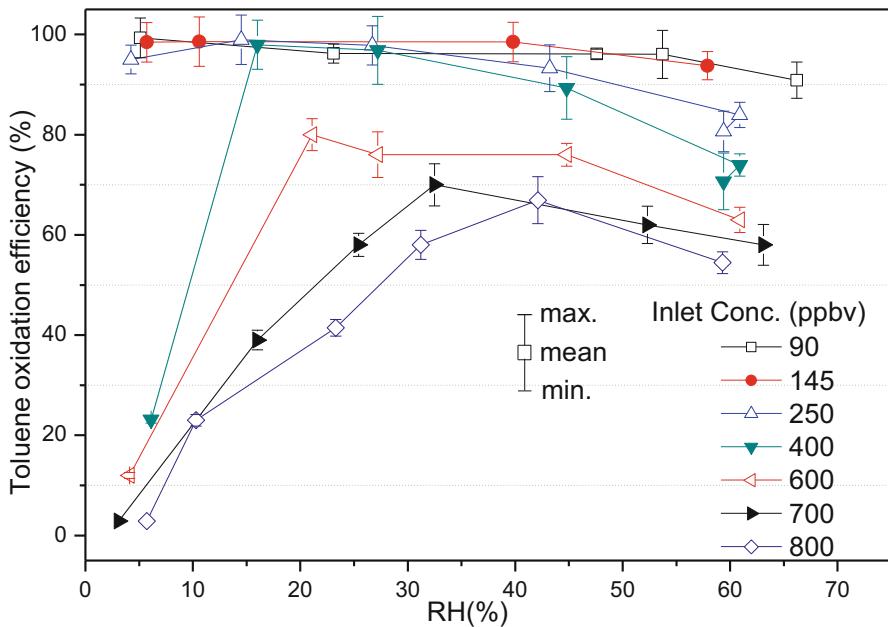

Fig. 7 Toluene oxidation efficiency versus relative humidity at inlet toluene concentrations of 90–800 ppbv with UV intensity of 0.43 mW/cm^2 (Mo et al. 2013)

only on the surface activated by UV. Such advantages make it more suitable than other techniques for indoor formaldehyde removal.

Various TCO catalysts have been investigated for their formaldehyde removal performance, including metal oxides (Sekine 2002), supported non-noble metals (Peng and Wang 2007), and supported noble metals on metal oxides (Zhang et al. 2006; Shen et al. 2008). Peng and Wang (2007) investigated the activities of a series of metals (Pt, Pd, Rh, Cu, and Mn) supported on TiO_2 for the catalytic oxidation of formaldehyde. It was found that supported noble metals on metal oxides have much better low-temperature activeness, and the activities were correlated with the dispersion of the noble metal on the supporting material. Foster and Masel (1986) studied the formaldehyde oxidation rate on nickel oxide at 220°C using the rate equation derived from Conner and Bennett's mechanism. Imamura et al. (1991) found that Ru/CeO_2 completely oxidized formaldehyde at 200°C . The complete removal temperature for formaldehyde and methanol on Pd–manganese oxide catalyst was found to be about 88°C (O'Shea et al. 2005). These studies showed high formaldehyde removal performance; however, their operating temperatures were much higher than the normal room temperature range. The Pt/TiO_2 catalyst by Zhang et al. (2005) and the $\text{Pt}/\text{MnO}_x\text{--CeO}_2$ catalyst by Tang et al. (2008) were proved to be efficient for formaldehyde decomposition at room temperature. Formaldehyde of 102 ppm through the Pt/TiO_2 catalyst was found to be totally oxidized into CO_2 (Zhang et al. 2005). Tang et al. (2008) found that formaldehyde of 30 ppm was

completely decomposed into CO₂ and H₂O on Pt/MnO_x–CeO₂ without deactivation over a 120 h reaction period, and the humidity has a negligible influence on the activity of a MnO_x–CeO₂ catalyst (Tang et al. 2006). However, there were few studies concerned with the reaction's kinetic mechanism, the relevant parameters, and the influencing factors for TCO, especially for concentrations below 1 ppm (Sekine 2002; Zhang et al. 2005; Tang et al. 2008). This limited the design and development of TCO air cleaners for removing indoor formaldehyde.

Formaldehyde Removal by TCO

This section introduced the formaldehyde removal performance by room-temperature TCO. The catalyst Pt/MnO_x–CeO₂ was prepared by a conventional impregnation process (Tang et al. 2008). The ratio of Mn and Ce in the catalyst was 1:1. The platinum loading was about 1.0 wt%. Excess water was removed in a rotary evaporator at 50 °C until dry. The resulting sample was dried at 110 °C for 12 h and then further thermally processed at 400 °C for 4 h. The physical properties of the catalyst are listed in Table 3.

The experiments were performed in a stainless steel once-through fixed-bed reactor (Fig. 8). The reactor was located in a steel chamber with temperature control in the range of 20–200 °C. Gaseous formaldehyde was generated by bubbling a formaldehyde solution using a nitrogen gas flow. The flow rate was controlled by a mass flow controller. The gaseous formaldehyde was diluted by synthetic air (O₂ 20 vol%, N₂ balance). The total flow rate through the reactor was 2.5 l/min and the gas hourly space velocity (GHSV) was $4.43 \times 10^6 \text{ h}^{-1}$. The inlet formaldehyde concentration was controlled by adjusting the flow ratio of formaldehyde gas. The concentration range was between 280 and 3000 ppb, which was a compromise for minimizing the test error and close to the indoor concentration level. The water vapor in the airflow was controlled at 7500 ppm by a water bubbling bottle. The concentrations of the inlet and outlet were monitored by a PTR-MS. A steady-state condition was achieved after several minutes to several hours, depending on the temperature. The final outlet concentration was determined under steady-state conditions.

^a Measured by nitrogen adsorption BET method

^b Measured by mercury porosimeter method

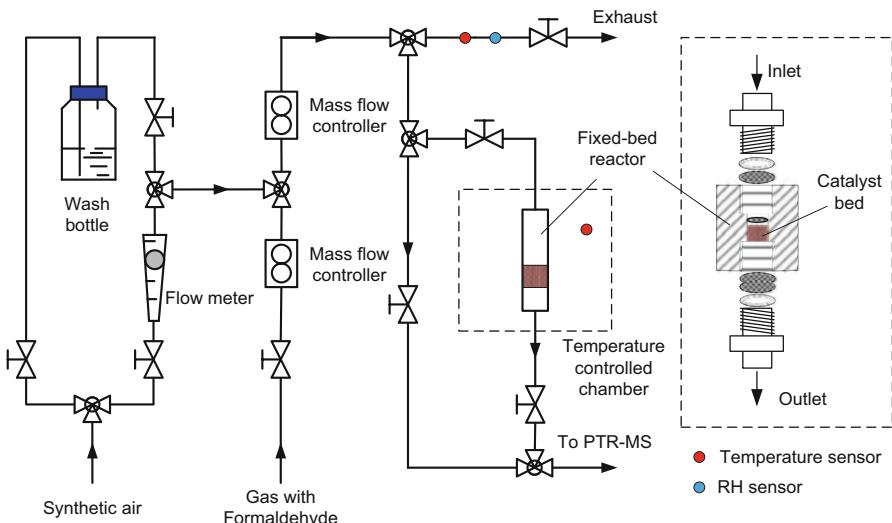

Fig. 8 Schematic of the experimental setup and fixed-bed reactor (Xu et al. 2011)

Data analysis. The once-through formaldehyde conversion, ε , is written as follows:

$$\varepsilon = \frac{C_{\text{in}} - C_{\text{out}}}{C_{\text{in}}} \quad (34)$$

where C_{in} and C_{out} are the steady-state inlet and outlet formaldehyde concentrations, ppb, respectively.

The average reaction rate was obtained from the mass balance in the reactor

$$r = \frac{G(C_{\text{in}} - C_{\text{out}})}{A_{\text{BET}}} \quad (35)$$

where r was the average reaction rate per BET surface area, ppb m s^{-1} ; G the gas flow rate, 1 min^{-1} ; and A_{BET} the total BET surface area, m^2 .

The apparent reaction factor K_{app} , m s^{-1} , was defined as the reaction rate divided by the surface concentration

$$K_{\text{app}} = \frac{r}{C_s} \quad (36)$$

Generally, the reaction takes place on the catalyst surface, so the mass transfer from bulk air to the surface needs to be considered (Yang et al. 2007). At the steady-state condition, the reaction rate in the reactor equals the external mass transfer rate,

$$K_{\text{app}} C_s(x) = \frac{h_m A_s}{A_{\text{BET}}} \Delta C(x) \quad (37)$$

where h_m was the mean external mass transfer coefficient, m s^{-1} ; ΔC the concentration difference between the bulk flow and the surface, ppb; A_s the total external surface area, m^2 ; and x the location in flow direction, m. h_m can be estimated by an empirical correlation (Wakao et al. 1979).

h_m and K_{app} were assumed as lumped parameters along the reactor. By deriving Eq. (37), the following equation was obtained:

$$\frac{\bar{C}_s}{\Delta \bar{C}} = \frac{C_s(0)}{C_{\text{in}} - C_s(0)} = \frac{C_s(L)}{C_{\text{out}} - C_s(L)} \quad (38)$$

where $\Delta \bar{C}$ was the logarithmic mean concentration difference between the bulk flow and the surface.

$$\Delta \bar{C} = \frac{(C_{\text{in}} - C_s(0)) - (C_{\text{out}} - C_s(L))}{\ln(C_{\text{in}} - C_s(0)) - \ln(C_{\text{out}} - C_s(L))} \quad (39)$$

The average surface concentration was obtained by solving Eqs. (37), (38), (39):

$$\bar{C}_s = \frac{C_{\text{in}} - C_{\text{out}}}{\ln(C_{\text{in}}) - \ln(C_{\text{out}})} \cdot f_m \quad (40)$$

where f_m was the external mass transfer correction factor

$$f_m = \frac{h_m A_s}{h_m A_s + K_{\text{app}} A_{\text{BET}}} \quad (41)$$

The value of f_m stands for the ratio of the reaction resistance in the series process of external mass transfer and the surface reaction.

There are three unknown parameters (K_{app} , f_m and \bar{C}_s) in Eqs. (36), (40), and (41). By solving these three equations, K_{app} and f_m can be obtained. To avoid the influence of external mass transfer, a high flow rate condition is necessary, which results in f_m being closer to 1. The reaction kinetics was studied by analyzing the variation of the reaction rate with the average surface concentration.

Once-through formaldehyde conversion. Figure 9 shows the result of ε at different temperatures. At inlet formaldehyde concentrations of 280–500 ppb, ε achieved 35.4%, 39.5%, 55.4%, 79.0%, and 96.3% at 25 °C, 40 °C, 60 °C, 100 °C, and 180 °C (GHSV $4.43 \times 10^6 \text{ h}^{-1}$), respectively. The formaldehyde conversion showed a significant decrease with decreasing temperature and increasing concentration. The mass scan result of PTR-MS showed that no significant increases of any signals were detected by PTR-MS in the effluent air. The impact of external mass transfer was studied by measuring the reaction rates at flow rates between 1.0 and 3.0 l/min. The measured apparent reaction coefficient and the external mass transfer correction factor are shown in Fig. 10. From the result, f_m was more than 0.95 when GHSV reached $4.43 \times 10^6 \text{ h}^{-1}$ (flow rate 2.5 l/min). Based on Eq. (41), the external mass transfer effect can be neglected, which was necessary to obtain the kinetic mechanism.

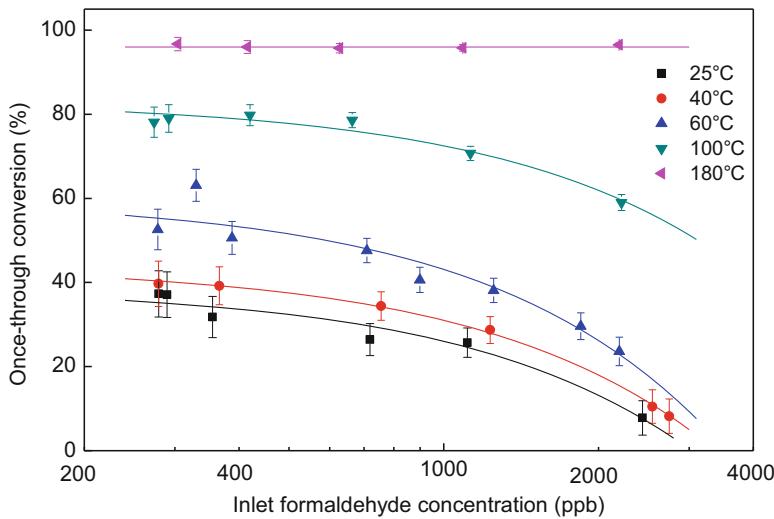

Fig. 9 Once-through formaldehyde conversion at different temperatures with GHSV $4.43 \times 10^6 \text{ h}^{-1}$; O₂ 20 vol%, N₂ balance; water vapor concentration 7500 ppm (Xu et al. 2011)

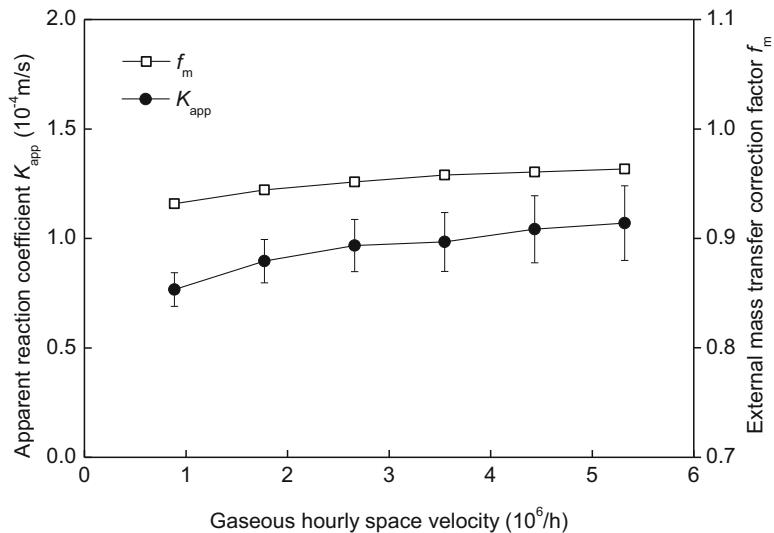

Fig. 10 The apparent reaction coefficient in the reactor: impact of external mass transfer; 700 ppb inlet formaldehyde; O₂ 20 vol%, N₂ balance; water vapor concentration 7500 ppm; reaction temperature 60 °C (Xu et al. 2011)

Effect of temperature and oxygen concentration. The reaction rate is related to the surface formaldehyde concentration. Figure 11 shows the reaction rate of different surface formaldehyde concentrations under different reaction temperatures.

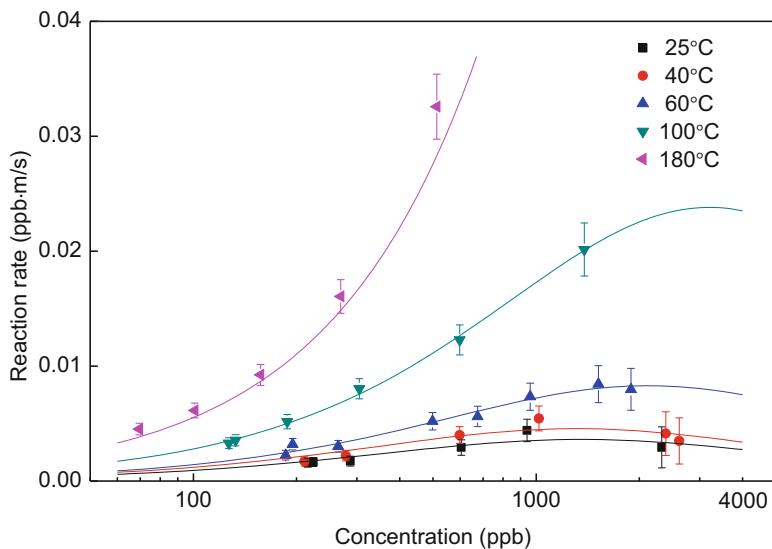

Fig. 11 The reaction rate at different surface formaldehyde concentrations under temperatures of 25 °C, 40 °C, 60 °C, 100 °C, and 180 °C. GHSV $4.43 \times 10^6 \text{ h}^{-1}$; O₂ 20 vol%, N₂ balance; water vapor concentration 7500 ppm. Points: experimental data; solid lines: nonlinear regression by bimolecular L-H model (Xu et al. 2011)

The reaction rate increased with increasing temperature and increasing concentration (below ppm levels). As the formaldehyde concentration kept increasing, the reaction rate peaked and began to decrease. The concentration at the turning point was higher at higher temperatures. The influence of oxygen concentration on the reaction rate was not very significant (Fig. 12). The decrease of oxygen concentration by a factor of 10 changes the reaction rate by less than 40%.

Kinetic Reaction Model

The kinetic reaction model is important for designing and developing TCO air cleaners for removing indoor formaldehyde. A recent study on Au/Co₃O₄–CeO₂ catalyst supposed a reaction route of formaldehyde oxidation (Ma et al. 2011), where HCOOH was found to be an intermediate on the catalyst surface during oxidation formaldehyde into CO₂. According to the results in section “Formaldehyde Removal by TCO,” no gaseous HCOOH yields (m/z 47) were detected. It indicated that the rate of HCOOH further oxidizing into CO₂ is higher than that of its generation. It may be due to the low product generation rate caused by low inlet concentration. And the effect of product desorption rate also can be ignored.

Several kinetic models (Yang et al. 2007; Chuang et al. 1994; Zhang et al. 2003; Obree 1996; Zhou and Akgerman 1995) (see Table 4 for the details) were assumed for the reaction. The experimental data were fit into those models to regress the kinetic

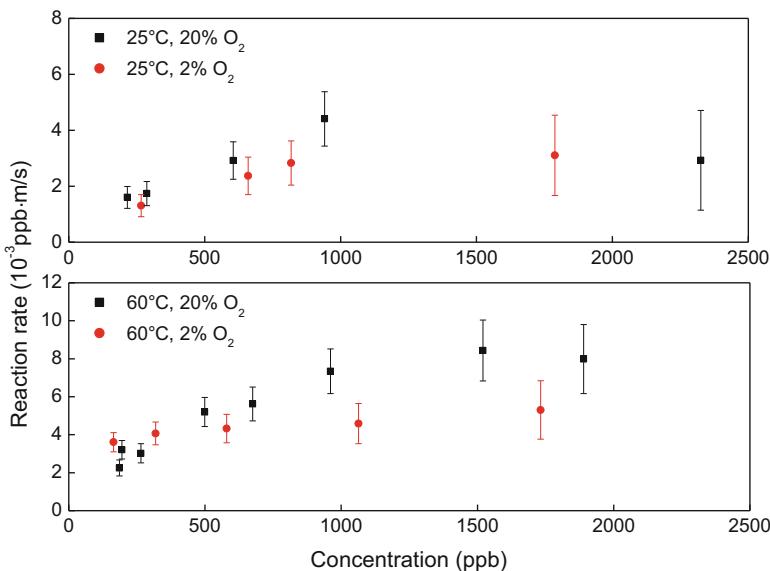

Fig. 12 The reaction rate of different surface formaldehyde concentrations under O₂ 20 vol% and O₂ 2 vol%; N₂ balance; GHSV 4.43×10^6 h⁻¹; and water vapor concentration 7500 ppm (Xu et al. 2011)

constants at each reaction temperature. The fitting results are also shown in Table 4. These results show that the model with bimolecular L-H kinetics, based on the competitive adsorption mechanism, provided the best fit to the data (with the highest R^2 value). The fitting parameters for bimolecular L-H kinetics are shown in Table 5.

The bimolecular L-H kinetics implies that two reactants in the rate-determining step compete with one another for adsorption sites. According to the reaction mechanism, the reactants were probably formaldehyde and oxygen (both in adsorbed phase). Tang et al. (2008) has reported the importance of the surface active oxygen in the reaction. In addition, from the experimental result (Fig. 12), there was little impact of gaseous oxygen concentration on the overall reaction rate. It indicated the surface active oxygen in the rate-determining step was not directly from the air oxygen, but from the metal oxide. CeO₂ is reported as a good oxygen storage material, which may help to store and provide the surface active oxygen (Campbell and Peden 2005). Under conditions of high formaldehyde concentration, adsorbed formaldehyde prevented surface active oxygen from transferring to the adsorption sites, so that the reaction rate decreased. At indoor formaldehyde concentrations (usually lower than 500 ppb), the effect of competitive adsorption appears to be negligible (Fig. 11), and the model also can be reduced to a unimolecular L-H model by neglecting the square term of concentration in the denominator.

Temperature impact. The Arrhenius equation can describe the temperature dependence of a specific reaction coefficient and adsorption coefficient

$$\ln k = \ln A - E/RT \quad (42)$$

where A was frequency factors for the specific reaction coefficient, the same unit as k ; E the activation energy, J mol⁻¹; T the absolute temperature, K; and R the universal gas constant, J mol⁻¹ K⁻¹. By applying the Arrhenius equation to correlate the reaction coefficient and adsorption coefficient at different temperatures, the bimolecular L-H kinetics were expressed as:

$$r = \frac{k_0 \exp\left(\frac{-E_1}{RT}\right) K_0 \exp\left(\frac{-E_2}{RT}\right) C_s}{(1 + K_0 \exp\left(\frac{-E_2}{RT}\right) C_s)^2} \quad (43)$$

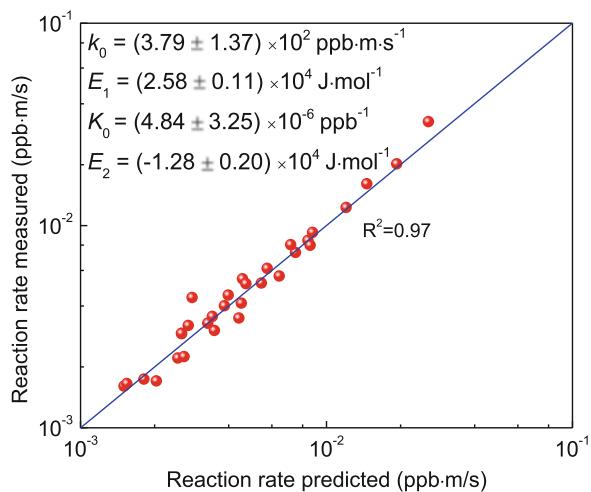

where k_0 and K_0 were frequency factors for the reaction coefficient and the adsorption coefficient, ppb m s⁻¹ and ppb⁻¹, respectively, E_1 the activation energy of the reaction, J mol⁻¹; and E_2 the activation energy of adsorption, J mol⁻¹. The activation energy is the minimum energy required to overcome the potential barrier to start the reaction. In a thermal catalytic oxidation reaction, the energy of the reactant molecule is expressed as the reaction temperature. The activation energy reflects the influence of temperature on the reaction rate. When the activation energy is higher, the influence of temperature is larger.

The parameter values and the fitting results are shown in Fig. 13. The coefficient of determination R^2 is 0.97, which indicates the model fits well with the experimental data. The apparent activation energy of oxidation was estimated as 25.8 kJ mol⁻¹. It is clear that pollutant-removal efficiency and energy costs are taken into account in practical air cleaners. Through Eq. (43), the performance and energy cost of the TCO technique can be evaluated when it is used in a practical honeycomb-type reactor.

A simulated honeycomb reactor of 100,000 channels, channel size 1 × 1 mm, length 2 cm, catalyst coating thickness 10 μm, and flow rate 360 m³/h, was used in this calculation. The reactor was assumed to be thermally insulated, so the auxiliary heating energy was equal to the heating energy removed by the airflow. A heat and mass transfer correlation for honeycomb reactors (Hawthorn 1974) was applied for the calculation. The environment temperature was 20 °C, and the formaldehyde concentration was 200 ppb.

The performance of an air reactor is evaluated by its clean air delivery rate (CADR), which is defined as the volume of fresh air generated per hour (ANSI/AHAM AC-1988 1988). CADR can be expressed by the following equation:

Fig. 13 The predicted versus experimental reaction rates for the catalytic oxidation of formaldehyde (Xu et al. 2011)

$$\text{CADR} = \varepsilon G \quad (44)$$

The clean air delivery rate per power input (CADR/P) has been considered as part of the present analysis to evaluate the energy consumption of air purifiers with a certain CADR, where P is the energy consumption rate, including fan power and any auxiliary heating rate. The energy of auxiliary heating is zero when the reaction occurs at room temperature. Figure 14 shows that the CADR value of this reactor increases with the temperature almost linearly, while CADR/P decreases with temperature exponentially. So the catalyst needs much more energy input to increase the same amount of output at a higher temperature.

In a real indoor environment, when the reactor is connected to an indoor heating device (such as the heating radiation surface or system), the heating can help to increase the efficiency of the catalyst; otherwise, it needs extra heating energy to first heat the air (or heat the catalyst), then cool the air. In addition, based on the kinetic parameters from Fig. 13, such a simulated reactor has a CADR of about $118 \text{ m}^3/\text{h}$ at room temperature, which shows good performance compared with other commonly used indoor air cleaners ($1.4\text{--}40 \text{ m}^3/\text{h}$) (Chen et al. 2005). Thus, operating at room temperature without auxiliary heating is the favorable mode for the catalyst operation.

Comparison of TCO and PCO for indoor air purification. Catalytic oxidation reactors are suitable for solving chronic emission problems such as formaldehyde in indoor air since they are expected to have a longer effective life than various adsorption methods. A comparison was made between TCO and PCO for the removal of formaldehyde. Since the reaction with PCO also has bimolecular L-H kinetics, the parameters in the equation are comparable. For the conditions of temperature at 25°C , water vapor concentration of 7500 ppm, and UV intensity of $330 \mu\text{W}/\text{cm}^2$, the k and K of PCO were estimated to be 138 ppb m s^{-1} and

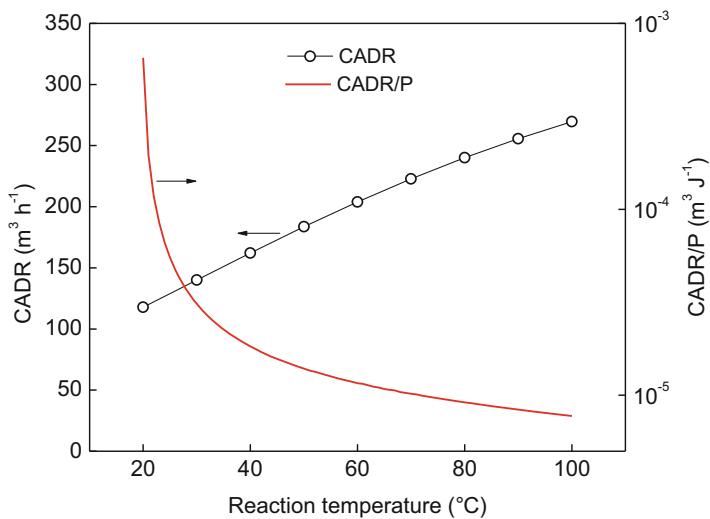

Fig. 14 The influence of temperature on clean air delivery rate (CADR) and clean air delivery rate per power input (CADR/P). Honeycomb reactor with 100,000 channels, length 2 cm, channel size $1 \times 1 \text{ mm}$, catalyst thickness $10 \mu\text{m}$, flow rate $360 \text{ m}^3/\text{h}$, formaldehyde 200 ppb, and environmental temperature 20°C (Xu et al. 2011)

$4.2 \times 10^{-4} \text{ ppb}^{-1}$, respectively (Obee 1996). The value of k represents the reaction rate per reaction area. The result indicates that k for PCO was four orders of magnitude larger than that for TCO (Table 5). However, these k s have different respective reaction areas. The reaction area of PCO is limited to its irradiated surface (about $0.1 \text{ m}^2/\text{g}$) (Mo et al. 2009a), while the reaction area of TCO is the total BET surface ($60.6 \text{ m}^2/\text{g}$). Accounting for the reaction area, by coating more catalysts to the surface within reasonable thickness limits, the reaction rate of TCO would be larger than PCO. The value of the equivalent adsorption constant K represents the adsorption ability of the catalyst. The K of TCO is about 1.8 times that of PCO, so it tends to perform better than PCO at low formaldehyde concentrations. Although the cost will be greater when using noble metals in the TCO catalyst, it can be made acceptable by distributing the catalyst more efficiently in the reactors. The good performance shown by the honeycomb reactor calculated above (Fig. 5) only needs about 100 g of the TCO catalysts (including 1 g Pt). This is not too costly and is economically feasible when compared with other on-sell air cleaners.

In real indoor environments, the influence of humidity, particles, and other VOCs on the performance of the TCO needs to be considered.

Conclusions

In summary, PCO and room-temperature TCO are promising technologies to reduce indoor VOCs. The VOC removal bottleneck of the PCO reactor can be determined by analyzing the dimensionless parameters. The lack of coordination of the reaction

structure and the UV sources makes it difficult to design a high-efficiency PCO reactor. Another challenging point for PCO is the various and unwanted by-products. The room-temperature TCO can only decompose formaldehyde but not other compounds, which limits its application indoors. It may be the trend to combine PCO, TCO, and adsorption to solve the indoor VOC problem.

Abstract

Indoor air quality (IAQ) is vital to human health, comfort, performance, and wellbeing as people typically spend over 80% of their time indoors. The indoor pollutants people are exposed to originate from both indoors and outdoors. In order to devise an energy-efficient and cost-effective approach to improve IAQ, it is necessary to consider strategies across multiple scales—from the outdoor environment around buildings to inside buildings, to rooms, and to the microenvironment around the occupants that directly affect the human exposure and intake of the pollutants. In this chapter, we present a 3-dimensional view of the IAQ engineering: the scales (of environments), the species (of pollutants), and strategies (of IAQ control). The objective is to improve the understanding of and assess the potential and limits of the various source control, ventilation, and air purification strategies across the different scales so that an integrated approach can be developed for managing IAQ. Existing data from previous research on the effectiveness of various IAQ strategies at the different environmental scales are discussed along with an outlook to the future work and challenges.

Introduction

Motivation and Challenge

Good indoor air quality (IAQ) is vital to human health, comfort, performance and wellbeing for several reasons: (1) people spent vast majority of their time indoors (as high as 80–90%); (2) people's exposure to air pollutants in their lifetime takes place primarily indoors, and this is not only the case for pollutants of indoor origin, but also for some pollutants of outdoor origin; (3) air pollutants found indoors can be odorous, cause irritations to skins, eyes and membranes, respiratory diseases, cardiovascular diseases, and cancer; (4) poor IAQ has been associated with increased sick leaves, significant productivity loss as well as sick building syndrome and building related illnesses; and (5) good IAQ provides a solid foundation for reducing the risk of infectious diseases such as COVID-19 since most IAQ control strategies are also effective for reducing the dose exposure of building occupants to the virus-containing aerosols (Zhang 2020; Shen et al. 2021). Since buildings account for about 40% of the total energy consumed, it is also vitally important to devise energy-efficient and cost-effective IAQ strategies to save energy and minimize the

associated carbon emissions in an effort to combat the global climate change. Providing good IAQ while saving energy and reducing carbon emissions remains a significant challenge.

Multi-scale Nature of the Built Environmental System

A built environmental system involves multiple scales in space and time (Fig. 1). Spatially, it ranges from the microenvironment around an occupant, to a cubical, a room, a floor, a whole building, and the building's surrounding airshed. Temporally, its state variables such as temperature, relative humidity and pollutant concentrations vary with time scales ranging from seconds to hours, days, months, seasons, and years depending on the perturbing events and the response times of the environmental scale. Different management and control strategies can be applied at different scales to improve the indoor environmental quality (IEQ including IAQ, thermal comfort, acoustic, lighting and visual quality), energy efficiency, and safety and security of the occupants. As we refine the management and control from a larger scale to a smaller and smaller scale with an occupant-centered approach, it is possible to significantly improve the satisfaction of building occupants from the acceptable level (80%) to near 100% satisfaction level. In this chapter, we focus on strategies for improving IAQ, which alone is affected by a multitude of factors including the media/materials where pollutants reside, the

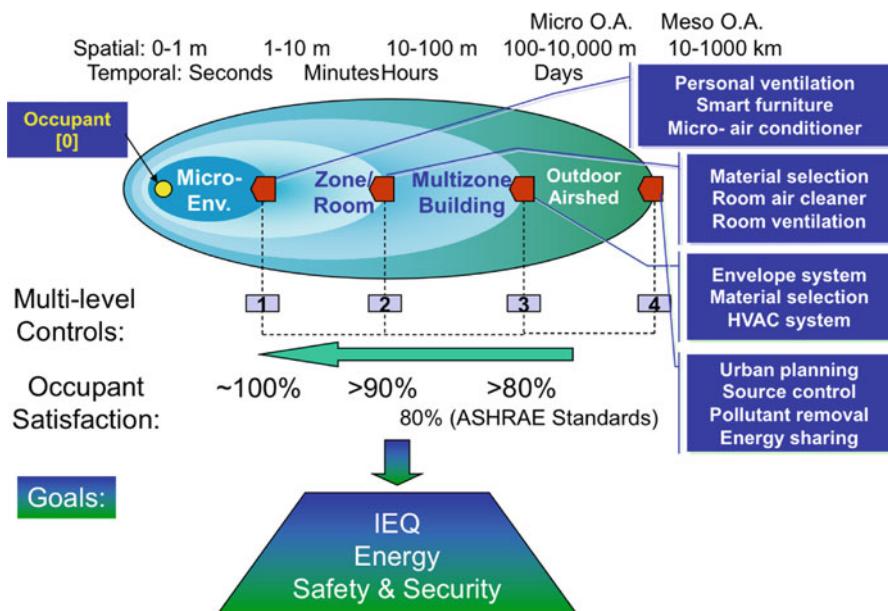

Fig. 1 Managing IEQ and energy of a built environmental system across multiple scales (Zhang 2005)

environmental conditions, and the species of pollutants—i.e., the media, environment, and species (MES) in short.

Multitudes of Pollutants Indoors and Their Sources

IAQ is a complex problem largely because it involves many types of pollutants (Fig. 2): (1) inorganic compounds (e.g., CO, CO₂, SO₂, NO_x, and O₃); (2) organic compounds including volatile organic compounds (i.e., VOCs such as formaldehyde, acetaldehyde, benzene, toluene, styrene, 1,4-dichlorobenzene, and 4-phenyl cyclohexene or 4-PC) and semi-volatile organic compounds (i.e., SVOCs such as di-n-butyl phthalate or DnBP, butyl benzyl phthalate or BBP, and di(2-ethylhexyl), Phthalate or DEHP); (3) radioactive gases (e.g., radon); (4) particulate matters (PM10, PM2.5, and ultrafine particles); (5) bioaerosols derived from virus, bacteria, fungi, protozoa, dust mites, and pollen; and (6) Ozone-initiated oxidation products (e.g., methacrolein, methyl vinyl ketone, nitrogen dioxide, acetone, 6-MHO, geranyl acetone, 4-OPA, formaldehyde, nonanal, decanal, 9-oxo-nonanoic acid, azelaic acid, and nonanoic acid). Some indoor pollutants mainly come from indoors (e.g., CO₂, VOCs and SVOCs emitted from building materials and furnishings); some mainly from outdoors (e.g., SO₂ and NO_x); some from both indoors and outdoors (e.g., PM2.5 from outdoor air pollution and indoor emission from occupant activities, and O₃ from outdoor air pollution or due to indoor emissions from printers, copiers and some ionization-based electronic air purifiers); and some from the interaction between the pollutant from the outdoor air and the indoor air and indoor surfaces (e.g., O₃-initiated chemical reaction products). As a result, different source control and removal strategies or technologies are needed for effective reduction of different target pollutants. The effects of the co-existence of multiple pollutants on the

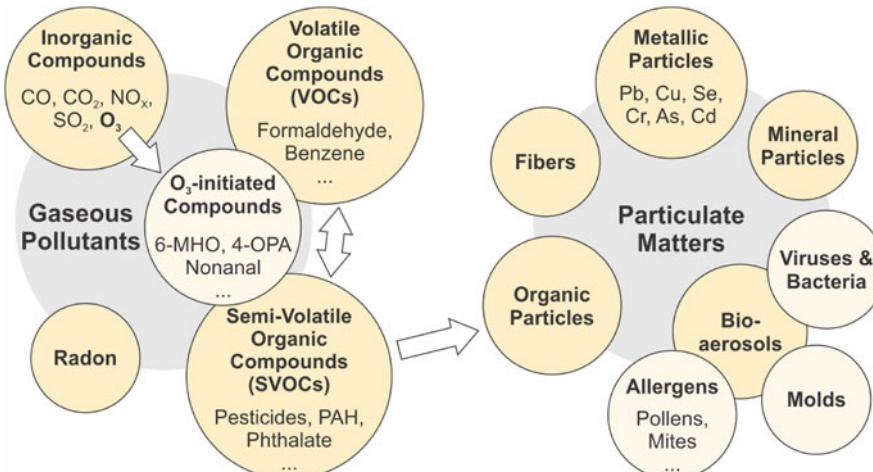

Fig. 2 Classification of indoor pollutants. (Adapted from Abadie and Wargocki 2017)

effectiveness and efficacy of IAQ strategies or technologies should be considered. For example, a particular air purification technology may have very different pollutant removal efficiencies for different gaseous pollutants. Dilution by ventilation is non-discriminative to different gaseous pollutants.

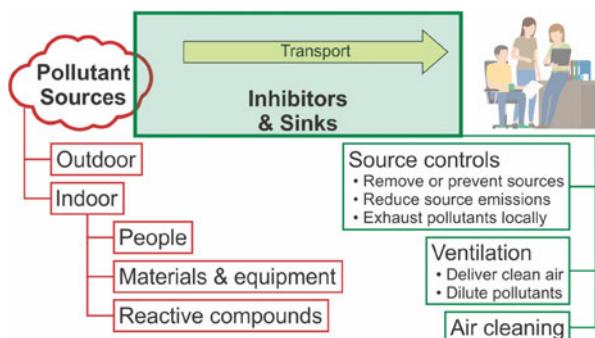

IAQ Control Principles and Strategies

Air pollution takes place when the pollutants emitted from sources transport to the space where occupants reside. IAQ control means providing inhibitors or sinks to reduce the exposure. This can be achieved by various source control, ventilation, or air purification strategies (Fig. 3). Source control is often the most effective approach and should always be considered first. Ventilation is a non-discriminative approach applicable for diluting all types of pollutants in the space. It however has an energy implication as more outdoor air needs to be conditioned to maintain the desired thermal condition in the space. In order to reduce the energy consumption while meeting the IAQ requirements, air purification can be used to remove specific compounds of interests (target compounds) so that the ventilation rate for pollutant dilution can be reduced. In addition, moisture and temperature control and management is also vital for IAQ control, especially for reducing the bio-contamination. For example, the formation and growth of mold heavily relies on prolonged access to favorable moisture and temperature conditions (WHO 2009).

A 3-D View of IAQ Engineering

IAQ engineering can be viewed as a dynamic “3-D” process in which the various management and control *strategies* are applied over *time* to the different *spaces* of different scales to reduce the occupant’s exposure to various pollutant *species* of health concern (Fig. 4). In this chapter, we focus the discussion on source control, ventilation, and air purification strategies. Hygrothermal control requires the understanding of the water vapor sorption/desorption and moisture retention

Fig. 3 Air pollution process and control strategies

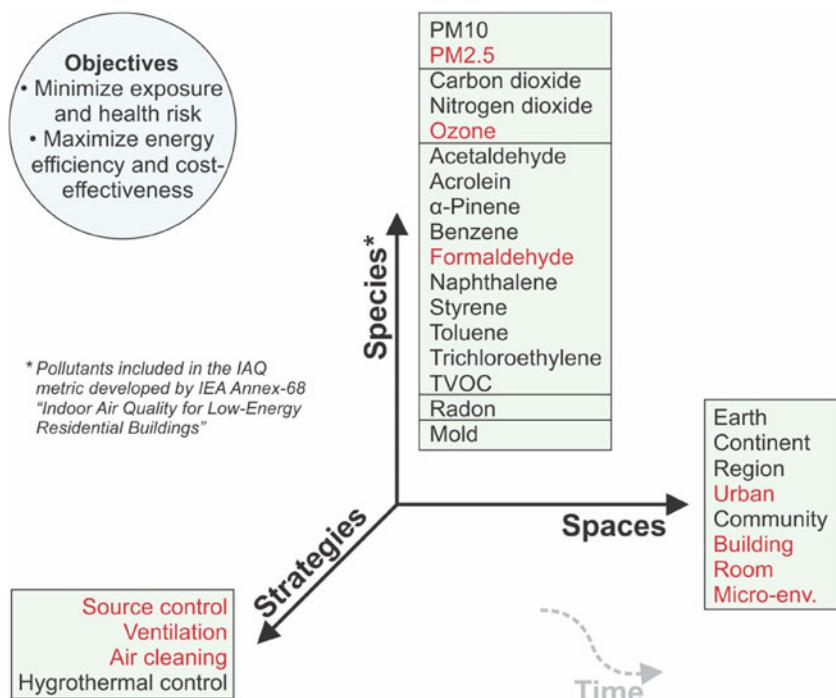

Fig. 4 “3-D” view of indoor air quality engineering

characteristics of various building and indoor materials as well as mechanical systems for humidification and dehumidification, which deserves a dedicated chapter. In the remaining discussion, we make the assumption that space air is maintained within the thermal comfort zone as defined by the ASHRAE standard 55, and the applications of the other three strategies are discussed under such hygrothermal condition unless explicitly stated otherwise. The discussion on the spaces is limited to the microenvironment around the occupant, room, building, community and urban scales with the understanding that the regional, continental and global/earth scales have significant impact on the boundary conditions of urban, community, and building environment (e.g., regional wildfires directly impact the air quality in nearby urban, community and building environment). For the pollutant species, we limit the discussion to a few representative compounds including formaldehyde (a carcinogen and a typical VOC found indoors with a low allowable concentration), PM2.5, and O₃ and SARS CoV-2 as examples to illustrate the 3-D IAQ engineering process. The goal is to understand and quantify the potential and limit of various IAQ control strategies across the different scales of the built environmental system (BES), and discuss how they can be integrated to improve IAQ while saving energy and reducing carbon emissions.

Approach and Model for Assessing the Effectiveness of IAQ Control Strategies

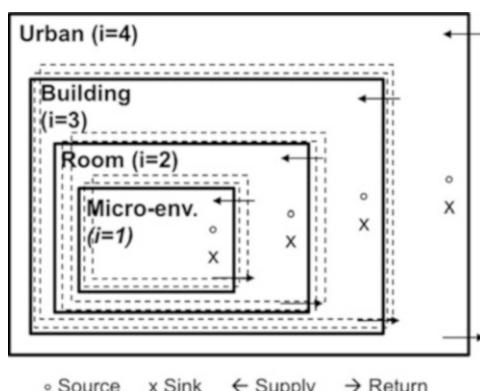

Overview

For the purpose of assessing the effectiveness of various IAQ control strategies, we first consider a simplified multi-scale IAQ model that can account for the interactions between different scale levels as well as between the zones within the same scale level. The model is then further simplified to focus on the effects of IAQ strategies at the different scales on the air quality in the breathing zone of occupants (i.e., in the microenvironment). Pollutant concentrations at a higher scale level are considered as the boundary condition (input) to the immediate lower scale level. A baseline IAQ condition is established based on ASHRAE standard 62.1 and 62.2 considering typical range of building operating conditions for heating, ventilating, and air conditioning of specific building types. Various IAQ strategies and their combinations are then evaluated relative to the baseline conditions. A similar approach has been developed and applied for estimating the effectiveness of various mitigation strategies for reducing the risk of COVID-19 infection in different types of buildings (Shen et al. 2021).

A Simplified Multi-scale IAQ Model

Consider a multiscale built environment system with four nested scales: microenvironment, room, building, and urban air surrounding the building (Fig. 5). Each scale level provides supply air to the level below and returns air to the level above. Each scale level can contain multiple zones, with each having its own sources and sinks. A zone receives a fraction of the total supply air from the upper scale level and returns air to the upper scale level as well as exchanges air with zones in the same scale level (represented by dashed blocks). As a simplified model, we assume that:

Fig. 5 A simplified model of multiscale pollutant transport in built environmental system (dashed lines indicate multiple zones in the same scale)

1. Air within each zone is perfectly mixed.
2. Exchange between the scale levels take place in an aggregated way. That is, a scale level receives the total airflow rate ($m'_{i+1 \leftrightarrow i, sa}$) from the upper level and distributes them to the zones with the scale according to the fractions required by each zone. The return/exhaust air from each zone is mixed and return to the upper scale level with a total airflow rate and an equivalent concentration of the mixed air ($m'_{i \leftrightarrow i+1, ra}$).
3. The total airflow rate supplied to and returned from a lower scale level is balanced at all times (i.e., $m'_{i+1 \leftrightarrow i, sa} = m'_{i \leftrightarrow i+1, ra} = m'_{i+1 \leftrightarrow i, a}$).

Under the above assumptions, the mass conservation of pollutant species k in zone j of scale level i can be represented by

$$\begin{aligned} \frac{\partial}{\partial t} (M_{i,j,a} C_{i,j,k}) &= R'_{i,j,k} - S'_{i,j,k} + \sum_{l(l \neq j)}^{n_i} \left[m'_{l \rightarrow j,k} C_{i,l,k} - m'_{j \rightarrow l,k} C_{i,j,k} \right] \\ &\quad + f_{i+1 \rightarrow i,j} m'_{i+1 \leftrightarrow i,a} (C_{i+1,sa,k} - C_{i,j,k}) \\ &\quad - m'_{i \leftrightarrow i-1,a} (C_{i,sa,k} - C_{i-1,ra,k}) \end{aligned} \quad (1)$$

where,

$C_{i,j,k}$ = mass concentration, kg/(kg of air)

$f_{i+1 \rightarrow i,j}$ = fraction of mass flow rate that zone j receives from the adjacent upper scale level

$M_{i,j,a}$ = air mass in zone j of scale level i

m' = mass flow rate of air mixture, kg/s

n_i = number of zones at the scale level i

R' = source's emission rate, kg/s

S' = sink's removal rate, kg/s

Subscripts: i = scale level ($i = 1, 2, 3, 4$), j = zone number ($j = 1, 2, \dots, n_i$),

k = species, sa = supply air, ra = return air.

Equation (1) states that the rate of mass change for a pollutant k in zone j of scale level i is balanced by the source and sink rates in the zone, the exchange rate between zones within the same scale level, and the exchange with the upper and lower scale levels.

The source rate is the summation of emissions of pollutant k from all sources in the zone (e.g., formaldehyde emissions from building materials, indoor furniture, and office equipment and releases from O₃-initiated oxidation processes). The sink rate is the summation of the rates of removal of pollutant k from the air by all processes taking place in the zone (e.g., adsorption/deposition on surfaces, removal by air cleaners and chemical reactions). The supply air flow rate along with its pollutant concentration represents the input from the upper scale level. For a building space, it includes the outdoor ventilation rate and the infiltration rate.

The return air flow rate and its pollutant concentration represent the aggregated impact of the current scale level on the upper scale level. The microenvironment inside a room is affected by the source and sink strengths and distributions, room and local air distributions, and space partitioning. For a given space configuration, the combined effect can be represented by the *relative room ventilation effectiveness* defined as

$$\eta_v = \frac{C - C_s}{C_\mu - C_s} \quad (2)$$

where C , C_s and C_μ represent the concentrations in the room under perfect mixing condition, room supply air and the air in the microenvironment, respectively. For a perfectly mixed room air, $C_\mu = C$, so that $E_v = 1$. For displacement and personal ventilation, $C_\mu < C$, so that $E_v > 1$. Note that definition of the E_v is different from the conventional definition of ventilation efficiency or contaminant removal effectiveness where C is replaced by the C_e , the concentration in the room exhaust air. The pollutant concentration in the microenvironment in a room space can then be determined by first solving the mass conservation for a room zone using Eq. (1) to obtain C under the perfect mixing condition, and then be estimated with Eq. (2).

Considering a single zone/room space with outdoor ventilation rate of Q_o , recirculation flow rate of Q_r , pollutant filtration efficiency in the recirculated airflow $\varepsilon_{\text{filter}}$, outdoor pollutant concentration C_o , pollutant penetration factor P , space volume V , net indoor pollutant emission rate R , and first-order deposition/removal rate constant of the pollutant k_d , Eq. (1) can be simplified to Eq. (3) for calculating the indoor pollutant concentration C :

$$\frac{dC}{dt} = \frac{PQ_o}{V}C_o - \frac{Q_o}{V}C - \varepsilon_{\text{filter}} \frac{Q_r}{V}C + \sum \frac{R}{V} + \sum k_dC \quad (3)$$

Definition of Baseline Cases

The specification in the prescriptive procedure for acceptable IAQ in the ASHRAE standard 62.1 and 62.2 can be used to define the baseline ventilation conditions for commercial and residential buildings. The baseline ventilation conditions for several space types of commercial buildings are presented in Table 1 (Shen et al. 2021).

The pollution loads for a baseline case should be specified based on the material/product emission test data, the quantity of materials/products used and occupant activities in the space type of interest. When such data are not available, the emission loads can be specified as the product of the maximum allowable concentrations of target compounds and the specified ventilation rate in the baseline case. The second approach is used here because it can be more universally applied in comparing different studies. The maximum allowable concentrations are defined as the chronic Exposure Limit Values (ELVs) of the reference compounds for quantifying IAQ (Table 2) (Abadie and Wargocki 2017).

Table 1 Configurations of baseline cases. (Adapted from Shen et al. 2021)

Scenario		Space layout		Occupant status		Minimum ventilation requirement (per ASHRAE 62.1)

Assessment Procedure

Once the ventilation and pollution load for a baseline case are defined, the simplified multi-scale IAQ model can be used to first calculate the concentrations of the target compounds under the baseline conditions, and then determine the potential and limits of individual and combined strategies in improving the IAQ relative to the baseline case.

Potentials and Limits of Source Control, Ventilation and Air Purification at Different Scales

Urban Scale

The major atmospheric pollutants include particulate matter (PM), ozone (O_3), carbon monoxide (CO), nitrogen oxides (NO_x), sulfur dioxide (SO_2), and volatile organic compounds (VOCs), which can originate from industry emissions, vehicle exhausts, chemical products, construction dusts, household stove combustions, and the reactions between these compounds and the compounds on material surfaces. Considering the heavy traffic and construction activities in urban areas that generate more pollutant emissions, as well as the high density of buildings that can enhance the accumulation of pollutants in urban areas, the air quality in urban areas, particularly densely populated areas, is likely worse than other areas in the city. Urban air quality can impact the health of people who are directly exposed to the ambient air. Outdoor pollutants may also enter the indoor environments through ventilation or

infiltration and affect the indoor air quality. Therefore, managing the air quality on the urban scale can benefit both outdoor and indoor environments and people's health.

Source control One approach to control the urban air quality is to control the emission sources of the concerned pollutants (Fig. 6). Pollutants generated by industry emission, vehicle exhaust, chemical products, construction dust, household stove combustion, and other potential sources should be controlled and limited. High-level air quality and pollutant emission standards/policies need to be developed and strictly implemented by the public agencies. It can promote relevant entities to upgrade their pollutant-producing facilities to reduce emissions to the atmosphere. Tremendous efforts and resources are required for mitigating emissions from various sources, but it has been proven to be effective for improving outdoor air quality. For example, the significant concentration declines in some air pollutants (e.g. SO₂, NO_x, and PM2.5) in China during the past few years is closely correlated with the implementation of the strict policies and actions on air quality, e.g. enhancing and enforcing industrial emission standards, upgrading industrial boilers, phasing out outdated industrial capacity, promoting clean fuels in the residential sector, phasing out small and polluting factories, and strengthening vehicle emission standards (Zhang et al. 2019).

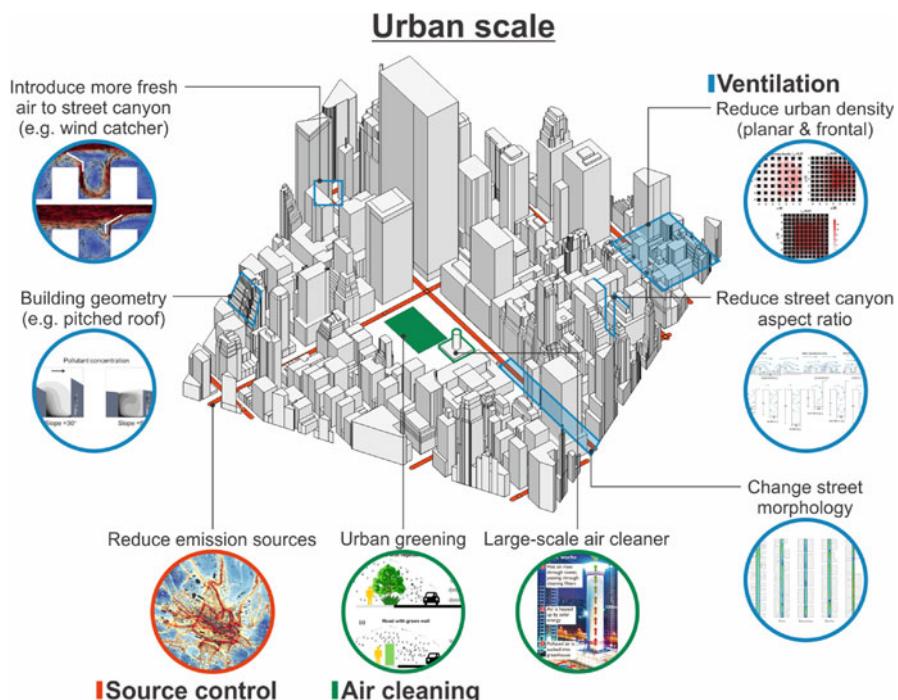

Fig. 6 Schematic of urban-scale air quality control strategies

Pollutant sources in the urban area should be managed to meet or exceed the national ambient air quality standards established by the respective government agencies. For example, in U.S. the ambient air quality standard established by the US Environmental Protection Agency (EPA) has been used as the criteria to determine if the outdoor air is sufficiently clean for ventilation or additional filtration is needed.

Ventilation Urban air quality can also be affected by urban ventilation. Wind from rural and suburban areas is usually believed to be clean and fresh for purging the pollutants emitted by vehicle exhaust and other activities in urban areas. However, the building density in urban areas impacts the urban ventilation. In-street pollutants can be accumulated within the street canyon in high-density compact urban areas due to the poor airflow patterns. Poor ventilation and unfavorable pollutant dispersion in the urban canopy result in poor air quality.

Pollutants generated in the urban canopy layer can be purged by horizontal air exchanges through street openings and vertical air exchanges through street roofs. Urban density, including planar density λ_p and frontal density λ_f (i.e., the ratios of the plan area and frontal area of buildings to the lot area, respectively) are key parameters that can significantly impact the airflow and pollutant dispersion in the urban canopy. Compact urban areas with higher planar and frontal density typically slow down the airflow velocity in the urban canopy, particularly at the pedestrian level. The mean wind velocity at the pedestrian level in urban areas can be decreased by over 35% when increasing the urban planar density from 10 to 35% (Kubota et al. 2008). The decreased wind velocity may reduce the pollutant removal and result in the accumulation of pollutants in the street canyon. It was observed that for a compact city with over 44% planar density, the city itself responds as a single obstacle, and the city breathability is greatly weakened and the pollutants tend to accumulate in the street canyon (Buccolieri et al. 2010). Increasing frontal urban density (i.e. building heights) causes pollutant accumulation in the urban canopy likely due to weaker air exchanges through the urban roof. Poor urban ventilation can be observed in urban areas with a frontal density of over 40% (Mei et al. 2017). Therefore, to improve the ventilation in the urban canopy, urban design with lower planar and frontal density is preferred. Urban heterogeneity, including planar urban non-uniformity and building height variation, can also affect the airflow pattern in the urban canopy. But its effect on urban ventilation is highly dependent on the specific urban morphology (Li et al. 2021a). The non-uniform planar building configuration may weaken the channeling flow inside the street canyon, which was supposed to purge in-street pollutants but can also decrease the vortices behind buildings, which was supposed to cause pollutant accumulation. The non-uniform building height arrangement can enhance the urban ventilation at the high-rise level of the urban canopy due to the improved vertical and horizontal air exchanges but may deteriorate the ventilation at the low-rise level because of more turbulent dissipation at the high-rise level. Thus, it requires professional designs and analyses before performing urban heterogeneity strategies to improve the urban ventilation potential.

The ventilation and pollutant dispersion in the urban canopy are determined by the airflow patterns in the street canyon, which is dependent on both direction and aspect ratio (i.e. the ratio of street height and width, H/W) of the street canyon. When the approaching airflow is parallel to the street, the airflow inside the street canyon can be accelerated due to the channelization effect, which can help to purge the pollutants and improve the street ventilation. A higher aspect ratio may reduce the pollutant removal due to less vertical air exchanges through the street roof, although stronger channeling flow can be observed. Higher street continuity and closure (reduced building setbacks and lateral openings) can lead to a stronger channeling flow, but it reduces the pollutant removal through lateral openings of the street (e.g. intersected streets) and street roofs (Ng and Chau 2014; Shen et al. 2017). When the approaching airflow is perpendicular to the street, the airflow pattern is closely related to the street aspect ratio. If the buildings are well apart ($0.05 < H/W < 0.3$), the airflow fields around buildings do not interact but act as isolated roughness flows. If buildings are too close ($H/W > 0.7$), a skimming flow pattern is formed and a stable vortex is developed within the street canyon, which is not beneficial for removing in-street pollutants (Oke 1988). More vertical vortices are developed inside the street canyon as the street aspect ratio increases, and the wind velocity near the ground becomes weaker, which further deteriorates the air exchanges and pollutant dispersion. Typically, a street canyon with an aspect ratio of 2 (i.e. $H/W = 2$) can form two vertical vortices, and three vortices are formed when the aspect ratio reaches 3 (i.e. $H/W = 3$). In many high-density compact cities, the aspect ratios of street canyons can be higher than 5, so that the ground-level airflow is mostly in calm conditions, and there are very few vertical air changes (He et al. 2019a). Therefore, street orientations are preferred to be designed parallel to the prevailing wind from the perspective of urban ventilation and pollutant dispersion. The aspect ratios of streets are suggested to be lower for improving the vertical air exchanges. The shape of buildings along the street also affects the airflow in the street canyon. For example, sloped/pitched building roofs can improve the pollutant dispersion in the street canyon compared to flat roofs (Li et al. 2021b). Building lift-up design can also improve the local air distribution. The first-floor lift-up design may result in a 34–50% reduction in the building intake fraction and daily pollutant exposure (Sha et al. 2018).

Ventilation in the street canyon can also be enhanced by introducing more wind into the street canyon using technologies such as street wind catchers (Chew et al. 2017), and pedestrian ventilation systems (Mirzaei and Haghhighat 2010). More fresh air can be introduced to the pedestrian level through wind pressure or thermal pressure gradient. But the practical effects of these potential technologies still require more studies and validations.

Air cleaning Air cleaning technologies at the urban scale aim to remove urban pollutants through sorption, deposition, or filtration. Urban greenings such as trees, shrubs, and grasslands, as well as green envelopes, play a significant role in mitigating urban pollutants (Nowak et al. 2006). The effectiveness of greenings

on air quality improvement depends on the plant species, the configuration of greening infrastructure, and the greening layouts. Trees can mitigate urban pollutants mainly through the deposition of gaseous and particulate matters onto leaf surfaces, and pollutant dispersion by the dilution with clean air. However, trees can also increase the flow resistance and reduce the airflow velocity, which likely results in local pollutant accumulation. Previous studies revealed that trees in the street canyon can result in a nearly 20–58% increase in the average concentration of in-canyon pollutants, owing to the reduced air exchanges between the air above the street roof and within the street canyon (Li et al. 2021b). However, in open areas, trees have a positive impact on air quality. Vegetation barriers with thick, dense, and tall trees can remove considerable pollutants when they are planted closer to the pollutant source and plume's maximum concentration. A reduction of over 50% was observed with a 10 m thick vegetation barrier for numerous pollutants in open roads (Abhijith et al. 2017). Parks with trees and shrubs can remove traffic pollutants at ground level by over 20% compared to the surrounding areas (Yin et al. 2011). Hedges consist of shrubs and usually grow smaller than trees, but they may have higher leaf density than trees. Hedges can also hinder airflow and air exchange, but not as significant as trees. Hedges can generally reduce pollutant concentrations and improve the air quality in both street canyons and open areas. Reduced pollutant exposure by 24–61% at the footpath areas in street canyons with hedges was observed in studies (Abhijith et al. 2017). Besides, green envelopes such as green walls and green roofs have been developed as sustainable building strategies providing benefits for urban environments, which play a significant role in mitigating pollutants in the street canyon without consuming spaces at street level. Pollution mitigation by green envelopes is dominated by deposition, as green envelopes are less likely to change the airflow within the street canyon. Green walls are generally more effective than green roofs for improving in-canyon air quality. However, their ability to remove pollutants is lesser compared to trees and vegetation barriers (Abhijith et al. 2017). In addition to possible air pollution reduction, urban greenings are also beneficial for urban heat island mitigation, potential reduction in energy consumption and noise pollution, better storm water management, urban biodiversity, and climate change mitigation (Abhijith et al. 2017).

Some other approaches for air cleaning at urban/street scale have also been proposed and implemented, e.g. large-scale air cleaning system. Traditionally, air cleaners are designed to clean the indoor air by filtering particles and gaseous pollutants. A large-scale air cleaning system is proposed to purify the urban air with a similar filtration mechanism as indoor air cleaners (Cao et al. 2015; Zhou et al. 2015). A solar-driven large-scale air cleaning system with a 60 m high solar chimney was built and tested in China (Cyranoski 2018). Experiments showed that this system reduced the PM_{2.5} concentration by 11–19% within a 10 km area around the system. However, its practical effectiveness has been questioned by many researchers, considering its limited effective area and, particularly, its high investment and maintenance costs (Cyranoski 2018).

Building Scale

Outdoor pollutants can be introduced to the indoor environment through building openings and cracks or enter through the HVAC system. Building materials (including construction and surface materials) also produce considerable pollutants, particularly VOCs. Some reactive pollutants (e.g. O₃) readily react with VOCs or building materials, which produce hazardous by-products. As people spend over 80% of their time indoors, properly managing the indoor air quality is essential for people's health, performance, and wellbeing.

Source control Building materials can be a major source of indoor pollutant emissions if not controlled properly. To control the potential sources of indoor pollutants, it is necessary to use the materials with less emissions during building design, construction, and decoration periods. Building materials such as plywood, carpet, and some painting materials can typically generate many VOCs of concern for human health and comfort (Won et al. 2003). Reactions between O₃ and these materials or the VOCs they emitted may also result in considerable oxidized by-product yields, including C1-C13 carbonyls, dicarbonyls, and hydroxycarbonyls (Shen and Gao 2018). Therefore, it is suggested to use materials with less emissions for constructing, flooring, and painting of the building (Fig. 7).

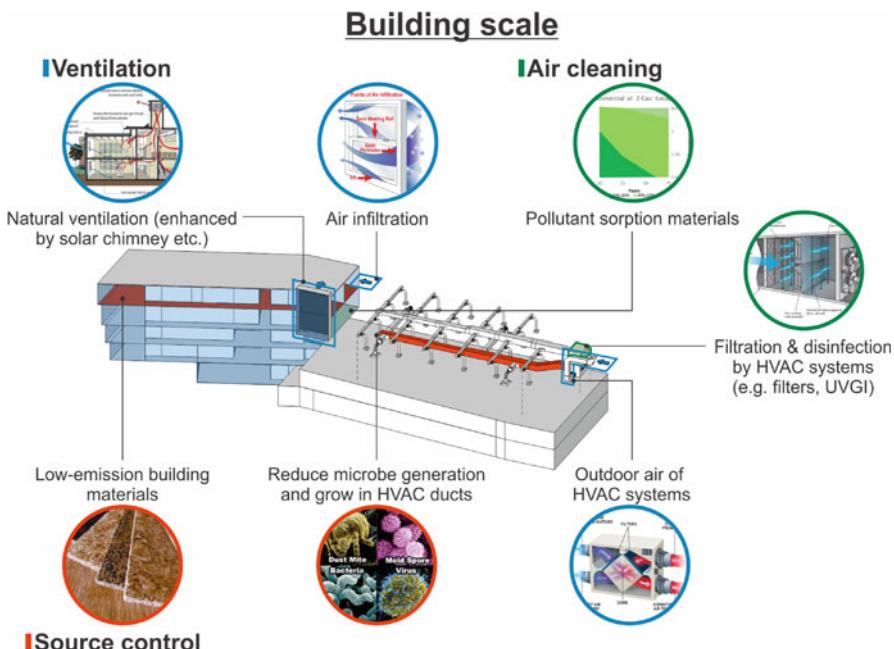

Fig. 7 Schematic of building-scale IAQ control strategies

HVAC system introduces outdoor air to ensure required ventilation of fresh air for occupants indoors. However, outdoor air may contain some pollutants that can be introduced to the indoor environment by the HVAC system. For buildings without significant indoor particle and O₃ emission sources, outdoor air is likely the primary source of indoor particle and O₃ pollution. Therefore, filters that can remove ambient pollutants (particularly the pollutants with considerable concentrations in the outdoor air, e.g. particles and O₃) are required in the HVAC system for controlling the outdoor sources of indoor pollution. Besides, due to poor control of humidity or inadequate maintenance of filters, microbes may generate and grow in the HVAC ducts or on the filters in the presence of moisture, and bioaerosols can be introduced to the indoor environment through the supply air (Batterman and Burge 1995). Elevated concentrations of VOCs such as formaldehyde and acetone may also be observed after the filters of HVAC systems, which are probably initiated from the microbes on filters (Schleibinger and Rüden 1999). Therefore, HVAC systems can also be possible sources of bioaerosols and VOCs in indoor environments. It is necessary to clean and maintain HVAC systems and their filters regularly.

Ventilation Proper ventilation can dilute indoor pollutants and improve indoor air quality. There are multiple standards or guidelines that define the minimum ventilation requirements in different buildings to keep CO₂ levels at an acceptably low level, e.g. 800 ppm or 1000 ppm (ASHRAE 2019a, b; IWBI 2019). Air infiltration through envelope cracks, natural ventilation through building openings, and mechanical ventilation by HVAC systems can contribute to the building air exchanges. Air infiltration is usually unintentional and uncontrolled and can result in heat loss and introduce outdoor pollutants and moisture condensation in building enclosures. It can be responsible for over 10% of the total annual heating and cooling energy consumption while it can even account for more than 40% of heating/cooling load in some scenarios (Han et al. 2015). Therefore, air infiltration should be minimized during construction or retrofitting. Data revealed that the average infiltration rate in buildings is generally below 0.5 h⁻¹ (Persily et al. 2010; Shi et al. 2015; Cheng and Li 2018; Ji et al. 2020). Natural ventilation provides air changes by thermal, wind, or diffusion effects through doors, windows, or other intentional openings in the building. When outdoor weather and air quality conditions allow, natural ventilation can be an effective approach to increase the indoor air changes and pollutant dilution. The effect is determined by factors like opening area, ambient wind direction and velocity, and temperature difference. It was found that more openings can result in the enhanced natural ventilation. Data showed the average air change rate in a residence to change from 0.76 h⁻¹ for no openings to 1.51 h⁻¹ for one opening, 2.30 h⁻¹ for two openings, and 2.75 h⁻¹ for three or more openings (Johnson et al. 2004). Besides, opening windows is a more effective method of increasing natural residential ventilation rates compared to the impact of continuously opening doors (Marr et al. 2012). Natural ventilation can introduce more outdoor air to the building incorporating with fans. Some passive technologies have been developed to improve the efficiency of ventilation, e.g. windcatcher and solar chimney. A windcatcher is a unit installed on the roof of the building, which

captures outdoor air through its openings and directs it toward the indoor space. It has been widely used in the Middle East to provide natural ventilation and passive cooling inside the building. A well-designed one-sided windcatcher can provide up to 4 h^{-1} ventilation of outdoor air to a dwelling while a configuration with two one-sided windcatchers can provide up to 5.6 h^{-1} ventilation (Jomehzadeh et al. 2020). A solar chimney uses solar energy to generate airflow movements that could be used for building ventilation, and it is usually attached to the south façade of the building to maximize the solar gain. A well-designed solar chimney can typically provide relatively consistent air change rates of about $2\text{--}5 \text{ h}^{-1}$ on average (He et al. 2021). But the effectiveness of windcatchers and solar chimneys is closely related to the local climate and to their designs. Their effects on building natural ventilation vary significantly case to case. However, natural ventilation also introduces ambient pollutants along with the outdoor air, which is not practical to filter or remove during the natural ventilation.

HVAC system is designed to control the indoor thermal comfort, but it also needs to introduce outdoor air to meet the ventilation requirement for occupants. Based on the ASHRAE 62.1 standard (ASHRAE 2019a), each person in a typical office with 5 persons per 100 m^2 requires approximately 8.5 L/s minimum outdoor air, which accounts for around 0.6 h^{-1} air changes. This requirement is based on the minimum accepted level of indoor CO_2 . Higher air change rates are preferred for improving the indoor air quality. The outdoor air fraction of the supply air in the HVAC system is typically 25% (Persily and Gorfain 2004). Increasing the fraction of outdoor air can elevate the ventilation rate but also require more energy for heating/cooling the outdoor air. Increasing the total supply air flow rate can provide more outdoor air but require more energy consumption as well. The extend to which the outdoor air supply can be increased is also limited by the HVAC system capacity. Considering that most HVAC systems have filters installed, the ambient pollutants in the outdoor air are probably not a significant risk for indoor air quality. If the filters in HVAC systems are not well-designed or maintained, the outdoor pollutants become a potential risk.

Air cleaning HVAC systems incorporated with in-duct air cleaning units can significantly improve the indoor air quality in the building scale. Typically, MERV 8 filter and activated carbon filter are installed in the HVAC system. A MERV 8 filter can remove approximately 50% of particles and bioaerosols $>0.3 \mu\text{m}$ in diameter. Higher MERV-rating filters can remove particles more efficiently, e.g. over 99.9% particle removal efficiency for HEPA filter, but also increase the flow resistance, resulting in higher energy consumption for delivering the same amount of air. Overall effectiveness of reducing particle concentrations depends on several factors, including filter efficiency, airflow rate through the filter, size of the particles, and location of the filter in the HVAC system. Activated carbon filters remove odors and some VOCs and can decompose O_3 readily without significant by-product yields. Other common in-duct filtration/disinfection components include UVGI lights (which is typically used for inactivating viruses, bacteria and fungi, but may also have O_3 leakage), and bipolar ionization units (which high voltage electrodes create

reactive ions in air that react with airborne contaminants, including viruses, but may emit O₃ as well) (ASHRAE 2020). Some units may intentionally generate O₃ in the duct to react with unsaturated VOCs. But the by-products become a new challenge for indoor air quality and they must be removed before recirculating the air to the room. The effectiveness of these in-duct air cleaning units may vary greatly.

Some building materials can also be considered to be air cleaning technologies due to the effects of sorption and deposition on the building surface. For example, some inorganic materials, e.g. bricks, clay-based plasters, perlite-based ceiling tiles, and activated carbon cloth, are usually considered as the most promising passive removal materials (PRMs) for indoor O₃, since they can remove substantial O₃ while yielding negligible by-products (Gall et al. 2011; Shen and Gao 2018). The use of these PRMs in the building construction/renovation may result in a lower level of O₃ and by-products, hence a better air quality, while they do not consume additional energy for ventilation or air cleaning. In addition, some sorption materials embedded in gypsum wall and ceiling boards have been developed as an effective solution on the market to reduce the formaldehyde concentration levels indoors (Pétigny et al. 2021). A formaldehyde deposition velocity of 2.08 m/h has been tested in commercial buildings and 1.02 m/h in residential settings, with a high level of formaldehyde removal (70–80% reduction in concentration) even after 50 years, which has a high potential for long-term IAQ improvement (Pétigny et al. 2021).

Room Scale

Source control The indoor pollutants in a room not only originate from the construction materials (i.e. constructing, flooring, painting materials), but also from indoor furnishing and equipment, as well as occupants and their activities. Indoor furnishing, equipment, and occupancy depend on the room function and settings. For example, an office has totally different settings of furnishing, equipment, and occupancy as compared to a residential space such as a bedroom. A typical office has multiple workstations (likely cubicles with partitions) with desktop computers, and some office devices such as printers and photocopiers. It may contain several occupants working from 9 am to 5 pm during the weekdays. A typical bedroom can have a bed, a table, and a closet with large areas covered by fabrics. Commonly, there are commonly two people sleeping during the night. Therefore, the potential indoor pollutant sources are in great differences for various spaces. Household furniture may generate considerable VOCs. Workstations or partitions in offices may also release pollutants. Some air cleaning/disinfection devices, e.g. portable UVGI lights and ionization-based air cleaners, and printing devices such as printers and photocopiers may generate abundant O₃ (Guo et al. 2019). Occupant activities like smoking and cooking generate a large number of particles and VOCs, which is hazardous for people's health. In order to control the emission sources, furnishing with less emissions are encouraged (Fig. 8). Emission devices should be used less frequently, in separated rooms or when nobody occupying the room. Smoking should be prohibited in indoor environment, especially when other people are

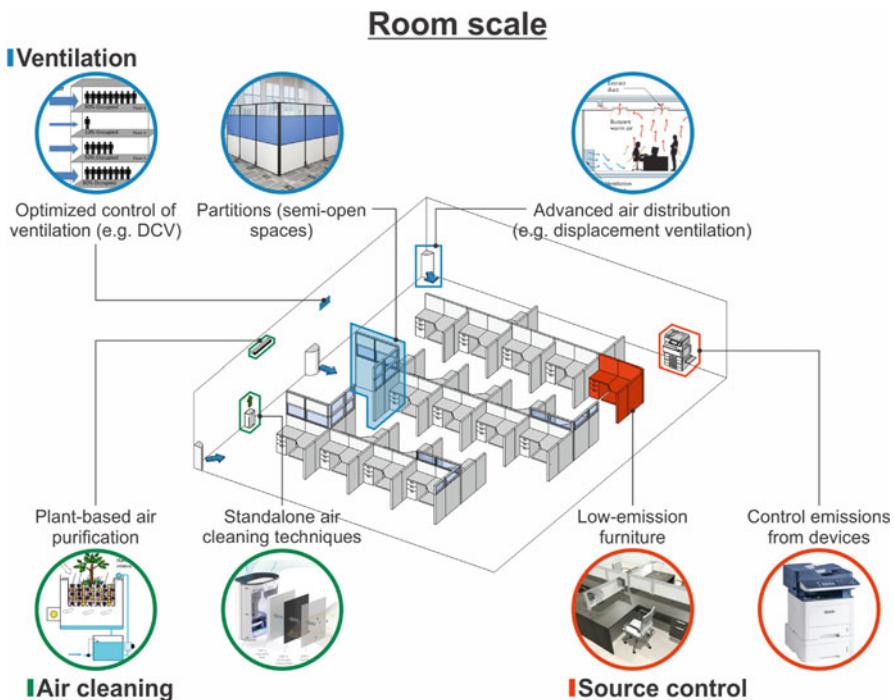

Fig. 8 Schematic of room-scale IAQ control strategies

sharing the same room. Cooking exhaust should be removed immediately and an efficient hood should be used.

Ventilation The design of diffuser and exhaust of the HVAC system can have an impact on the air distribution in the room. The air distribution affects the efficiency of ventilation and pollutant dilution in the room and people's exposure to pollutants. Typical HVAC systems provide mixing ventilation for the room, which is designed to supply sufficient conditioned fresh air to the whole space. The air circulation due to supply and return air can help to mix and dilute the pollutants. It ideally distributes the pollutants from emission sources to the room air uniformly, although the room air may not be perfectly mixed in real conditions. Ideally, the room air pollutant concentration equals the pollutant level in the return air, which is not a very efficient approach for mitigating pollutants and has the possibility of increasing the local pollutant concentration in some areas in the room and resulting in cross contamination. In terms of the control of airborne transmission for respiratory diseases, the mixing ventilation can cause cross contamination between the patients and other healthy people and increase the infection risk for susceptible people in the room.

Therefore, improved air distribution strategies are suggested for improving the ventilation efficiency. Displacement ventilation is a room air distribution strategy where conditioned air is supplied at a low velocity from air supply diffusers located

near floor level and extracted above the occupied zone, usually at ceiling height (Chen and Glicksman 2003). Displacement ventilation is typically used for cooling. The near-floor clean air is delivered to the breathing zone by the thermal plume around the human body, which ideally would not result in pollutant mixing in the room and reduce the risk of cross contamination. It can improve the clean air delivery efficiency with a typical ventilation effectiveness of 1.2–2 compared to the well-mixing ventilation (Chen and Glicksman 2003). But displacement ventilation requires professional design and implementation to maximize its performance. Underfloor air distribution (UFAD) system is also widely used in many commercial buildings like offices. Air can be delivered through a variety of supply outlets located at floor level (most common), or as part of the furniture and partitions. It usually exhibits better performance in removing indoor pollutants compared to conventional overhead (ceiling-based) systems. A well-designed UFAD system can provide as much IAQ efficiency improvement as a displacement ventilation system (Cermak and Melikov 2016). However, both displacement ventilation system and UFAD system are often claimed to bring contaminants at floor level to the breathing zone, resulting in an equivalent removal efficiency for floor pollutants as a mixing ventilation system (Cermak and Melikov 2016). For example, resuspended particles at the floor level can cause problems in an UFAD system (Zhang and Chen 2006). But both of them are highly effective in removing exhaled pollutants and reducing cross-contamination (Cermak and Melikov 2016).

The room air distribution can also be affected by the furnishing and partitions in the room, which may block the air flow. Partition screens have been widely used during the COVID-19 pandemic since they can ideally reduce the transmission of droplets. In terms of the transmission of airborne pollutants (including viruses), well-designed partitions can reduce the risk of cross contamination while poor designs may increase the risk in some locations (Rooney et al. 2021). Cubical workstations in open office plan settings are a common scenario with many partitions. The partitions can typically reduce cross contamination between cubicles with a typical ventilation effectiveness of 1.1–3.6 (require well-designed ventilation and air distribution) (Haghigat et al. 1996). When partitions are incorporated with other strategies such as displacement ventilation, the ventilation efficiency can be even higher (Halvoňová and Melikov 2010). But all these strategies require professional design of partition layouts in coordination with room air distribution and proper operation control to maximize their effectiveness. Poor design can lead to a worse performance than the conventional mixing ventilation.

The advanced/intelligent control of ventilation system also has the potential in improving IAQ and energy efficiency. Demand control ventilation (DCV) system estimates the occupant number in the room based on CO₂ detection or occupant detection, and then signals the system controller to change the ventilation volume, which is mainly designed for reducing energy consumed by heating/cooling outdoor air when less people occupying the room. But it also works for providing sufficient/required clean air to all occupants in the room when more people enter the room (within the system capacity). Some advanced control algorithms have been developed to optimize the effectiveness of DCV system, including PID control, model predictive control (MPC), or data-driven control. As an example, the application of

machine-learning-based CO₂ concentration prediction in DCV can reduce the HVAC energy consumption by 51.4% and provide ventilation as needed (Taheri and Razban 2021). The optimization of ventilation system control has been proved to have a high potential for IAQ improvement and energy efficiency.

Air cleaning Standalone air cleaning technologies can usually work efficiently for indoor pollutant removal. They have been widely used in indoor environments, which can typically improve IAQ through catalytic oxidation, filtration, ozone oxidation, plasma, sorption, or UVGI. Most catalytic oxidation air cleaning studies focus on UV or visible light photocatalytic oxidation (PCO). UVPCO technology has the potential to degrade organic contaminants efficiently with low airflow resistance (Chen et al. 2005). But it is not yet ready to be applied in practice due to potential byproduct formation and short service life. Other PCO technologies currently have low efficiency in pollutant removal (Zhang et al. 2011). Filtration is the most used technology in air cleaners. Particles can be filtered readily using high-efficiency filters such as HEPA filters (over 99.9% removal efficiency). Other filters such as activated carbon filter can remove some VOCs and O₃. In general, mechanical filters can efficiently remove particles, but are not as effective for organic and inorganic chemical pollutants. The main problem with mechanical filters is that they act as a pollution source if they are not properly used (Zhang et al. 2011). Therefore, filters are usually recommended to be replaced every 6–12 months. Ozone is an oxidant that can react with some indoor pollutants, and therefore, has been used in some air cleaners for oxidizing some organic chemical pollutants and disinfection. However, considering that ozone and ozone-initiated by-products are quite harmful for people, caution should be taken when using ozone-emitting air cleaning techniques. Plasma air cleaners have been reported to remove particles at high efficiency, e.g., within the range of 76–99% (Zhang et al. 2011). But it is not efficient at removing gas-phase pollutants. The production of secondary pollutants such as NO_x and O₃ is a major drawback of plasma technology. Sorption is good for gas pollutant removal (such as VOCs and O₃), while its efficiency depends on sorption mechanism, specific sorbent surface area, porosity, and diffusion characteristics of target pollutants. UVGI technique in standalone air cleaners is typically used for disinfection (e.g. inactivating viruses, bacteria, and fungi). Upper-room UVGI system has been developed to kill airborne pathogens, which refers to a disinfection zone located above people (the upper area of the room) preventing direct UV exposures to people. Proper use of upper-room UVGI system can typically provide an equivalent 6.7–33 ACH ventilation to the room, depending on its operating conditions and circumstance (Riley and Nardell 1989; Xu et al. 2003; U.S. CDC and NIOSH 2009). Its efficiency also relies on the room air distribution. For example, displacement ventilation may reduce the efficiency (around 78% of the efficiency incorporating with mixing ventilation (Kanaan and Abou Moughabay 2018)) as it decreases the residence time of pathogens in the disinfection zone. Some UVGI systems may produce unintended O₃, which also need certain caution.

The combined application of multiple air cleaning technologies in standalone air cleaners typically has elevated efficiency. For example, the combination of plasma

and UV-catalytic technology can provide improved removal efficiencies for formaldehyde, benzene, toluene, and xylene (Zhang et al. 2011). According to a market survey, a common room air cleaner can typically supply a median clean air delivery rate (CADR) of 361 m³/h to the room (Zhao et al. 2020). The CADR per square meter of room is roughly between 6 and 16 m³/h (Liu et al. 2017). The Association of Home Appliance Manufacturers (AHAM) recommended a minimum CADR of 12 m³/h per square meter when selecting an air cleaner for home use (AHAM 2021), which is in accordance with the U.S. EPA's guide (U.S. EPA 2018).

Potted plants have demonstrated abilities to remove VOCs indoors. However, the efficiency may not be very significant in real scenarios. The distribution of single-plant CADR spanned orders of magnitude, with a median of 0.023 m³/h, necessitating the placement of 10–1000 plants/m² of a building's floor space for the combined VOC-removing ability by potted plants to achieve the same removal rate that outdoor-to-indoor air exchange already provides in typical buildings (~1 ACH) (Cummings and Waring 2019). It is impractical to directly use potted plants for improving IAQ. One solution might be to integrate plants and mechanical air cleaning or ventilation system. Dynamic botanical air filtration (DBAF) system is therefore developed. It consists of an activated-carbon/hydroculture-based root bed for potted-plant, a fan for driving air through the root bed for purification, and an irrigation system for maintaining proper moisture content in the root bed. A well-designed DBAF system is effective for removing formaldehyde and toluene over a long period, and has the ability to supply an equivalent CADR of 476 m³/h (Wang and Zhang 2011).

Personal Microenvironments

Pollutant concentration and air quality in personal microenvironments, such as the space around a person or the breathing zone, are closely associated with people's exposure to air pollutants and health. A personalized environmental control system or micro-environmental control system has the potential to restore people's thermal comfort as well as provide fresh outdoor air to the people directly and hence save energy (Khalifa 2017; Kong 2017).

Source reduction Human body can produce considerable particles and VOCs through primary emission due to respiratory activities or sweating (Žitnik et al. 2016; Shen et al. 2021), or secondary emission caused by the reactions between O₃ and skin oil (Shen and Gao 2018). The average emission rate of total VOC (TVOC) from the whole-body was 742.8 µg/h, while the average TVOC emission rate from the breath samples was 41.4 µg/h (He et al. 2019b). People's movement can raise the floor dust and resuspend particles in the air. The thermal plume around the human body may introduce some pollutant-like particles from the floor level to the breathing zone and increase people's inhalation. Personalized/localized air exhaust aims to remove as much contaminants as possible directly from the occupants who produce pollutants before it can significantly mix with the bulk flow (Dygert and Dang 2010).

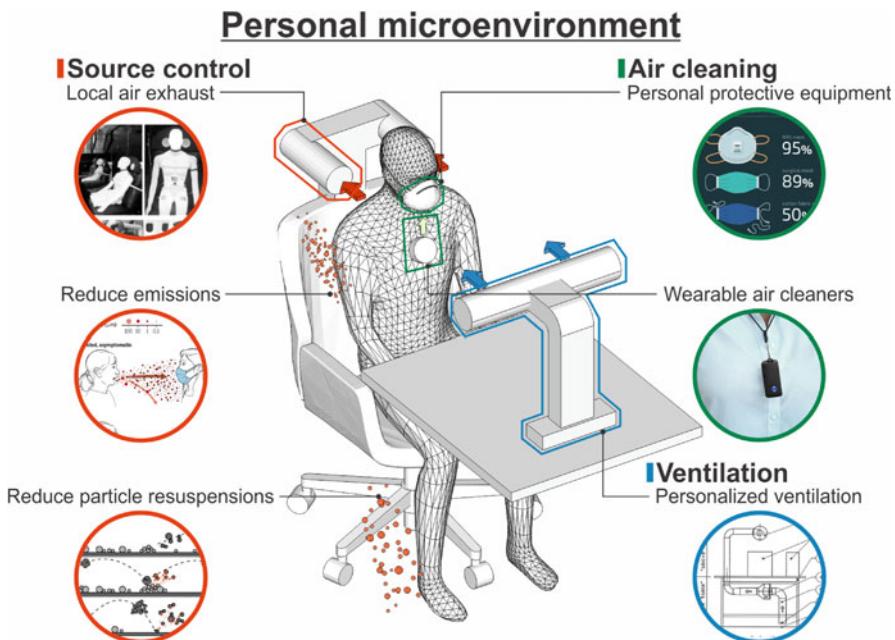

Fig. 9 Schematic of personal-scaled IAQ control strategies

The pollutant removal process is accomplished using localized suction orifices near and around the source occupant to unobtrusively ingest the individual's thermal plume and filter it or exhaust it from the occupied space. A well-designed local air exhaust system can reduce the cross-contamination with typical ventilation effectiveness of 1.4–10 (Dygert and Dang 2012). Source control can be performed in personal microenvironments by reducing the near-person emissions and chemical reactions or particle resuspension (Fig. 9).

Ventilation Personal ventilation increases clean air supply to the personal micro-environment and has the potential to improve the air quality by a typical factor of 1.7, depending on diffuser location and airflow rate (Melikov et al. 2007), which is close to the air distribution effectiveness in ASHRAE Standard 62.1 (ASHRAE 2019a). Local air exhaust ventilation is designed to remove the pollutants near the emission sources, which is usually used to reduce the exhaled pollutants by occupants and mitigate the cross contamination between occupants. It can reduce the cross contamination with a typical ventilation effectiveness of 1.4–10, depending on the local partition configuration, exhaust location and airflow rate (Dygert and Dang 2012).

Air cleaning There are some air cleaning technologies for personal microenvironment. Wearable air cleaner is a technique similar to portable room air cleaner but can directly deliver filtered/clean air to the breathing zone. It can provide corresponding

mass removal rates of PM 2.5 between approximately 0.5–5.4 h⁻¹. But some models with ionization units may produce a number of O₃ (up to 670 µg/h), which need to be considered in practice.

A low-cost air cleaning technique that protects the breathing zone is wearing masks, which can efficiently filter the inhaled air and remove particles. A cloth mask can provide an overall 30% particle filtration efficiency considering leakage from gaps caused by improper fit (Konda et al. 2020), while a surgical mask has an overall 50% particle removal efficiency and a N95 mask can provide over 95% particle reduction (Rothamer et al. 2020; Konda et al. 2020). Conventional masks can only remove particles through filtration, but some novel masks (e.g. with activated carbon cloth) can also remove reactive gaseous compounds (e.g. O₃) and/or some VOCs. Masks are also very useful for mitigating infection risk of respiratory diseases through airborne transmission, which has been highly recommended since the COVID-19 pandemic (Shen et al. 2021).

Integration of IAQ Strategies

To demonstrate the analysis for the potential of source control, ventilation, and air cleaning strategies at different scales, the standard open plan office environment (ANSI/BIFMA M7.1) presented in ► Chap. 56, “Testing and Reducing VOC Emissions from Building Materials and Furniture” of this book section (Testing and reducing VOC emissions from building materials and furniture to improve indoor air quality) is adopted to define the example case. An open plan office with ten workstations (ten occupants) is defined based on the information in Chap. 1. The space configuration parameters of the reference office are shown in Table 3. The total floor area is 59.5 m² since the standard floor area per workstation with common area is 5.95 m² and there is an assumption of ten workstations in the reference case. Four typical indoor pollutants are simulated to study the indoor air quality of the reference office, including PM 2.5, O₃, formaldehyde, and virus-laden aerosols (considering the serious situation of pandemic). The average pollutant concentrations of PM2.5, O₃, formaldehyde, and infectious aerosols in outdoor air in the U.S. are 8 µg/m³,

Table 3 Configuration parameters of the reference open plan office (per ANSI/BIFMA M7.1)

Parameter	Open plan office
Room information	
Total floor area (m ²)	59.5 (5.95 × 10)
Room height (m)	2.7
Room volume (m ³)	162.8
Total wall area (m ²)	93.5
Workstation/occupant number (#)	10
Workstation components	
Total panel vertical area (m ²)	110.8 (11.08 × 10)
Total work surface horizontal area (m ²)	61.0 (6.10 × 10)
Total storage external surface area (m ²)	45.7 (4.57 × 10)

135 $\mu\text{g}/\text{m}^3$, 7.2 $\mu\text{g}/\text{m}^3$, and 0 quanta/ m^3 , respectively (WHO 2010; U.S. EPA 2021a, b; Chirizzi et al. 2021). The infiltration rate for the reference office case is assumed to be 0.2 h^{-1} . The penetration factor for O_3 and formaldehyde through building envelope is typically 1, while the penetration factor for particles is assumed to be 0.9 (Chen and Zhao 2011). The indoor emission source of PM 2.5 is assumed to be 600 $\mu\text{g}/\text{h}$ per occupant (due to generation or resuspension through occupant activities) (Qian et al. 2014), while no significant O_3 source exists in the reference case. For infection risk analysis, only one infector is assumed to be in the office, which can exhale 58 infectious quanta of virus-laden particles (one quantum in the inhalation risk estimation model represents an infectious dose that would infect 63% of the population with the exposure) (Shen et al. 2021). Formaldehyde is released from building materials (Salthammer 2019) and workstation components (Carter and Zhang 2007), as well as through the oxidation reactions between O_3 and building materials (Gall et al. 2013), workstation components, and occupant surfaces (e.g. skin or clothes) (Rai et al. 2014). The reactions between the chemicals on these surfaces and O_3 can remove considerable O_3 due to irreversible oxidation, resulting in O_3 deposition on surfaces (Di et al. 2016; Shen and Gao 2018), and yield secondary by-product emissions, which can be quantified by the molar yield factor (Gall et al. 2013; Rai et al. 2014). The O_3 deposition and formaldehyde production by different materials are illustrated in Table 4, which are from the literature data (Carter and Zhang 2007; Gall et al. 2013; Rai et al. 2014; Di et al. 2016; Shen and Gao 2018; Salthammer 2019). The particle deposition relies on an approximate

Table 4 Ozone deposition and formaldehyde production by different materials

	Ozone deposition factor	Formaldehyde emission factor	
	Deposition velocity, v_d (m/h)	Primary emission rate ($\mu\text{g}/\text{m}^2 \text{ h}$)	Secondary molar yield factor (ozone oxidation reactions)(–)
Room surfaces			
Floor (carpet)	3.4	3.9	0.01
Wall (painted drywall)	1.4	2.3	0.01
Ceiling (painted drywall)	1.4	2.3	0.01
Workstation components			
Panel	1.5	50	0.01
Work surface	0.2	15	0.01
Storage	0.2	0	0.01
Occupant surfaces			
Occupant Skin/Clothes	10.8	0	0.02

estimate of gravitational settling (Nicas et al. 2005), while the deposition of formaldehyde is not considered. The inactivation rate of the virus-laden particles is defined based on the data for SARS-CoV-2 (i.e. 0.63 h^{-1}) (van Doremalen et al. 2020). The pulmonary rate for occupants is $0.3 \text{ m}^3/\text{h}$, while the exposure time is 8 h (U.S. EPA 2011). The ventilation rate of outdoor air provided through the HVAC system is defined to be 0.9 h^{-1} based on the ANSI/BIFMA M7.1 standard (Carter and Zhang 2007). Considering that the average outdoor air fraction for building ventilation system is around 25% (Persily and Gorfain 2004), the total supply airflow rate of the HVAC system in this simulation is 3.6 h^{-1} . A MERV 8 filter is included in the HVAC duct, which can remove approximately 20% of PM2.5 particles and 50% of infectious particles (Shen et al. 2021). Mixing ventilation is used in the reference case (ventilation effectiveness = 1).

The simulation through the simplified multiscale pollutant transport model (Eq. 3) revealed that the steady-state concentrations in the breathing zone for the reference open plan office case are $23.1 \mu\text{g}/\text{m}^3$, $25.2 \mu\text{g}/\text{m}^3$, $48.1 \mu\text{g}/\text{m}^3$, and $0.1 \text{ quanta}/\text{m}^3$ for PM 2.5, O₃, formaldehyde (HCHO), and infectious aerosols, respectively. The infection risk for the susceptible occupants is 20.4%, which is estimated by the inhaled dose of infectious quanta through the Wells-Riley model (Shen et al. 2021). Several selected IAQ control strategies at different scales are applied in the reference office case (Table 5). The effectiveness of each strategy is analyzed comparing to the IAQ metrics of the reference case (reduction percentage).

Reducing ambient pollutant concentrations by 50% can improve indoor PM 2.5, O₃, and formaldehyde concentrations by 8.2%, 50.0%, and 8.9%, respectively. But it does not impact the indoor infection probability due to the exposure to viral particles exhaled by the infector. Using green building materials (ceiling, wall, and floor materials) with 50% less primary and secondary formaldehyde emissions can reduce the formaldehyde concentration by around 4%, while using green furniture (workstations) can reduce formaldehyde exposure by 37.8%. Improving building ventilation by using 100% outdoor air improve indoor PM 2.5 level by 34.6%, formaldehyde level by 59.3%, and infection risk by 24.0%, but also increase the indoor O₃ concentration since it is mainly from the ambient air and there is no O₃ filtration for the HVAC system. Increasing building airtightness (reducing building air infiltration) can reduce indoor O₃ (by 11.5%) but increase other indoor pollutants. Natural ventilation that provides 0.5 h^{-1} more indoor ventilation also introduces more O₃ indoors (by 34.1%) while it reduces concentrations of other pollutants of indoor origin. Upgrading HVAC system filter to HEPA filter at the building scale can reduce indoor PM2.5 level by over 59% and infection probability by 24% but has no effects on improving indoor O₃ and formaldehyde levels. It has a high potential for reducing indoor particle exposure and infection risk. Using additional activated carbon filter in the HVAC system that has 80% efficiency on O₃ reduction has a high potential on decreasing indoor O₃ exposure, which has a 74.6% O₃ reduction and 2.3% formaldehyde reduction due to reduced secondary emission. Replacing wall and ceiling materials by depolluting materials that can absorb formaldehyde with a deposition velocity of 2.08 m/h can greatly improve the indoor formaldehyde level (by 93.1%), indicating a high potential for indoor formaldehyde improvement.

Table 5 Effectiveness of selected IAQ control strategies in the reference office case

Scale	Category	Strategy	Description	IAQ metrics				Effectiveness on IAQ improvement			
				PM2.5 ($\mu\text{g}/\text{m}^3$)	O_3 ($\mu\text{g}/\text{m}^3$)	HCHO ($\mu\text{g}/\text{m}^3$)	Infection probability (%)	PM2.5 (%)	O_3 (%)	HCHO (%)	Infection (%)
Outdoor air				8.0	135.0	7.2	0				
Reference open plan office				23.1	25.2	48.1	20.4				
Urban	Source control	Reducing emissions	50% reduced ambient pollutant level	21.2	12.6	43.8	20.4	8.2	50.0	8.9	0
	Ventilation	Higher ventilation	20% reduced ambient pollutant level	22.4	20.2	46.3	20.4	3.0	19.8	3.7	0
	Air cleaning	Urban greenings	10% reduced ambient pollutant level	22.8	22.7	47.2	20.4	1.3	9.9	1.9	0
Building	Source control	Low-emission building materials	50% less primary and secondary formaldehyde emissions	23.1	25.2	46.1	20.4	0	0	4.2	0
	Ventilation	Higher ventilation	20% more total supply airflow rate of HVAC system	20.6	28.5	42.5	18.5	10.8	-13.1	11.6	9.3
			50% outdoor air fraction of HVAC	19.0	39.7	30.1	18.5	17.7	-57.5	37.4	9.3

		100% outdoor air fraction of HVAC	15.1	59.7	19.6	15.5	34.6	-136.9	59.3	24.0
Higher airtightness	Reduced air infiltration (0.05 h^{-1})	24.5	22.3	54.3	21.2	-6.1	11.5	-12.9	-3.9	
Natural ventilation	0.5 h^{-1} more ventilation	19.8	33.8	35.6	18.3	14.3	-34.1	26.0	10.3	
Air cleaning system	Upgrading filter of HVAC	10.3	25.2	48.1	18.6	55.4	0	0	8.8	
	Using HEPA filter	9.4	25.2	48.1	15.5	59.3	0	0	24.0	
	Adding activated carbon filter (80% efficiency on O ₃ reduction)	23.1	6.4	47.0	20.4	0	74.6	2.3	0	
Formaldehyde absorption material	Deposition velocity for HCHO = 2.08 m/h (area = wall and ceiling area)	23.1	25.2	3.3	20.4	0	0	93.1	0	
Room	Source control	Low-emission furniture	23.1	25.2	29.9	20.4	0	0	37.8	0

(continued)

Table 5 (continued)

Scale	Category	Strategy	Description	IAQ metrics				Effectiveness on IAQ improvement			
				PM2.5 ($\mu\text{g}/\text{m}^3$)	O ₃ ($\mu\text{g}/\text{m}^3$)	HCHO ($\mu\text{g}/\text{m}^3$)	Infection probability (%)	PM2.5 (%)	O ₃ (%)	HCHO (%)	Infection (%)
Ventilation	Displacement ventilation	Ventilation effectiveness = 1.5	17.9	33.0	36.5	16.1	22.5	-31.0	24.1	21.1	
Air cleaning	Portable air cleaner	CADR = 361 m ³ /h (HEPA filter and activated carbon filter)	10.7	19.4	47.7	13.4	53.7	23.0	0.8	34.3	
Personal control	Local air exhaust	Reduced viral particle exhalation (ventilation effectiveness = 5)	23.1	25.2	48.1	6.5	0	0	0	68.1	
Ventilation	Personal ventilation	Ventilation effectiveness = 1.7	16.5	35.8	33.5	14.9	28.6	-42.1	30.4	27.0	
Air cleaning	Wearing mask	50% on particle filtration	11.6	25.2	48.1	5.5	49.8	0	0	73.0	

Displacement ventilation (ventilation effectiveness = 1.5) can improve indoor PM2.5, formaldehyde, and infection risk levels but also increase the indoor O₃ concentration owing to less O₃ deposition because of imperfect air mixing. Portable air cleaner that has a CADR of 361 m³/h (with HEPA filter and activated carbon filter) can reduce indoor PM2.5, O₃, formaldehyde, and infection probability by 53.7%, 23.0%, 0.8%, and 34.3%, respectively. Improving the IAQ in personal microenvironments by using local air exhaust technique that can remove viral particle exhalation with a ventilation effectiveness of 5 can reduce the infection risk by 68.1%, which has a high potential on reducing the infection risk. Personal ventilation (effectiveness = 1.7) can improve indoor PM2.5, formaldehyde, and infection risk levels but also increase the indoor O₃ concentration. Masks can remove 50% particles (including PM2.5 and infectious particles). Wearing masks can reduce PM2.5 inhalation by almost 50% and infection risk by 73% (reduction on both infectious particle exhalation and inhalation).

It can be found that most IAQ control strategies cannot remove all indoor pollutants effectively. They may be effective against certain pollutants, but ineffective against others. Some strategies may even introduce some pollutants when working against other pollutants. To meet certain IAQ criteria, the integrated implementation of multiple IAQ control strategies in indoor environments are usually necessary. Like the optimization of HVAC system control, the optimal control of other strategies (e.g. standalone air cleaners and local air exhaust) also has great potential of IAQ improvement. Especially, the coordination of different strategies can be optimized through optimal control algorithms, e.g. the combination of UFAD, personal ventilation, and partitions in office settings (Kong et al. 2015). Intelligent/optimized control of IAQ strategies has great potential in improving IAQ while saving energy.

Case Study: IAQ Design and Control Strategies for a LEED Platinum Building: SyracuseCOE Headquarters

The Syracuse Center of Excellence (SyracuseCOE) Headquarters is a five-story building located at the southeastern corner of the intersection between two interstate highways (I-81 and I-690), near the downtown of Syracuse, NY (Fig. 10). This LEED Platinum certified office building was built for environmental and energy technologies and building research, development and demonstration, equipped with the facilities such as green roof, geothermal system, natural ventilation, personal ventilation systems, advanced building heat recovery/reuse systems, air quality monitoring of outside air and integrated controls for improving/protecting indoor air, etc. The HVAC system in the building uses 100% outdoor air and can coordinate with natural ventilation (window opening). The narrow-shape design is good for the application of natural ventilation as well as for maximizing the benefit of daylighting. High-efficiency filters are used to filtrate outdoor air before supplying it to indoor spaces. Low-emission materials and furniture (per ANSI/BIFMA M7.1) are selected and used in the building to minimize indoor pollutant sources.

Fig. 10 SyracuseCOE case study

The Total Indoor Environmental Quality (TIEQ) Lab is located on the fourth floor of SyracuseCOE. The lab space spans two floors. There is an open mechanical space on the fourth floor and two configurable suites with raised floor systems on the fifth floor, directly above. The configurable spaces can be used for simulating multi-zone office and classroom settings, testing various ventilation, air distribution, and environmental control technologies, and studying the control of the micro-environments around individual occupants. When the configurable spaces are used for office settings, each space can typically contain up to 12 workstations (cubicles) (Fig. 10). The building management system of the lab is isolated from the building's main HVAC system. The main air handler and 12 individual air treatment modules are combined to control the relative humidity (RH), temperature and CO₂ levels. Temperature, RH, CO₂, and VOCs can be monitored at the supply, room, or the individual level at each workstation. Demand-controlled underfloor air distribution (UFAD) ventilation system can be applied in the space. Personal ventilation system is mounted on the desk of each cubicle and can be used to control the micro-environments around occupant. The major IAQ control strategies at different scales used in the SyracuseCOE case are illustrated in Table 6.

At the urban scale, the I-81 highway on the west side of the SyracuseCOE building is planned to be rerouted in a few years. Though this is primarily from the urban transportation and community interaction planning point of view, it can also reduce the pollutant emissions from traffic. It has been found that traffic is the primary source of the particles near the highway. According to the field measurement near I-81, the traffic on I-81 has a significant impact on the particle level in nearby communities (Kong et al. 2016). Particularly, the particle level in the downstream area is much larger than the particle level in the upstream area. Considering that the prevailing wind in Syracuse is from the west, traffic emissions from I-81 can very likely have a considerable impact on the local air quality surrounding the SyracuseCOE building.

Table 6 Major IAQ control strategies at different scales used in the SyracuseCOE case

	Source control	Ventilation	Air cleaning
Urban scale	Removing traffic emissions by I-81 (planned)	First-floor lift-up design	Green roof
Building scale	Low-emission building materials (per ANSI/BIFMA criteria)	100% outdoor air mechanical ventilation Natural ventilation (potential strategy)	High-efficiency filters in HVAC (MERV 13 + activated carbon)
Room scale	Low-emission furniture (per ANSI/BIFMA criteria)	Underfloor air distribution system Demand control ventilation	Standalone air cleaner (potential strategy)
Personal scale		Personal ventilation	

Therefore, rerouting I-81 is assumed to have the ability to reduce the outdoor particle level around the SyracuseCOE building by 50%. First-floor lift-up design of the building can ideally improve the local ventilation and reduce the pollutant accumulation in local areas. But its effectiveness on air quality improvement is questioned since the building is located in the downstream side of the pollutant source. Green roof is mainly used for improving local thermal and hydrologic environment. However, due to the limited area of the green roof on the SyracuseCOE building, its impact on pollutant removal is probably very little. Thus, first-floor lift-up design and green roof are assumed to have insignificant impacts on local pollutant reduction.

Building materials and furniture in the SyracuseCOE building were selected per ANSI/BIFMA criteria (see Chap. 1). They are assumed to have 50% lower emissions than regular materials and furniture. The HVAC system in the building uses 100% outdoor air and MERV 13 and activated carbon filters for filtration. The demand controlled UFAD system is assumed to improve the ventilation by an equivalent effectiveness as the displacement ventilation (ventilation effectiveness = 1.5). A field test in the TIEQ lab revealed that the studied personal ventilation system can improve the IAQ in the breathing zone by a factor of 3–5 (Kong et al. 2015). In this study, its ventilation effectiveness is assumed to be 3.

In addition, natural ventilation can also be utilized by opening windows. However, currently, windows can only be opened manually, which means natural ventilation probably cannot be utilized very well. An optimal control that coordinates mechanical and natural ventilation has the potential for enhancing indoor ventilation and improving IAQ. It can be assumed that the use of natural ventilation can provide additional 0.5 h^{-1} outdoor air to the room. Standalone air cleaner is another potential strategy that can further improve IAQ of the building. The studied air cleaner is assumed to use a HEPA filter (99.9% removal efficiency on particles) and an activated carbon filter (80% removal efficiency on ozone), which can provide a CADR of $361 \text{ m}^3/\text{h}$.

The TIEQ lab ($6.3 \text{ m} \times 10.5 \text{ m} \times 3.2 \text{ m}$) is defined as the studied case, with 12 cubicles arranged in 2 rows. A reference case with same dimensions and

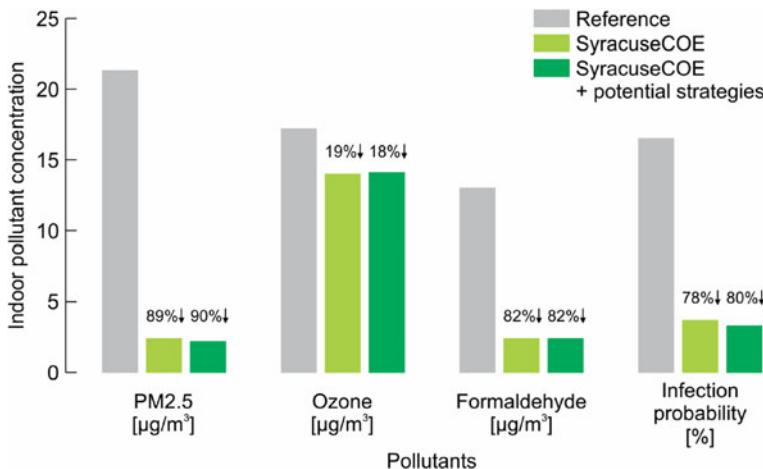

Fig. 11 IAQ metrics in studied cases

occupancy settings is also defined. The reference settings defined in the previous section are adopted to define the building systems of this reference case. The total supply airflow rate of the HVAC system is assumed to be 3.6 h^{-1} (25% outdoor air for the reference case while 100% outdoor air for the SyracuseCOE case). The potential strategies, including controlled natural ventilation and standalone air cleaner, are used to define a case with potential improvement. The outdoor concentrations of PM2.5, O₃, and formaldehyde in Syracuse are around 6.4 µg/m³, 84 µg/m³, and 2.6 µg/m³, respectively (Han et al. 2014; U.S. EPA 2020).

Based on the analysis approach introduced in the previous section, it can be observed that the current strategies used in the SyracuseCOE case (TIEQ lab) can significantly improve IAQ compared to the baseline case (Fig. 11), particularly for pollutants that are mainly generated indoors (such as PM2.5, from occupants activities, formaldehyde, and infectious particles; see the reference settings in the previous section). Potential strategies can further reduce these pollutants but with minimal effect on the O₃ concentration, because more outdoor air is introduced through natural ventilation while outdoor air is the main source of indoor O₃. Therefore, the LEED Platinum certified SyracuseCOE building can provide quite a good IAQ for occupants with the existing control strategies, while the potential strategies, including controlled natural ventilation and standalone air cleaner would only have small further improvement (1–2% reduction comparing to the baseline condition).

Concluding Remarks and Future Outlook

In the foregoing sections, we introduced a simplified IAQ model and used it to assess the effectiveness of source control, ventilation, and air purification at urban, building, room, and personal microenvironment scales in reducing the occupant's exposure to various pollutants with indoor or outdoor origins. Baseline cases were

defined for various commercial and institutional building spaces so that the various IAQ strategies can be evaluated as relative percent of improvement against the defined baselines. In particular, results for typical open plan office spaces were obtained and a case study analysis was presented for a LEED Platinum-certified building. The same approach can be extended to other types of buildings such as residential buildings.

The analysis has been limited to several individual pollutants of indoor or outdoor origins, and to the reduction of concentrations. Future work should include an analysis of the combined effects of major indoor pollutants on the overall IAQ and of how the various IAQ improvement strategies at different scales can be integrated and optimized in building design and urban planning. Such analysis would require the development and use of more comprehensive IAQ metrics such as the DALY (Disability-Adjusted Life Years) metric or the ELV method that accounts for a pre-defined set of indoor pollutants (Abadie and Wargocki 2017).

The analysis has also been limited to steady state conditions. It can be extended to dynamic conditions in which both indoor and outdoor pollution loads can vary over time, and building occupancy also changes over time. Analysis for dynamic conditions also offers additional opportunity for further optimizing the implementation and integration of the various IAQ strategies. For example, outdoor ventilation rate and air purification at the building scale can be optimized to improve indoor air quality while saving energy (Han et al. 2014). Model predictive control method can be applied to further optimize the application of the various IAQ strategies in real or near real time (Woldekidan 2015). The arrival of Internet of Things (IOT) technologies is expected to make the implementation of the dynamic control and optimization more convenient and at a lower cost as it would depend less on initial infrastructure setup. It would make it easier to install and operate a plug and play system with the different products/IAQ strategies that communicate and coordinate with each other for whole system optimization.

Energy and cost implications of the various IAQ strategies at the different scales have not been discussed in detail. Future work should include the quantification of energy consumption, cost, and carbon emissions of the IAQ strategies. Such data are needed to perform multi-objective optimizations of the built environmental systems (BES) as pertaining to IEQ improvement, energy saving and reduction of carbon emissions and building safety (Fig. 1).

Abstract

Indoor air pollution has become a broad problem due to various indoor or outdoor pollutant sources and limited ventilation. A performance-based approach, which is built upon accurate modeling and simulation of indoor air pollutant characteristics, has obvious advantages over the prescription-based method to achieve a better indoor environment. Moreover, the simulation could play a key role in actively preventing indoor air pollution from happening in the first place. In this Chapter, we introduce the working procedures of the performance-based approach including identification of purpose, model assumptions, governing equations, determination of model inputs, specification of model outputs, simulation case design, simulation running, and analysis of simulation results for indoor air quality (IAQ) design. Single-zone, multi-zone, and detailed computational fluid dynamics (CFD) models are discussed along with a brief review of example software tools available for implementing the simulation models. Discussions are focused on modeling volatile organic compound (VOC) sources, sinks, ventilation, and their impact on the concentrations indoors. As for the public concerned SARS and SARS-CoV-2 virus, a brief discussion is provided based on the real cases.

Keywords

Indoor air quality (IAQ) · Simulation · Model · Design · Volatile organic compound (VOC)

Introduction

Modern built environments are filled with various natural or man-made air contaminants, leading to the increased sensitivity of the public to indoor air quality (IAQ). Investigations on IAQ have demonstrated that indoor pollutant concentrations such

as volatile organic compound (VOC) and particulate matter 2.5 (PM_{2.5}) may reach a high level (Shin and Jo 2012; Weschler and Nazaroff 2012). The prescription-based approach has been adopted to eliminate indoor pollutants (JGJ/T 436-2018 2018). In this approach, control strategies, such as material using area and ventilation rate, were proposed mainly based on experience. However, such an approach is not reliable all the time. Once the pollution occurs, a huge cost is needed to remedy the pollution.

Recently, the performance-based approach has attracted public attention (Liang et al. 2012). Compared with the prescription-based method, this approach is characterized by active design rather than passive repairment. Rough estimates of the effectiveness of active prevention indicate that it is at least 4 times less costly than remediation of damage after the fact to achieve comparable IAQ (Hal 2016). Even so, performance-based design for IAQ has not been widely adopted in practice due to a much larger number of parameters than thermal comfort analysis, because pollutant mass transfer within buildings is an extremely complex process.

Taking VOC as an example, its emissions from building materials to indoor air is a dynamic process, involving mass transfer inside the material, at the material-air interface, and in the bulk air (Little et al. 1994). The processes are likely to be affected by environmental conditions, such as temperature, humidity, and velocity of air flow, leading to more challenges in an accurate description of pollutant emissions (Liang et al. 2016). Meanwhile, some porous building materials can act as sinks. Therefore, VOC emitted from one material can be adsorbed by other materials and then gradually released into the air under suitable conditions, affecting the indoor concentrations in the long term (Won et al. 2001). The airflow exchange between a building and outdoors plays a key role in diluting indoor-generated pollutants. In addition, the internal airflows determine the pollutant inter-exchange between zones. Both external and internal airflows vary with outdoor meteorological and indoor environment conditions (Caron et al. 2020). The possible uses of air cleaning devices, such as portable air cleaners can reduce indoor pollutant load to some extent, including the adsorption process of pollutant molecules from the air to inside of the activated filter (Pei and Ji 2018).

The key point of the performance-based approach is to accurately assess the impact of these influencing factors on indoor pollutant concentration. Two main research methods are available for this purpose: experimental investigation and computer simulation. In principle, direct measurements give the most realistic information for concerned problems. However, the experimental method requires full-scale, well-controlled facilities (e.g., a test house), meaning a high initial investment. In addition, direct measurements of the pollutant distributions in a full-scale room are time-consuming and technically difficult. In this case, simulation becomes a more efficient option.

Simulation is a technique for implementing various hypotheses over time even those that cannot be tested experimentally. It is most likely the only opportunity that the designer can improve the design before its final implementation (Sokolowski and Banks 2010). Problems and flaws can be avoided in advance, not only saving time and money but also probably saving lives if we are dealing with life safety building services. If reasonably designed, a simulation is fully capable of obtaining the same

results as an experiment, but with significantly less cost and time. Therefore, simulation is regarded as a time- and cost-effective technology, and can be advanced enough to be applied to daily design and operation. Successful simulation is of course inseparable from the support of the predictive models.

Predictive modeling is the art of developing a set of equations that faithfully represent the complex mass transfer phenomena and then solving the equations to predict the pollutant behaviors (Sokolowski and Banks 2010). Modeling is a powerful tool that is being used extensively by scientists to design IAQ in modern buildings. A model can be physical, mathematical, or otherwise logical representations, determined by the concerned IAQ problems. However, it should be noted that a model is not required to represent all aspects of the issues being studied. That would be too timely, expensive, and complex – even impossible. Instead, the model should be developed as simply as possible, representing only the key aspects that affect the performance of the system being investigated. Generally speaking, modeling is full of challenges. Modelers need to have not only a professional background but also mathematical and analytical ability.

The purpose of this chapter is to introduce the performance-based approach in IAQ design and evaluate its effectiveness. The principle is presented in section “[Principle of the performance-based approach](#)” to show how to use the performance-based approach to deal with an IAQ problem at the design stage. Then, typical models and their simulation processes in the performance-based approach, including single-zone model, multi-zone model, computational fluid dynamic (CFD) model, and date-driven model, are summarized, respectively. Finally, a conclusion and future perspectives are presented.

Principle of the Performance-Based Approach

The key point of the performance-based method is to accurately predict various indoor pollutant concentrations at the design stage. Different pollutants require different models and simulation processes, which should be determined in advance. Pollutants that attract public concern in recent years may include PM_{2.5}, VOC, severe acute respiratory syndrome coronavirus (SARS), and corona virus disease (SARS-CoV-2) (Paterson et al. 2021; Baboli et al. 2021; Wu and Weng 2021; Shen et al. 2021). Their sources are shown in Fig. 1. Most indoor PM_{2.5} comes from the outdoor atmosphere, and others are contributed by human activities (Long et al. 2021; Yang et al. 2020). Indoor VOC is mainly from building material and furniture (Liang et al. 2014). VOC emitted from interior materials to indoor air involves a series of mass transfer processes. Mechanism of VOC emission and transmission has been studied for over 20 years, and some novel conclusions have been drawn (Yang 1999). Both SARS and SARS CoV-2 belong to viruses and are derived from infected people. Up to now, their transmitted behaviors have been realized by the public, but generation and pathogenicity are yet to be well addressed (Shen et al. 2021; Tang et al. 2022). Considering the urgency of the problem and maturity of current research, VOC is selected as the target pollutant to show the principle of the

Fig. 1 Indoor pollutants and their sources

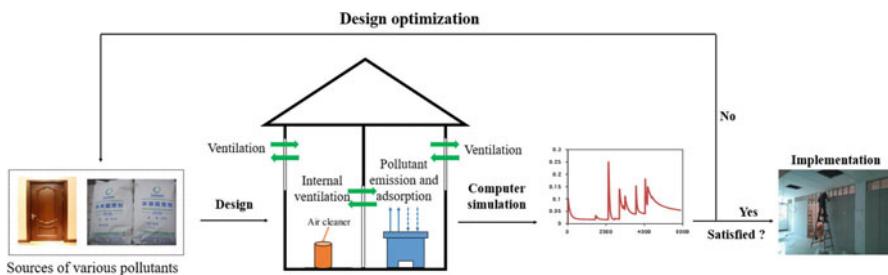

Fig. 2 Schematic of using the performance-based approach to prevent indoor VOC pollution

performance-based method. For the public concerned SARS and SARS-CoV-2, a brief discussion is provided based on real case studies.

Figure 2 shows the schematic of the performance-based approach to prevent indoor VOC pollution. Before interior construction, the pollutant-concentration goal, i.e., the level that must not exceed at a certain time, should be set. Some may choose “meeting the minimum indoor air-quality standard requirement two weeks after the indoor decoration is complete” as their goal, while others may select a higher standard (lower concentration levels). Then, indoor VOC concentration will be previewed using a computer, according to the construction plan. If the simulation finds that a design cannot achieve satisfactory results, optimization work will be performed until the requirement is achieved. A key feature of the aforementioned approach is that a prescient result will be provided at the design stage, it would not be too late to propose necessary correctional actions before the plan is finalized or implemented if a potential problem is foreseen.

The principle of the performance-based approach is not difficult to understand, but its application in engineering is not simple, involving complex and rigorous procedures:

Identification of Purpose

A clear understanding of the design purpose is the first step. Different purposes require different modeling and simulation methods. For example, the model used in a small room may not be suitable in a large space. This requires the designers to collect data and knowledge of the studied issues in advance. The abundant information will improve the designer's insight, and help to make the correct choice when modeling.

Model Assumptions

As noted previously, a model should not be required to reflect all aspects but should focus on using mathematics and logic to describe the expected behavior. Therefore, only those significant behaviors to the study or research need to be represented in the model, others could be assumed or simplified based on the studied issues to ensure a fast and efficient solving process.

Governing Equations

With clear purpose and necessary assumptions, the pollutants transmission (physical behavior or phenomena related to IAQ) within buildings can be described by models. Models can be mathematical or any other logical expressions. Normally, models based on mathematical expressions are concise and convenient to use, and are thus welcomed by users. One or more mathematical expressions for the concerned problems constitute the model governing equations.

Determination of Model Inputs

Mathematics-based model governing equations usually contain a series of letters or symbols, which are so-called model parameters. These parameters can be classified into input parameters and output parameters. Normally, the model input parameters are related to various control strategies in an IAQ problem. They can be determined by the experimental method, simulation method, or combination of both, depending on their complexity.

Specification of Model Outputs

Corresponding to the model inputs, model outputs are related to the control results and typically represent a dynamic response of a given set of inputs and conditions. Model outputs should be specified before simulations depending on the study

purpose. Model outputs are often the parameters that the designers are most concerned, and cannot be directly obtained through experiments.

Simulation Case Design

The purpose of a simulation is to compare the influence of various control strategies (model inputs) on the results (model outputs). Before this, a good design for the simulation case is needed, which may be a challenging job. It requires the designer to comprehensively consider all feasible control strategies, and then provide a series of logical and operable conditions to ensure a more correct and representative simulation result.

Simulation Running

The next procedure is running the simulation. When the simulation technology was first applied in the IAQ field, the designer was required to write the code in the computer and manually complete the calculation process. With the improvement of computer power, a variety of commercial software has been developed. When the designers provide model inputs according to the requirements of the program, computers can rapidly give the expected results. These significant advancements provide convenience for the users, which are beneficial for the wide spread of simulation technology in the IAQ field.

Analysis of Simulation Results

After the simulation step, computers will output a series of data. Simulation analysis is converting these data into meaningful information that describes the effectiveness of control strategies on IAQ. One optimal design will undoubtedly take several iterations of the simulation cycle. The first iteration often provides information for modifying the model. It is a good practice to repeat the cycle as often as needed until the simulation results are close enough to the designer's expectation.

Almost any IAQ case can be designed through the above-mentioned procedures but may require different types of models depending on the characteristics of the designed case. Typical models and their applications will be introduced as follows.

Single-Zone Modeling and Simulation

VOC mass transfer in the indoor environment is a dynamic and complex process. The theory behind the transfer phenomena has been established and mathematically documented over the years by the scientific community. The single-zone model, as

one typical physics-based model, can be used to describe this physical process taking place in the building environment. Its principle and application are discussed in this section.

Purpose Identification and Model Selection

Single-zone model is the simplest IAQ model. The purpose of single-zone modeling and simulation is to predict and/or analyze the average concentrations of target pollutants in a space of interest. The space can be the microenvironment around an occupant (e.g., in an office cubical), a room, or an entire building. The entire space is represented by a single zone in which the spatial concentration gradients are not considered. The single-zone model is useful for providing an overall estimation of the indoor air quality in the space under a given building condition, and for predicting the effectiveness of various IAQ control strategies including pollutant source reduction, ventilation, and air purification at building design stage (Zhang and Shaw 1999; Liang et al. 2012). Single-zone model can also be used to simulate the dynamic behavior of pollutant concentrations in the space to devise optimized IAQ control strategies considering the variations of the indoor and outdoor pollution loads, weather conditions, and the building occupancy in an effort to minimize energy consumption while maintain the pollutant concentrations below the acceptable threshold values (Woldekidan et al. 2013).

The single-zone model is one typical physics-based model. It is established based on first principles, also known as the mass balance model (Liang et al. 2012). The building is considered as one whole space, represented by a single node, as shown in Fig. 3 (Abdalla and Peng 2021), and the average VOC concentration is thus of interest. It is particularly suitable for IAQ design in buildings with uniform indoor VOC concentrations, such as:

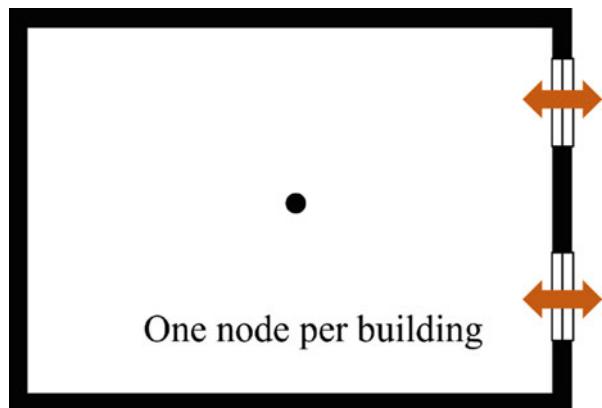

- Small office
- Classroom

In terms of a small office, the limited interior space facilitates the rapid mixing of gaseous pollutants. As for the classroom, the regular source (desk and chair) distribution helps to eliminate the VOC concentration gradient. Both of these features help to create a uniform concentration and ensure the good performance of the single-zone model.

Model Assumptions and Governing Equations

Despite the good performance of the single-zone model, it is based on assumptions that simplify the building representation, which also constrain the use of the model. One major assumption for the single-zone model is that the investigated zone or zones are well mixed (Liang et al. 2012). Besides the above-mentioned limited interior space and regular source distribution, the well-mixed assumption may also include the following aspects (Sparks 2016):

Fig. 3 Schematic of VOC mass transfer by single-zone model: Plan view of a one-store building. (Modified from Abdalla and Peng 2021)

- Time scales of interest are several minutes or longer.
- Concentrations very close to large sources are not of interest.
- There are no local airflow disturbances close to the location of interest.

With the well-mixed assumption, the single-zone model for VOC concentration prediction can be characterized by the following ordinary differential equation:

$$V \frac{dC_{in}}{dt} = Q_{out} \cdot C_{out} - Q_{in} \cdot C_{in} + \sum R - \sum S \quad (1)$$

where V is the zone volume (m^3), C_{in} is the indoor VOC concentration (mg/m^3), t is the simulation time (s), Q_{out} is the ventilation rate introduced into the zone (m^3/s), C_{out} is the VOC concentration introduced into the zone (mg/m^3), Q_{in} is the ventilation rate escaped out of the zone (m^3/s), R is the source term, S is the sink term.

Normally, indoor pressure is a constant value for most building types, meaning a balanced ventilation rate between indoor and outdoor. Therefore, the single-zone model can be simplified as:

$$V \frac{dC_{in}}{dt} = Q(C_{out} - Q_{in}) + \sum R - \sum S \quad (2)$$

where Q is the ventilation rate between indoor and outdoor (m^3/s), and other parameters have the same meanings as those in Eq. (1).

Model Input Parameters and Their Determination

The quality of model predictions depends on not only the correct mathematical expression but also the adequacy of the input parameters. From a broad view, input parameters in the single-zone model include the source, sink, and ventilation terms.

For most cases of interest, they are not constants and may be determined by additional models or eqs. A summary is given below.

Emission Source

Emission sources are the original cause of VOC pollution in a building and can affect indoor concentrations especially during the early days, weeks, and months after their installation. In modern buildings, VOC sources are everywhere and of numerous types, including but not limited to building materials and furniture, various appliances, cooking devices, office equipment, lighting, and occupants (Philip 2016). Among these, building materials and furniture contribute a considerable part (Zhang et al. 2018), and a major focus is putting to address their emission mechanism. While others are summarized in the research (Lee et al. 2001; Ahn et al. 2015; He et al. 2019b) and are not repeated here.

Based on the emission characteristics, building materials can be broadly classified into dry material, “wet” material, and assembled one (Zhang et al. 1999a). Their emissions behavior and representative models are summarized below.

Dry Material

Dry materials contribute a considerable part for indoor VOC pollution. Dry materials commonly used in buildings include plywood, particleboard, medium density fiberboard, wood paneling, carpets, etc. (Jia et al. 2020; Katsogiannis et al. 2008). Normally, VOC diffusions from interior material to indoor air is a slow process, resulting in a long emission life. Emissions of formaldehyde from medium density fiberboard have been measured more than 3 years after the products were installed (Liang et al. 2015). Accurate prediction of material emissions in such a long period is usually difficult.

One challenge is how to cognize the complex mass transfer mechanism. Little et al. (1994) pioneered that VOC mass transfer inside the material is dominated by molecular diffusion and follows Fick’s law as shown in Fig. 4. Later, focuses have been paid to the improvement of Little’s model (Yang 1999; Huang and Haghightat 2002; Xu and Zhang 2003; Kumar and Little 2003; Wang et al. 2006; Hu et al. 2007), so that material emissions with more complicated boundary conditions can be predicted. Up to now, the improved Little’s model has been widely used to simulate VOC emission from various dry building materials and achieve satisfied prediction results in the laboratory.

Another challenge is how to evaluate the impact of environmental conditions such as temperature and humidity on the VOC emission process. The improved Little’s model performed well under constant temperature and humidity conditions but was downgrade once the environmental parameters change. Liang et al. (2016) proposed a physics-based model to describe formaldehyde emissions influenced by coupling temperature and humidity (shown in Fig. 5). The model makes it possible to predict dry material emissions under varied and realistic environmental conditions.

Fig. 4 Schematic of VOC mass transfer from dry building materials (Little, 1994)

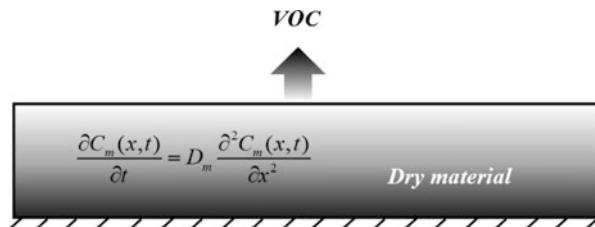

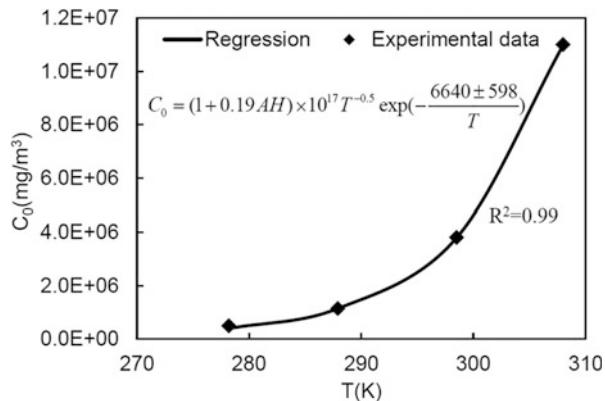

Fig. 5 Correlation between initial emittable concentration (C_0) and the combined effects of temperature and absolute humidity (Liang et al. 2016)

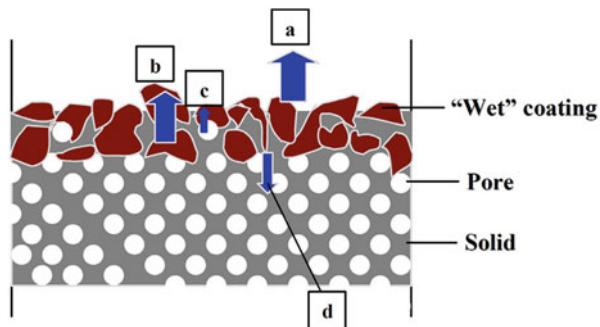

“Wet” Material

Materials like paints, adhesives, wood stains, vanishes are widely used in buildings (Yang 1999). These materials are generally named “wet” materials because they are in wet conditions when initially applied. Normally, “wet” materials cure quickly and emit the majority of their VOC during the first few days, weeks, or months of their service life. Compared to dry materials, the emission mechanism of “wet” materials is much more complicated.

A previous study (Zhang et al. 1998) has indicated that the “wet” material appears to have three emission phases as shown in Fig. 6. The first phase represents the period shortly after the material is applied but is still relatively wet. VOC emissions in this phase are characterized by high emission rates but fast decay. It appears that emissions are related to evaporation at the surface of the material. In the second phase, the material dries as emissions transition from an evaporation-dominant phase to an internal-diffusion controlled phase. In the third phase, the material becomes relatively dry. The VOC off-gassing rate decreases and so does the decay rate. The dominant emission mechanism in this phase is just like dry material.

At the beginning of model development, attention was paid to the first phase of “wet” material emissions. Guo and Tichenor (1992) initially developed the Vapor pressure and Boundary layer (VB) model to simulate VOC emissions from “wet” materials. This model focused on the evaporation dominant process but ignored the

Fig. 6 Schematic representation of the emission mechanisms of a “wet” material embedded in a porous substrate. (a) evaporation; (b) movement of free and bound VOC; (c) vapor flow; (d) diffusion to the substrate (Yang 1999)

diffusion process in the material film. Therefore, the model performed well at the early emission stage but accuracy decreases as time went by.

Yang (1999) proposed a physics-based model to describe VOC emission from a “wet” coating material based on the theory of stratified convection and diffusion. Compared with the VB model, one improvement of Yang’s model is that all the above-mentioned three emission phases are considered so that the model shows good performance in the entire prediction phase. Additionally, using one equation to describe the entire emission process (from “wet” to dry) provides convenience for model users and is usually welcomed in practical engineering.

Currently, “wet” material with a more complex emission mechanism can be considered with the maturity of modeling. One example is the silicone adhesive, whose major VOC is generated by a chemical reaction during the curing process. In addition, the continuously moving interface of chemical reactions makes modeling more challenging. He et al. (2019a) developed a one-dimensional curing model to describe such a complex process and achieved satisfying prediction results. The model helps to accurately interpret the emission behavior of silicone adhesive and is of significance for correctly providing the inputs for concentration simulation.

Assembled Material

In practice, different individual materials are usually used together to form material systems/assemblies. Examples are:

- carpet // adhesive // concrete,
- paint // gypsum wallboard // vapor barrier,
- carpet // under-pad // plywood (or OSB) sub-floor // wood joists,
- wax // vinyl sheet // adhesive // concrete,
- polyurethane floor varnish // wood stain // hardwood strip flooring// plywood (or OSB) // wood joists.

In order to estimate the actual contributions of each individual material to the VOC concentrations in a building, it is necessary to understand the emission

characteristics of these material systems/assemblies as well as the associated individual materials.

Normally, “wet” materials are rarely used alone, but in combination with dry materials to form assembled materials. According to the spatial location of “wet” materials, assembled materials can be divided into two categories. One is to apply the wet material on the dry material, and another is to cover the dry material on the wet material.

In terms of the former, the surface to which “wet” materials are applied will considerably affect their emission life cycle. For example, when wall paint is applied to the gypsum board, a part of VOC will directly release into the air, while others will move into the gypsum board and then re-emit to indoor air once environmental conditions permit. In contrast, a sealant applied to smooth glass will not result in much adsorption and most of VOC will directly emit into the air. VOC mass transfer process for a “wet” material applied on a solid substrate has been well analyzed and summarized in the literature (Yang 1999).

As for the latter, VOC emissions from “wet” materials are considerably affected by the materials that cover them. One example is to apply wooden floor or carpet on the adhesives. The coverings change the emissions from adhesives by providing a mass transfer barrier. This can reduce the VOC exposure at the early emission stage but may result in long-term indoor pollution (Dong et al. 2013).

Although the assembled materials behave differently from a single material, their emission behaviors can be deduced based on the emission model of dry and “wet” materials if the assembling and using conditions are adequate. When a material assembly involves complex sources such as adhesives, the complex source layer may be modeled by the diffusion model with diffusivities varying as a function of the VOC concentration (Zhang et al. 1999a, b). This approach was used to predict the concentrations of VOCs emitted from an adhesive in a “vinyl tile // adhesive // stainless steel” assembly. Stainless steel was used as a backing to simplify the emission scenario. The predicted results agreed reasonably well with those measured in a small chamber test (Bodalal 1999). For assemblies involving only dry material layers, the fundamental Fick’s law of diffusion can be applied to each individual material layer with their respective diffusion and partition coefficients plus the equilibrium partition coefficients at the interface between two adjacent material layers (Zhang et al. 1999a, b). This approach was applied to model the VOC emissions from a large wall assembly of typical wood-framed residential houses, which including gypsum wallboard, fiberglass insulation, oriented strained board (OSB), and vinyl siding (Li et al. 2005). The study also investigated the effects of infiltration on the VOC emissions and transport to the indoor space.

Adsorption Sink

From a broad view, any material or device which can absorb or capture VOC molecules from indoor air can be regarded as a sink. Based on adsorption characteristics, sinks can be classified into chemical sinks and physical sinks.

Chemical sinks are to use specific methods or technologies (photocatalysis, negative ions, and catalytic oxidation, etc.) to capture indoor VOC molecules

(Filho et al. 2019; Saoud et al. 2019). Then the adsorbed molecules are degraded or eliminated through chemical reactions, consequently reducing indoor VOC concentrations. The chemical sinks usually have a high removal efficiency for specific VOC, but the by-products pollution associated with chemical reactions limits its popularity in the building environment (Xu et al. 2018).

In contrast, physical adsorption is usually safe and reliable. Physical adsorption has a considerable removal efficiency on both high and low VOC concentrations (Zhu et al. 2018). Moreover, the relatively low cost also makes it welcomed in engineering. Physical sinks in the indoor environment mainly include two types. One is VOC adsorbed by building materials, which can be called adsorbed materials. Another is VOC adsorbed by equipment, such as air cleaners. The mechanisms and models of these two types of sinks are introduced separately.

Adsorbed Material

Adsorbed materials are characterized by pore structures and rough surfaces, such as sofa cushions, and carpets. VOC moves from air to the specific sites within these adsorbed materials to complete the so-called adsorption behavior. Mass transfer in such a process includes interfacial diffusion in the gas phase, adsorption at the material-air interface, and diffusion inside the material for a permeable material (Yang et al. 2001). Note that, VOC adsorption by building material is usually a reversible process. The adsorbed VOC can re-emit into the air when indoor condition permits, and elevate indoor concentrations even long after the original source is depleted or removed. Therefore, materials capable of depositing, adsorbing, and/or accumulating VOC can influence IAQ during the entire service life of a building (Yang et al. 2001).

Researchers initially used equilibrium models to describe the material adsorbed behavior (Axley 1991). The equilibrium models assume that the adsorption and desorption simultaneously occur on the material surface and an equilibrium is achieved at the material-air interface. One commonly used equilibrium model is the Langmuir model (Axley 1991). Despite the simple principle, neglecting both the interfacial mass transfer and the material-phase diffusion may result in a doubtful model prediction.

The kinetic model is another type of adsorption model (Axley 1991; Dunn and Chen 1993; Little and Hodgson 1996). Different from the equilibrium model, VOC diffusion in the material phase is considered in the kinetic model. Additionally, the model parameters are the physical characteristics of materials, which can be obtained independently from experimental data. However, the kinetic model is based on a few assumptions, and its usage is limited to some simple cases.

Yang et al. (2001) subsequently proposed a “wall function” model to describe the material adsorbed behavior. Different from the equilibrium model and kinetic model, the “wall function” model has clear physical meanings for the entire adsorption process and is thus suitable for more general conditions. The validation results indicate that the model can achieve promising predictions if the diffusion coefficient and partition coefficient are accurately provided, which needs the support of necessary measurement data.

Zhang et al. (2002), Zhang and Chen (2002, 2003) provided a comprehensive review of the physical sorption models and how they compare with experimental data for a variety of building materials under different temperature, humidity, temperature and air velocity conditions.

It should be mentioned that VOC adsorbed by building materials is driven by the concentration gradient, which can be regarded as a passive adsorption process. The adsorption rate in this process is usually slow, especially compared with active adsorption.

Air Cleaner

VOC captured by air cleaners is a typical active adsorption process. Dirty air flows through the filters under the running of fans. Then the cleaned air return back to the room to dilute indoor VOC concentration. Models and performance data are available for filters packed with adsorbents (Pei and Zhang 2010, 2011). According to a survey in literature, activated-carbon-based technology is widely used in household air cleaners (Zhu et al. 2019a). These devices normally have a robust and stable working efficiency at the initial running time, and the performance will gradually decay as time goes by. If VOC adsorption efficiency at the initial few hours is focused, the clean air delivery rate (CADR) could be an effective indicator, which represents the equivalent fresh air volume flow rate that the air cleaners can provide. If long-term working performance is desired, the actual physical mass transfer process needs to be well addressed.

VOC adsorbed by air cleaners involves three physical processes as shown in Fig. 7: (1) Convection mass transfer from the bulk air to the outer surface of the activated carbon; (2) Diffusion mass transfer from the outer surface to the interior pore of the activated carbon; (3) Adsorption process by the inner wall of the pore. Zhu et al. (2019a) proposed a physical model to describe the above-mentioned mass transfer processes. The model has been proved to be capable of giving accurate responses to the dynamic operation of air cleaners. Agreements were observed between model predictions and measurements in both laboratory and actual rooms.

Adsorb-based air cleaners can easily reach saturation under long-term running. If the filters are not replaced in time, they will become pollution sources. To avoid

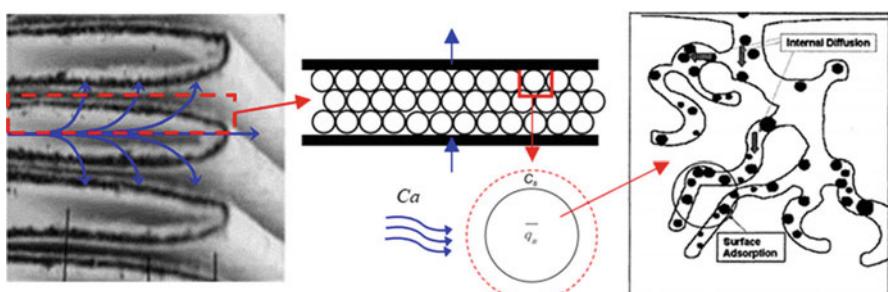

Fig. 7 VOC mass transfer process in an adsorptive air cleaner (Zhu et al. 2019a)

this, it is necessary to estimate their service life and replace the filter before saturation to ensure a continuous and stable purified capacity. These can also be accurately evaluated with the proposed model (Zhu et al. 2019b).

More recently, sorbent materials have also been integrated into building materials such as gypsum wallboard to take advantage the large surface area available in the space and the high adsorption capacity of the sorbents. A model was developed to predict the product's formaldehyde removal performance over its service life (Pentigny et al. 2021).

Ventilation

Ventilation is to provide unconditioned outdoor air or conditioned, combined, outdoor, and recirculated air for diluting pollutant concentrations and achieving acceptable IAQ. Ventilation can be broadly categorized into mechanical ventilation and natural ventilation. Generally, mechanical ventilation is driven by fans and can provide ventilation at the exact demanding rate and in the expected time. The ventilation rate is robust when the system is running and can be estimated by cross-sectional area and air velocity in the pipeline.

Natural ventilation depends on natural forces like the wind from the surrounding environment as well as buoyancy forces that develop due to temperature differences between inside and outside the building. Compared to mechanical ventilation, natural ventilation is almost uncontrollable. Many factors can affect behaviors of natural ventilation, such as climate region, terrain, surrounding buildings, the studied building geometry, ventilation opening shape, size, and direction, as well as the occupant activities (Lai et al. 2018). Therefore, estimating the natural ventilation rate is usually difficult.

Many buildings rely on infiltration for basic fresh air demand and open windows to provide increased ventilation when needed. Infiltration means no window or door is opened so that outdoor air enters the rooms through leakages in the building envelope under the drive of wind and thermal pressure between indoor and outdoor. The tracer gas decay method is usually used for evaluating the infiltration rate (Reardon and Zhang 1995; Kabirikopaei and Lau 2020). Previous studies show that the infiltration rate varied in a limited range within a few hours but shows obvious changes with the seasons (Shi et al. 2015). This means that a constant infiltration assumption is acceptable when considering the ventilation effect in a few hours. However, infiltration rate changed with time needs to be evaluated once a few months simulation is focused.

When the door or window is opened, the outdoor air enters the room through the large opening driven by wind pressure. In this case, even slight fluctuations of the outdoor environment will rapidly transmit to the indoor space, consequently resulting in a rapid change of ventilation rate. The uncontrollable ventilation behavior also brings challenges for ventilation rate assessment. Field investigation is rough in this situation. Simulation based on accurate model evaluation then becomes a choice. Up to now, different types of software, including CONTAMW, EnergyPlus, and VentSim, have been developed to predict ventilation rates under various complex conditions (Han et al. 2014; Zhang et al. 2013; Wei et al. 2011).

Model Output and Analysis of Cases

With the input parameters of source, sink, and ventilation, defining the model output becomes the next task. In the single-zone model, the average concentration curve is one of the desired outputs. It can be obtained by simultaneously solving the mass balance and additional source, sink, and ventilation model equations. Due to the complexity of these models, pursuing an accurate analytical solution is unrealistic. The numerical method, therefore, becomes an alternative choice. First, the ordinary differential equations are discretized in time and then converted into computer code. Computer code must be written to algorithmically represent the mathematical statements of the models. Next, the code is typed into a computer for the iterative calculation to complete the so-called simulation running process. The computer then gives a large amount of calculating data. Data analysis is then performed to convert the data into meaningful information. With this knowledge, improvement suggestions can be provided to ensure the achievable design purpose.

A recent study was conducted to verify the long-term performance of the single-zone simulation model (Liang et al. 2021). A full-scale experimental room was built with a single formaldehyde source of medium density board inside the room. Interior temperature and humidity, as well as the air change rate between outdoor and indoor, were allowed to vary naturally with the ambient environment. Indoor environmental monitoring data indicated that the temperature varied from $-10.9\text{ }^{\circ}\text{C}$ to $31.4\text{ }^{\circ}\text{C}$, while that of relative humidity fell into a range between 46.5% and 83.6%, almost covering the range of indoor environmental parameters commonly observed in buildings. In such a complex environment, time-varying indoor formaldehyde concentration was simulated, and the results indicated the concentrations varied seasonally with peak values decreasing with year (shown in Fig. 8). Meanwhile, frequent field sampling (ranging from a few days to 4 weeks) of actual indoor formaldehyde concentration was conducted from October 2012 to February 2015, and the results agreed well with that of simulations. Such a long-term model verification, especially in an actual room with environmental conditions changing sharply, gives a certain level of confidence to the simulation model.

Another study intended to test the feasibility of the simulation tool in predicting potential IAQ problems in an actual apartment (Lv and Yang 2019). In this case, the block-board is planned to use in the interior decoration of an apartment. The model predicts that its installation will significantly elevate the indoor formaldehyde concentration (the 0–72 h curve in Fig. 9). Although not shown in the figure, the simulation results showed that such a high level of formaldehyde concentration would last years before decreasing to an acceptable level. Hence, the suggestion of using another low-emitting material instead of the block-board was put forward to the owner. Unfortunately, it was not adopted and the block-board was introduced into the apartment. This led to the generation of indoor formaldehyde pollution as expected. The field concentration results (measurement point at 72 h) confirmed the correctness of the model predictions. This prompted the owner to admit that the block-board is a strong source of formaldehyde. However, the owner still hesitated to dismantle the installed block-board in a hope that the problem would not last long.

Fig. 8 Comparison between simulation and measurement (Liang et al. 2021)

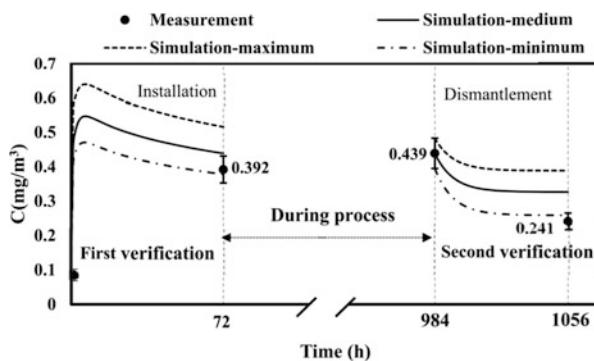

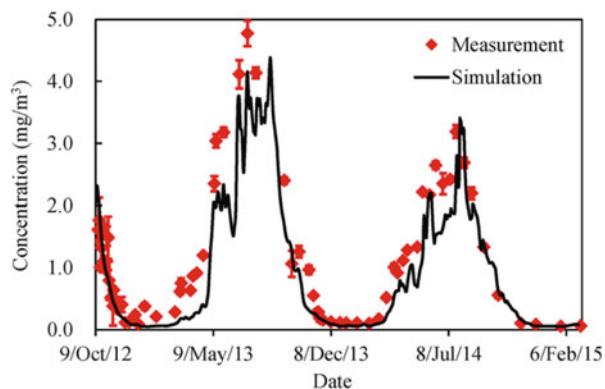

Fig. 9 Comparison of formaldehyde concentrations between measurement and simulation, in the apartment. The first part (0–72 h) represents the introduction of the blockboard indoors. The middle part (72–984 h) is the duration between the material introduction and removal. The third part (984–1056 h) represents the removal of the blockboard (Lv and Yang 2019)

Hence, the board remained inside the apartment and other decoration work continued. After approximately 40 days, another field measurement result (measurement point at 984 h) indicated that indoor formaldehyde was still at a high level, and this prompted the decision to remove the block-board. The concentration change resulting from the blockboard removal was simulated again using the single-zone model (the 984–1056 h curve in Fig. 9). Indoor formaldehyde concentration was tested 3 days after the material was removed, and the result was close to the predicted result, which verified the accuracy of the model predictions for the second time. From the IAQ control point of view, this is not a successful case because of the failure in preventing the formaldehyde emission source in the first place. Despite the lesson learned from such a mistake, an unexpected “benefit” was that the rigorous simulation exercise is a useful tool for IAQ design, and can help prevent VOC pollution from occurring initially.

The single-zone model has many advantages, including concise mathematical expression, easy-to-understand mechanism, relatively fast calculation, and clear physical meaning, etc. These characteristics provide the convenience for applying the single-zone model in engineering. However, the single-zone model predictions heavily depend on the accuracy of the input parameters, which requires a professional background. This undoubtedly brings challenges to modelers. Additionally, the well-mixed assumption for the whole zone leads to lumped parameters for simulations, and the flow conditions among rooms are neglected in the model. Therefore, a single-zone model may not be adequate when pollutants are not perfectly mixed throughout the building.

Example Software Tools

The example computer software tools based on the single-zone model are MEDB-IAQ (Zhang 1999), IA-Quest (Magee et al. 2002; Won 2008). Descriptions of both software are given below.

MEDB-IAQ

The Materials Emission DataBase and Indoor Air Quality (MEDB-IAQ) simulation program was developed by the Institute for Research in Construction (IRC) of the National Research Council of Canada (Zhang 1999). It is characterized by using the single-zone model to simulate the indoor VOC concentration contributed by building materials. Input parameters of the software involve source, sink, and ventilation terms. VOC mass transfer for source and sink is described by a material emission database in which VOC emission rates of typical building materials are represented by empirical or semi-empirical models such as the power-law model for dry materials and the vapor evaporation and boundary layer model (VB) for wet materials, respectively. Key parameters in both models are determined by the environmental chamber method. Space volume, ventilation rates and schedule, and quantity and time of materials used in the space are specified by users. The program output is the time-varying indoor VOC concentrations. The MEDB-IAQ provides a convenient platform for evaluating the influence of building materials on IAQ.

IA-Quest

The Indoor Air Quality Emission Simulation Tool (IA-Quest) was developed by National Research Council Canada, as an extension to the MEDB-IAQ. A database and a simulation component are included in IA-Quest. The database provides information on the emission of health-relevant “target” VOC, abundant VOC, and TVOC (total VOC). The material emission database currently consists of about 2,300 data sets of emission characteristics based on emission testing of 69 building materials commonly used in Canada. For the simulation component, IA-Quest used empirical models to describe the material emission characteristics, such as the power-law model and the peak model. Emission coefficients in models are based on environmental chamber tests conducted at conditions of 23 °C and 50% and a

period of 120 h on average. Other program inputs include the volume of a space, ventilation schedule, material emission area, in-time, and out-time of materials, simulation duration, time step for calculation. The IA-Quest could be used for evaluating the impact of material selection choices and ventilation schedules on IAQ.

Mult-Zone Modeling and Simulation

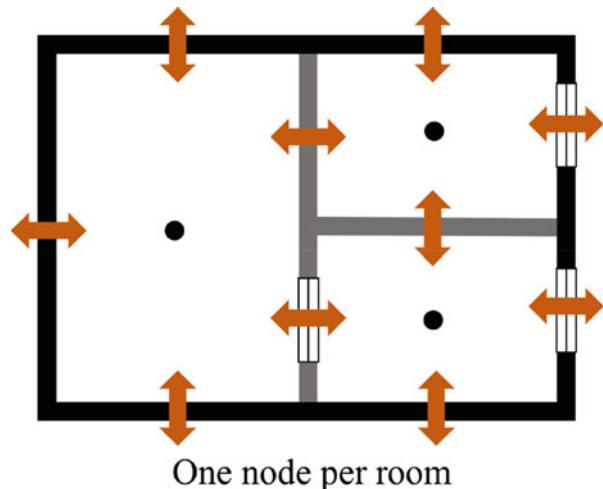

As the name implies, a multi-zone model is used to describe pollutant mass transfer in different regions. Compared with the single-zone model, it is a more general IAQ prediction model. Its principle and application are introduced in this section.

Purpose Identification and Model Selection

The multi-zone model also belongs to the physics-based model. It is established based on the mass balance theory. Compared with the single-zone model, the multi-zone model still focuses on average concentration, but can separately give average concentration in each zone (as shown in Fig. 10). Hence, it is suitable to describe the pollutant transport among rooms. Such an improvement is due to the introduction of inter-zonal airflows as model input. The multi-zone model is particularly suitable for solving IAQ problems in the following buildings:

- Residence
- Hotel
- Library

Fig. 10 Schematic of VOC mass transfer by multi-zone model: Plan view of a one-store building. (Modified from Abdalla and Peng 2021)

- Fitness room
- Prison
- Comprehensive office building

These buildings usually contain more than one room, and source characteristics are different among zones due to various uses. However, interior volume for each space is limited, and a well-mixed assumption is still acceptable. Therefore, VOC concentration in each room can be replaced by an average value.

Model Assumptions and Governing Equations

In the multi-zone model, a building is represented by several connected spaces. It can essentially be regarded as a combination of several single-zone models. Therefore, model assumptions in each room are the same as the single-zone model.

The multi-zone model can be deduced by applying the same mass balance concept for every zone. The general equation for the mass balance of room i in a building with N zones can be written as:

$$V_i \frac{dC_i}{dt} = Q_{out-i} \cdot C_{out} - Q_{i-out} \cdot C_i + \sum_N Q_{j-i} \cdot C_j - \sum_N Q_{i-j} \cdot C_i + \sum R_i - \sum S_i \quad (3)$$

where V_i is the volume of zone i (m^3), C_i is the average VOC concentration in zone i (mg/m^3), t is the simulation time (s), Q_{out-i} is the ventilation rate from outdoor to zone i (m^3/s), C_{out} is the outdoor VOC concentration (mg/m^3), Q_{i-out} is the ventilation rate from zone i to outdoor (m^3/s), Q_{j-i} is the airflow rate from zone j to zone i (m^3/s), C_j is the average VOC concentration in zone j (mg/m^3), Q_{i-j} is the airflow rate from zone i to zone j (m^3/s), R_i is the source term in zone i , S_i is the sink term in zone i .

When the air is well mixed among all zones, the multi-zone model can be simplified as the single-zone model. Hence, the single-zone model is a special condition of the multi-zone model.

Model Input Parameters and their Determination

As can be seen from Eq. (3), room VOC concentration is a function of room-to-room airflow, airflow between indoor and outdoor, sources, and sinks. Among these, source and sink terms have the same meaning as those in the single-zone model. Therefore, the major focus is paid on the inter-zonal flow rate term.

Inter-zonal airflow is normally dominated by the forced airflow provided by a mechanical ventilation system or by naturally driven airflow resulted from the

temperature differences. The tracer gas decay method can still be used for determining multi-zone ventilation rates. A recent study has proved that the airflow rate in two zones can be estimated by monitoring the dynamic CO₂ concentration changes (Remion et al. 2020). The feasibility of the tracer gas decay method heavily depends on the number of investigated rooms. If the zone number is more than two, increasing demand for both trace gas type and corresponding monitoring facility will be found. This will not only increase the test uncertainty but also increase the initial investment. Due to these notable flaws, more efforts have been paid to modeling multi-zone ventilation (Pan et al. 2019; Zhuang et al. 2021). Up to now, commercial software has been developed to calculate the multi-zone ventilation rate (Walton and Denton 2000; Chen et al. 2015). The typical one is the CONTAM, which can be used for calculating airflows if sufficient data on openings, wind speed and direction, temperature differences, mechanical ventilation parameters, and so forth, are provided (Walton and Denton 2000).

Model Output and Analysis of Typical Cases

Although the multi-zone model adds the airflow among rooms as model input, it is essentially a lumped parameter model. Average VOC concentration is normally the primary concern. Besides, the model output can also include material emission rate, pollution load rate, and source contribution rate, etc., depending on the user's demands. The abundant outputs can provide designers with more useful information to finally make an optimal technical route.

IAQ problem has been designed using the multi-zone model in a comprehensive office building (Liang 2015). The focused building has 11 rooms. Formaldehyde concentration in each region at the delivery phase is simulated, and the results are shown in Fig. 11a. The model predicted that the office located in the northwest corner (called head office) has a significantly higher formaldehyde concentration than other rooms due to insufficient ventilation. This brings a challenge for material selection if a comparable concentration level is to be achieved. Further analysis is performed based on another model output, that is dynamic source contribution rate shown in Fig. 11b. At the initial decoration stage (2112–2880 h), room formaldehyde mainly comes from wet materials, such as wall paint. As time goes by (2880–5040 h), the added dry materials replaced the wet materials to became the main sources. At the time of building delivery (5040 h), emissions from furniture and carpets are significantly more than other materials, contributing more than 90% of the indoor formaldehyde. Hence, an improvement suggestion is to replace furniture and carpets with other low-emission materials indoors. Although not shown in the figure, the model predictions show that the improved design can significantly decrease formaldehyde concentration in the head office. Subsequently, interior decoration was carried out according to the improved design. The field investigations at the delivery time showed that formaldehyde concentration in the head office was comparable with those in other offices. Besides, formaldehyde concentrations in all the rooms were lower than the standard recommended value of 0.1 mg/m³ (GB/T

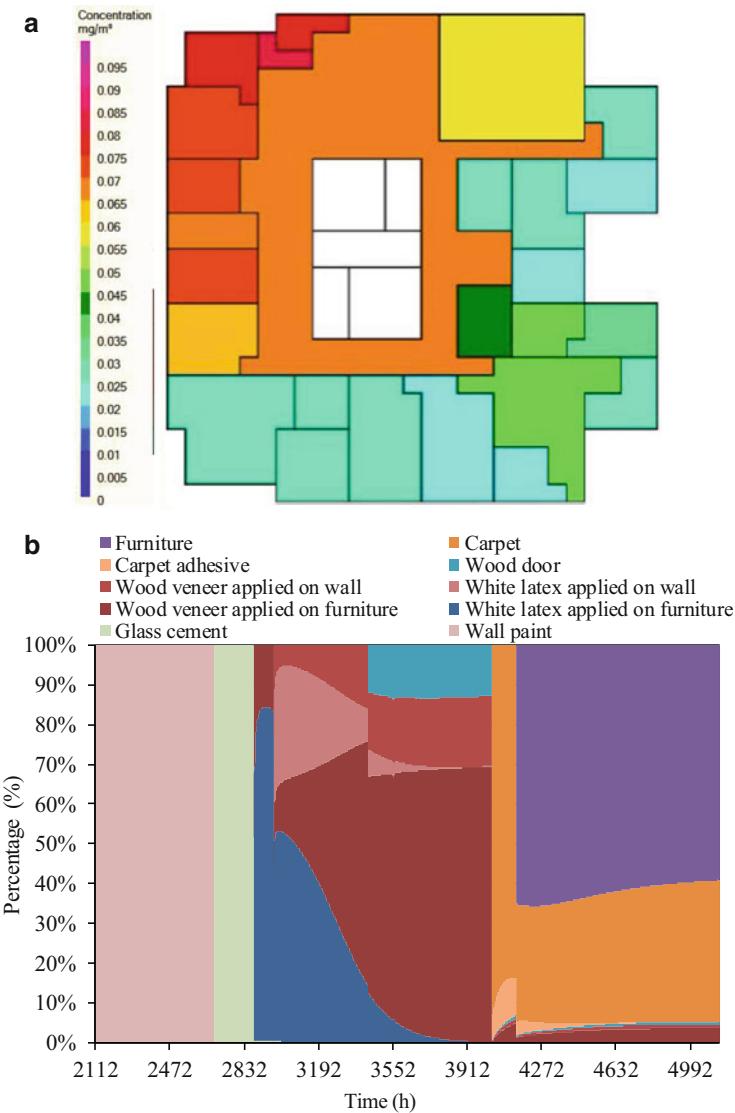

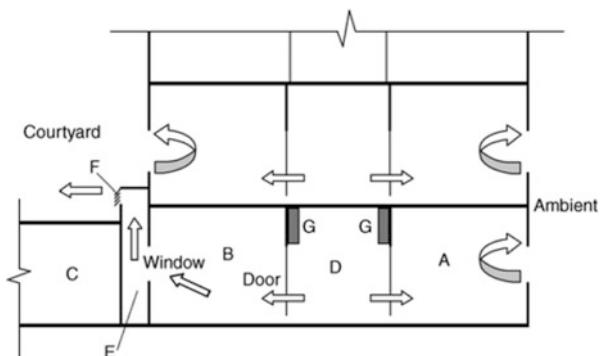

Fig. 11 Application of the multi-zone model in an office building: (a) Simulated formaldehyde concentration at the building delivery time; (b) Dynamic source contribution rate for the head office (Liang 2015)

18883-2002 2002). The good agreement between measurement and simulations indicates that the multi-zone model can prevent possible VOC pollution from initial occurring.

The multi-zone model can also help to analyze the transmission of respiratory infectious diseases, such as SARS. One previous study has reported a cross-infected

Fig. 12 The layout of the corridor and adjacent rooms with possible flow directions (plan view). A-orthopedic clinic room A; B-orthopedic clinic room B; C-critical care room; D-corridor; E-interlayer; F-grille; G-patient beds (Jiang et al. 2010)

incident occurred in an actual hospital (Jiang et al. 2010). Figure 12 is the layout of the focused building. The corridor near the emergency treatment center was where the infections occur. A total of 12 SARS patients were hospitalized here from April 17 to 22, 2003. Rooms A and B were offices with four orthopedic physicians working in each room. Room A was connected to the outside through a window, which was open for most of the 6 days. Room B was connected through a chimney that only enabled air to exit the room as the outside temperature was cooler than the inside temperature during that period. A few days later, all four physicians in Room B were diagnosed with SARS while none of the physicians in Room A was infected. All the 8 orthopedic physicians in Room A and Room B had never direct contact with SARS patients and their daily routines were very similar. The only identified difference was their office rooms' ventilation. Room A was well ventilated with outside air through a window while Room B was ventilated with air from the corridor where the 12 SARS patients were hospitalized.

Jiang et al. (2010) simulated the virus concentration in Room B to expect to find the infected reason. Trace gas SF₆ was released in the same locations as the SARS patients' bed to simulate the SARS virus exhaled by infectors. Combined with field ventilation, the average SF₆ concentration in Room B was calculated using the multi-zone model. As the red line shown in Fig. 13, the SF₆ concentration in Room B was predicted to reach 800 ppm, which resulted high infective risk. To validate the simulation results, SF₆ concentration at a series of points along the corridor and different locations in Room B were sampled, and the results are shown in Fig. 13. Good agreements were observed between the simulation and the measurement, indicating that the multi-zone model is capable of predicting the transmission of SARS before the virus actually spreads. In addition, the study also reproduced the SARS infected cases in another two hospitals in Beijing. By comparing the released SF₆ concentrations with those measured in the room in these typical cases, Jiang et al. (2010) concluded that a 10,000 times dilution can significantly reduce the risk of SARS infection. These findings show that reproducing actual infective and non-infective cases with simulation is a valid method for determining safe

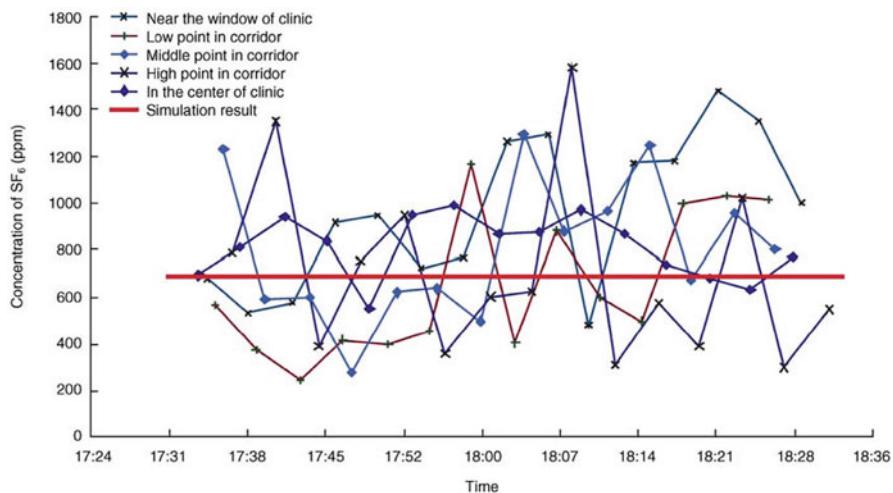

Fig. 13 Comparison of measured and simulated results of the SF₆ concentration in the corridor (Jiang et al. 2010)

ventilation rates for the purpose of maintaining an infection-free building environment. Further, simulation and modeling provide a methodology for preventing respiratory infective diseases and designing a safe building environment.

The multi-zone model is established based on the mass balance theory. It thus has some similar characteristics as the single-zone model, including concise mathematical expression, easy-to-understand mechanism, and clear physical meaning. Besides, the ability to distinguish concentration differences among zones enables broader application of the multi-zone. For example, it has been applied to predict the dynamic variations of chemical concentrations in 73 different zones of an educational building as a result of chemical release inside a zone or at outdoor air supply inlet, and use the information in an evaluation planning model to minimize the exposure of occupants to the pollutant (Zhang et al. 2005). However, the multi-zone models cost more computer power than the single-zone model and require accurate knowledge or modeling of the inter-zonal airflows. Additionally, no information is provided on the spatial distribution of the contaminants, and local VOC exposure cannot be evaluated using this type of model.

Example Software Tools

Compared with the program based on the single-zone model, existing multi-zone contaminant simulation software are more abundant, including IAQX, RISK, MCCEM, CONTAMW, and COMIS. Their simulation procedures and applications have been well summarized in the literature (Guo 2000; Sparks 1996; Koontz and Nagda 1991; Dols and Walton 2002; Feustel 1999). However, the limitation of these

programs is that source and sink models are either simplified or empirical, making these tools perform well only for certain specific conditions. To explore general use, more integrated tools have been developed including CHAMPS-Multizone and PACT-IAQ (Zhang 2005; Wei et al. 2012; Liang et al. 2017).

Champs

Syracuse University developed a Coupled Heat, Air, Moisture, and Pollutant Simulation (CHAMPS-Multizone) software in collaboration with the Technical University of Dresden of Germany. Models used in the tool are physics-based. Identifications of model input and their determinations have been well summarized in the literature (Zhang 2005). The program output includes not only the VOC concentration but also the airflow, moisture, and energy consumption. Therefore, CHAMPS is a comprehensive simulation tool. Applications of the CHAMPS may include, but are not limited to:

- Understanding and predicting the material emission characteristic and their impact on IAQ;
- Locating pollutant sources;
- Optimal placement of distributed sensors for intelligent control of building environmental system;
- Development of new materials for the built environment that have the required transport properties for heat, air, moisture, and pollutant control in buildings.

Pact-IAQ

PACT-IAQ was jointly developed by Tsinghua University and Shenzhen Institute of Building Research Co., Ltd. It is characterized by estimating the dynamic pollutant loads and concentration variations by considering the coupled effects of source, sink, and ventilation. Models used in the program are physical-based. Compared with other programs, one obvious improvement is that the PACT-IAQ can give accurate responses to dynamic environmental changes, and model predictions have been examined by a series of actual engineering applications. Such an advantage extends the IAQ predictions from the laboratory to real buildings. More importantly, the PACT-IAQ develops a comprehensive database containing hundreds of materials and provides sufficient support for IAQ design. Required inputs include key parameters, applying areas, and installed schedules of sources and sinks, ventilation among zones, ventilation between indoor and outdoor, hourly indoor temperature and humidity, and room volume. The user has a wide selection of simulation output including:

- Hourly indoor VOC concentration;
- Hourly pollutant load or emission rate contributed by each building material;
- Optimal material selection based on the designed concentration;
- Suggested check-in time based on exposure assessment;
- Effectiveness evaluation for various ventilation modes.

Computational Fluid Dynamics Modeling and Simulation

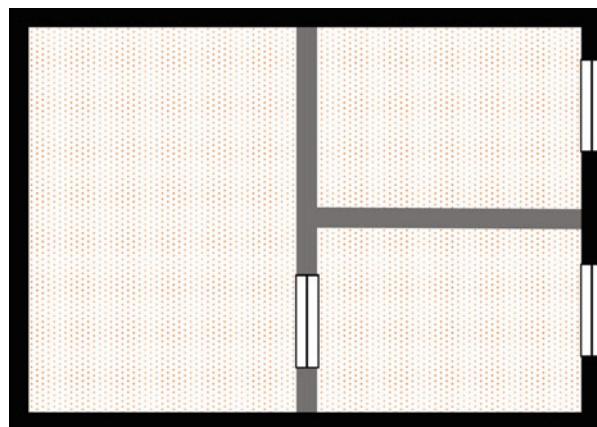

Both single-zone and multi-zone models focus on average in-room VOC concentrations. However, there are situations where the local concentration is of interest instead of the average in-room concentration. For this type of application, the CFD model may provide the desired predictions. Its principle and application are summarized in this section.

Purpose Identification and Model Selection

CFD model is also one physics-based model which can be used for predicting airflow distributions or air movement within buildings (as shown in Fig. 14). Coupled with the source and sink models, the CFD model can give the spatial distribution of pollutant concentration. Therefore, it is particularly welcomed for IAQ problems where the airflow parameters or the local personal exposures are needed. Buildings that are suitable for applying CFD models include:

- Shopping mall
- Factory
- Theater
- Gym
- Hospital
- Cleanroom
- Chemical laboratory

Fig. 14 Schematic of VOC mass transfer by CFD model: Plan view of a one-store building. (Modified from Abdalla and Peng 2021)

Multiple nodes per room

The first four types of buildings usually have enormous interior volumes. In these buildings, IAQ control for the whole space is expensive and sometimes unaffordable. Creating a locally healthy and comfortable environment through reasonable airflow design becomes a more realistic choice. In contrast, the last three types of buildings have limited space, but pollutants in rooms may cause serious health problems. Personal exposure becomes an important design parameter in these buildings. Both demands can be realized with the help of CFD models.

Governing Equations and Solving Methods

CFD model is developed based on the Navier-Stokes equation, which is for describing viscous fluid flow. It was developed first by Navier in 1827 and extended later by Stokes in 1845. One general expression of the Navier-Stokes equation can be written as:

$$\frac{\partial \vec{v}}{\partial t} + (\vec{v} \cdot \nabla) \vec{v} = \vec{f} - \frac{1}{\rho} \nabla p + \frac{\mu}{\rho} \nabla^2 \vec{v} \quad (4)$$

where \vec{v} is the velocity vector (m/s), t is the time (s), \vec{f} is the external force per unit volume of fluid (N/m^3), ρ is the fluid density (kg/m^3), p is the pressure (N/m^2), μ is the dynamic viscosity coefficient (m^2/s).

As known, the Navier-Stokes equation is used for analyzing flow characteristics of the laminar viscous fluid. However, most of the real-life engineering problems, including indoor airflows, are not laminar but turbulent flows. To make turbulence prediction possible, more effort has been paid to the improvement of the Navier-Stokes equation, and a series of turbulence models were then developed. The well-known turbulent models for indoor airflows include the Prandtl mixing length model, the Spalart-Allmaras model, the Standard k-e model, the RNG k-e model, the Realizable k-e model, the Standard k-w model, the SST k-w model, and the Reynolds stress model (Obermeier 2010; Paciorri and Sabetta 2003; Cheng and Wang 1997; Sun et al. 2017; Thompson and Hassan 2015).

Note that, these models include a series of partial differential equations, meaning that they do not have an analytical solution in the full form. Hence, the numerical solution becomes the prior choice. The flow domain is divided into small computational cells or finite control volumes. For each cell, an algebraic set of the conservation equation can be developed based on the finite difference method, finite volume method, finite element method, or finite analytic method. The algebraic equation is then solved in each computational cell using an iterative manner. In this regard, the CFD method is a numerical approximation of the Navier-Stokes governing equation.

Model Inputs and their Determinations

Input parameters of the CFD models involve basic physical parameters and boundary conditions of the fluid. Physical parameters represent the basic characteristics of

fluids, and generally include fluid density, molecular weight, and viscosity, etc. They can be determined once the fluid being studied is confirmed. Boundary conditions are the physical conditions that variables should meet on the computational boundary, which can be divided into the following categories:

- Fluid inlet and outlet parameters: including inlet and outlet pressure, speed, and mass flow, etc.
- Surface boundary conditions: including parameters or equations at the outer boundary of the calculation domain and the solid walls within the calculation domain.
- Internal unit partition: including fluid partition and solid partition.

Determination of boundary conditions depends on actual engineering problems or design requirements so that a desired fluid flow prediction result can be obtained. If the spatial distribution of VOC concentration is going to be evaluated, input parameters of source and sink are also needed.

Model Output and Analysis of Typical Cases

Output parameters of CFD models include airflow velocity, temperature, pressure, and pollutant concentration, etc. The various types of output parameters and detailed spatial distributions provide designers with more useful information than single-zone mass balance models. Such an advantage makes CFD methods welcomed in IAQ design where spatial distributions of pollutants are of concern.

An important application of the CFD model is to design airflow patterns, usually by means of mechanical ventilation. Normal airflow modes include mixing ventilation, displacement ventilation, stratum ventilation, and personalized ventilation, etc. Zhang et al. (2020) compared the effect of mixing ventilation (Fig. 15a) and displacement ventilation (Fig. 15b) on the removal of formaldehyde in the office. CFD simulation results show the formaldehyde concentration is relatively uniform in the room with the ceiling-supply and floor-exhaust mixing ventilation, which may cause the cross mixing of airborne contaminants. In contrast, formaldehyde concentration is stratified by floor-supply and ceiling-exhaust displacement ventilation, with a relatively low concentration in the seated occupational zone and a high concentration near the ceiling. Such concentration stratification is very helpful for reducing airborne pollutant exposure to the occupants. The high concentration near the ceiling also improves the pollutant exhaust efficiency. Therefore, if IAQ at the occupational zone is concerned, airflow design should refer to displacement ventilation rather than mixing ventilation. Note that, airflow design based on CFD simulation is particularly suitable for the occupied apartments or new buildings where the decorations have been completed.

Evaluation of personal exposure is another important use of CFD models. This is especially important for the prevention and control of respiratory infective diseases. Fig. 16 shows the simulation results of SARS-CoV-2 spread in a restaurant using the

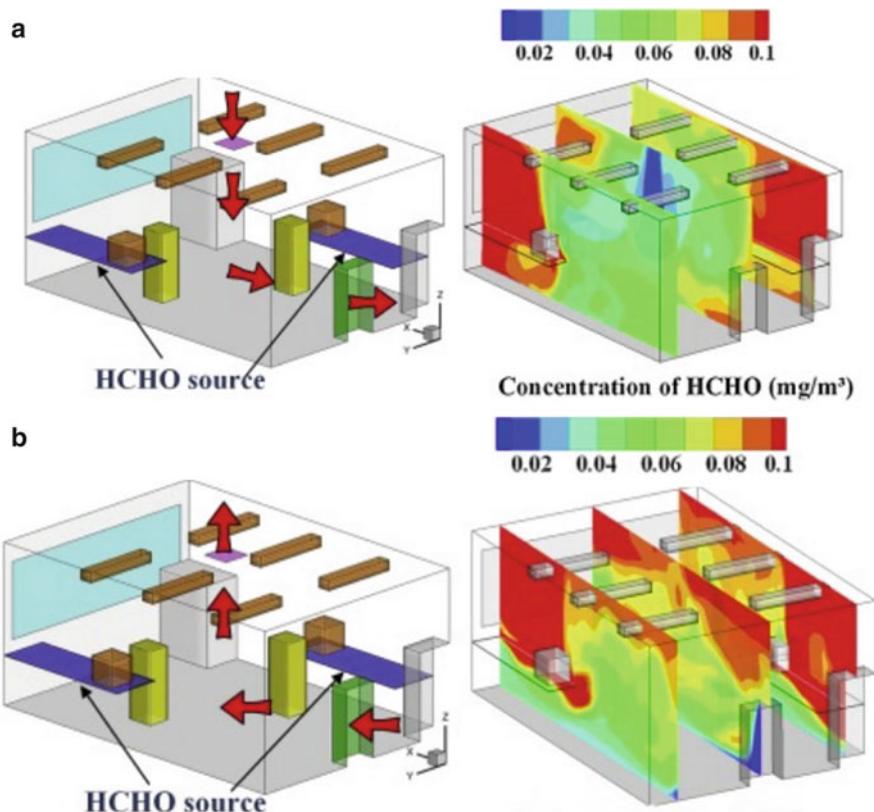

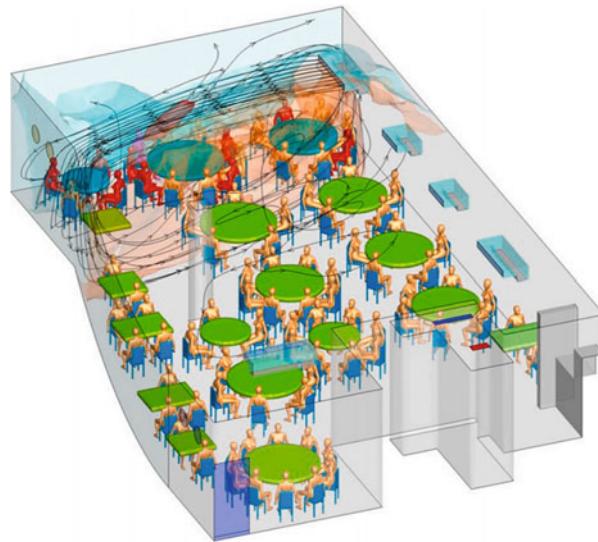

Fig. 15 Simulation of formaldehyde removal efficiency: (a) Mixing ventilation; (b) Displacement ventilation (Zhang et al. 2020)

CFD method (Li et al. 2021). A vortex zone is created due to the jet of the air conditioner. The virus is exhaled by the patients and then moves up to the vortex zone under the driven thermal plume. This will significantly increase the individual exposure of SARS-CoV-2 in the vortex zone. The model predicts that humans marked red color are possibly infected. Others, even in the same restaurant, have relatively low infection risk by staying away from the vortex zone. The model predictions successfully reproduced the SARS-CoV-2 infected event in a restaurant in Guangzhou. The good agreement between simulation and reality shows that the CFD model is capable of assessing individual exposure, which is of great significance for preventing the possible occurrence of respiratory infective diseases.

Compared with the single-zone mass balance model, the CFD models have the following advantages. CFD model predicts pollutant concentration at individual points in a room instead of the average concentration, which provides considerably more information for IAQ designers. More importantly, the CFD model considers the flow parameters of the bulk air when solving the equation, which means more robust and accurate prediction results. However, CFD models need to solve a set of

Fig. 16 The potential spread of coronavirus in a restaurant (Li et al. 2021)

partial differential equations instead of the ordinary differential equations, which requires significantly more computing power. It also requires good knowledge of the boundary conditions, which sometimes are difficult to obtain especially with regard to their spatial distributions (e.g., air velocity distribution across a diffuser outlet, spatial distribution of wall temperature). Therefore, the CFD method is more expensive. Besides, the abundant output will cost more time on results examination, and a high level of engineering background for the users is thus required.

Example Software Tools

With the improvement of CFD technology, more and more commercial software was developed to solve IAQ problems. Typical tools include Fluent, Phoenix, CFX, etc. (You et al. 2021; Stathopoulou and Assimakopoulos 2008; Majid et al. 2013).

Fluent

Fluent can simulate the complex flows ranged from incompressible fluid to highly compressible fluid, and therefore has a wide applying range. Uses include evaluation of the airflow efficiency for mechanical ventilation and natural ventilation, calculation of point pollutant concentrations, and assessment of individual exposure, etc. The programming language of the software is C++, which consumes less computer memory. Besides, Fluent contains advanced turbulence models, which can be used to analyze various engineering airflow problems. Moreover, Fluent adopts progressive solving methods and multi-grid convergent technologies, which significantly improve the prediction accuracy and calculation speed. Fluent has a user-friendly interface and provides a secondary input port for its users. This means that the

user-defined source and sink modules can be simultaneously solved in the Fluent program, and satisfy the individual needs to the greatest extent. These improvements enhance the competitiveness of Fluent in dealing with IAQ problems. Despite its indisputable strengths, strong engineering background, and a high level of computer skills are required for its users.

Phonics

Phonics is short for “Parabolic Hyperbolic Or Elliptic Numerical Integration Code Series,” and is the commercial software for computational fluid and computational heat transfer. Phonics provides three coordinate systems including right angles, cylinders, and spheres, which can analyze compressible or incompressible, single-phase or multi-phase, steady-state, or transient flow in three-dimensional space. Phonics has excellent openness, and allows users to modify the existing models or add new models in the software using the FORTRAN language. In addition, Phonics has good communications with external tools, such as the CAD program. Graphics files in the CAD can be directly imported into Phonics for use, which greatly facilitates the modeling process. Similar to Fluent, Phonics also contains a series of turbulence models, providing wide options for engineering problems.

CFX

CFX is a practical tool used to analyze flow problems in aerospace, energy, petrochemical industry, mechanical manufacturing, automobiles, biotechnology, water treatment, and environmental protection, etc. CFX uses the finite volume method to discretize the computational domain. Combined with the fully implicit and multi-grid coupled solving technology, both prediction accuracy and calculation speed of the software have greatly improved, but also consume more computer memory.

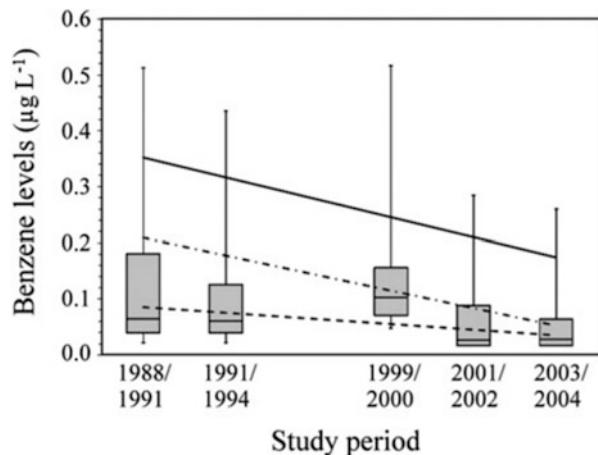

Data-Driven Models

Physical models are always trusted in IAQ design because they are developed based on the mass transfer mechanism. However, the physical model may suffer troubles in the following situations. One is that the mass transfer mechanism is too complicated or not well understood so that it is difficult to find a suitable mathematical description. Another is that the design process based on physical models is too time-consuming or expensive. In these situations, data-driven models become an alternative choice.

The data-driven model, also known as an empirical model or black-box model, is characterized by data causality and developed with advanced research or data collection. Data sources for this type of model can include actual measurement experience via laboratory tests or field investigations, available results from literature or reports, and even suggestions from the industry experts. Data used for this type of model is usually required to be large in quantity so that the potential associations behind the data can be discovered. Statistical analyses are also needed to give a correct mathematical expression.

Su et al. (2011) analyzed toluene personal exposures in the United States using the data-driven model. Data in the research come from the National Health and

Fig. 17 Box plot of benzene concentrations showing 0.05, 0.25, 0.50, 0.75 and 0.95 quantiles for each NHANES cohort. Linear QR trend lines for 0.5, 0.75, and 0.95 quantiles are shown as dashed, dashed and dotted, and solid lines, respectively (Su et al. 2011)

Nutrition Examination Survey (NHANES), which has collected tens of thousands of samples in 15 years. Figure 17 is a box diagram of toluene exposure, showing 0.05, 0.25, 0.50, 0.75 and 0.95 quantile distributions. The investigations show that overall toluene exposure decreases over time. Further, the statistical analysis found that 0.5, 0.75, and 0.95 quantiles follow a linearly decreasing trend, and corresponding mathematical equations are then provided. With these regressed mathematical equations, toluene individual exposures can be approximately estimated in the next few years. The prediction can help to improve policies or national standards and are of great significance for maintaining a safe exposure to indoor pollutants.

The data-driven model is more user-friendly compared with the physical model. Its development is independent of pollutant mass transfer mechanism, and thus has a lower requirement for professional skills. However, a data-driven model cannot provide insight into the physical processes, making it incapable of discovering some general conclusions. In addition, the data-driven model does not allow separation of influencing factors (sources, sinks, and ventilation, etc.), and special attention should be paid when the result scaling from one situation to another (from environmental chamber to actual buildings). Moreover, a data-driven model performs its best when large quantities of high-precision data are provided, which undoubtedly have more rigorous requirements for the data source.

Conclusions and Future Perspectives

Conclusions

This chapter introduces the performance-based IAQ control method that is based on modeling and simulation to accurately predict indoor air pollution characteristics at the design stage. It enables early intervention to prevent the possible occurrence of indoor air pollution. This performance-based approach is conducted without the

expense of large field experiments, and thus could prevent indoor air pollution in a time- and cost-effective way. The successful implementation of this method relies on models, which are built upon physical mechanism or experimental data to accurately predict the behavior of pollutants under key influencing factors including source, sink, ventilation, temperature, and humidity. For IAQ problems, commonly used models include physics-based and data-driven models.

The physics-based models include the single-zone, multi-zone, and CFD model. Single-zone and multi-zone models can provide the tools best suited for studying general IAQ problems in offices or residences with limited interior volumes. These models have an easy-to-understand mechanism. The numerical solution is recommended because of the complex differential equations for source and sink. A typical engineering case has confirmed that the mass balance model can give good predictions even under complex environmental conditions.

When indoor airflow characteristics or personal exposures are desired, the CFD model is a good choice. CFD model usually works together with the source and sink models in an IAQ problem. The numerical solution has become the only option due to the extremely complex mathematical expression of the Navier-Stokes equation. CFD model can provide point concentration rather than average concentration. Such an improvement makes it welcomed for local IAQ control or personal exposure assessment.

The data-driven model is independent of physical mechanisms and is developed upon abundant available data. Normally, statistical analysis is a good assistant for the data-driven model, which can help extract a mathematical description. A data-driven model is often simple and easy to use. If the data is sufficient and credible enough, the data-driven model can be tried in any type of buildings. However, the lack of communication with the mass transfer mechanism limits the flexibility of the data-driven model in data transfer, and a non-negligible deviation may be introduced once the environmental conditions are different. In this regard, the data-driven model is not as robust and scalable as the physics-based model.

Future Perspectives

Although the performance-based method based on modeling and simulation has been proved to be able to prevent possible air pollution, a lot more efforts are still required to make IAQ simulations readily useful in actual engineering applications, including:

Various Source Emission Models

With the improvement of living standards, more types of building materials may be installed indoors to satisfy the occupants' yearning for a comfortable life. The corresponding source emission model should be developed so that the pollutant transmitted behavior within buildings can be accurately predicted. This chapter has limited the discussion to primary emissions from building materials and furnishings. Emissions from occupant activities and secondary emissions due to chemical

reactions (e.g., ozone initiated indoor air and surface chemistry) should also be considered in the future.

Health Effect

Since different pollutants may have various effects on health even if they have the same concentration levels, and a health index of individual compounds and their interactions should be considered.

Occupant Behavior

Humans can be considered an important part of buildings. On the one hand, occupant behaviors can determine IAQ. On the other hand, the IAQ could influence occupant behaviors. The interrelation between occupant behaviors and IAQ needs to be considered.

Smart Sensors and Big Data

On-line air pollutant monitoring technology should be considered, which provides an extended “eye” to reach out to remote sites at a larger scale and collecting “big data.” Advanced simulation technologies combining these online monitors provide an effective tool to predict the indoor contaminant levels and optimize the control strategies.

Various Control Strategies

In terms of the new building, source control may be the most effective way to prevent air pollution. However, this strategy may face limitations in buildings where the interior decoration has been finished. In such cases, the focus may be paid to comprehensive control strategies combining source control, ventilation, and air cleaning.

Combined IAQ and Energy Modeling and Simulations

This chapter has focused on modeling and simulation of pollutant concentrations in buildings. As IAQ and energy efficiency strategies can affect each other. Combined IAQ and energy modeling and simulation methods and tools need to be further developed to evaluate tradeoffs and devise most energy-efficient and cost-effective strategies for improving IAQ.

Abstract

Considering the alarming rise in the rate of asthma and respiratory diseases among school children, it is of great importance to investigate all probable causes. Outside of the home, children spend most of their time in school. Many studies have researched the indoor air quality of elementary and secondary school buildings to determine the exposure of school children to indoor air pollution. However, studies of exposures to very young children in day-care centers are scarce. Unlike at elementary schools or universities, children in day-care centers are more vulnerable due to their physiology, inability to articulate discomfort, or to adapt their behavior to avoid exposures. This chapter reviews current studies on the indoor environment in day-care centers. It summarizes air pollution levels and related environmental and behavioral factors in day-care centers that have been reported in the literature. Additionally, exposure to indoor air pollution and related potential health outcomes are examined. This chapter concludes that indoor air pollution in day-care centers often exceeds current guidelines, and designers and policymakers should be made aware of the impact on the health and wellbeing of children in day-care centers. Proper interventions and guidelines should be considered to create a healthy indoor environment for children in day-care centers.

Keywords

Indoor air quality (IAQ) · Day-care center · Health impacts

Introduction

Day-care centers, also called kindergartens, nurseries, or preschools, offer children from 6 weeks to 6 years old daily care and early education before they attend elementary school. The age ranges of the children who attend day-care centers vary internationally. Day-care centers are not categorized by a specific building type. The variety and complexity of building characteristics pose a challenge when trying to assess the indoor air quality in a comprehensive and cohesive way. Some day-care centers are purpose-built structures, while others are repurposed commercial or residential buildings. Compared to the uses for which these retrofitted buildings were designed, day-care center classrooms tend to have higher occupant densities (Singh et al. 2019), which can make the indoor environment in day-care centers worse due to inadequate ventilation to meet the occupant load.

Children, especially those under 6 years old, are more vulnerable than adults to environmental pollutants because their immune and respiratory systems are not fully developed. Children have a larger surface area to volume ratio; and a faster rate of respiration. Furthermore, children spend more time indoors, averaging 7–11 h/weekday in classrooms alone (Almeida et al. 2011). It has been shown that indoor air pollutants have the potential to damage children's central nervous systems

(Calderón-Garcidueñas et al. 2014) and that exposure to air pollutants before the age of 1 year may contribute to the development of childhood asthma (Deng et al. 2015). The evidence that has been gathered for these observed outcomes has been primarily focused on offices and residential buildings. What research there is on schools tends to be on elementary and secondary schools. There is a substantial and important lack of data and guidance about the indoor air quality of day-care centers.

A lack in evidence is compounded by a large range in types of buildings, their activities, and occupancy. Context changes drastically between countries and education systems. Yet there are no large-scale studies to create a comprehensive picture. This gap in the research means there is significant difficulty in understanding underlying trends and key factors influencing IAQ in day-care centers. Many published findings are contradictory or inconsistent, in part due to the difficulties of monitoring and comparing across different measuring periods, climates, countries, and building characteristics.

Studies focusing on indoor air quality in nursery environments were conducted in Europe, including Portugal, France, and Poland, as well as in South Korea, Singapore, and Canada. Only a few studies were available from developing countries. Many studies focused solely on a single parameter of indoor air quality. Temperature, humidity, CO₂, particulate matter (PM), and volatile organic compounds (VOCs) were the parameters most often studied. The number of nurseries monitored varied from 1 to 310, and classroom sizes also varied between studies. Most of the investigated classrooms were naturally ventilated, and the age of children was mainly older than 3 years. For studies conducted in a location with a varied climate, few included any observed seasonal differences. Most studies only measured for 1 day during occupied hours. Few studies measured for more than 1 day, and for those that did the measurement periods lasted from 2 to 9 days. The environmental monitoring methods used in the studies also varied between studies.

This chapter documents the state-of-the-art in research on the indoor air quality of day-care centers. The aims of this chapter are: first, to explore the perception of thermal comfort of children in day-care centers; second, to describe current ventilation strategies in day-care centers; third, to identify the type and scale of exposure of children to pollutants in day-care center environments. An extensive review of the literature on IAQ in day-care centers can be found in Zhang et al. (2021). In the future, day-care centers should be designed and built with a comprehensive approach that integrates physical characteristics, occupant behavior patterns, and avoidance of harmful microbial and chemical exposures in their design and operation (Chatzidiakou et al. 2012).

Building Typologies

Day-care centers offer children from 6 weeks to 6 years old daily care and early education before they attend elementary schools. They can be either publicly funded and operated, or privately run. Dudek (2007) identifies three main design approaches for day-care centers. First, newly designed buildings which focus upon a strictly

codified room schedule. In this approach, a series of quasi-functional zones with predetermined floor areas are designed for a certain number of children. This approach is widely used, with the safety and security of children as its first concern. In the second approach, spaces in the day-care center are adapted for new forms of teaching. In this circumstance, architects may be inspired by the work of pedagogy, and spaces can keep changing to match the evolving curriculum. The third is a child-orientated design approach. This approach is more subjective and may be driven by architects' personal experiences of childhood (Dudek 2007).

Within the published IAQ research, day-care centers were categorized based on different factors including their location (urban or rural day-care centers), and the type of ventilation used (naturally or mechanically ventilated). Other factors that can impact IAQ are the types of building and furniture material provided, cleaning and personal care products used, and classroom activities (such as arts and crafts). These and other influencing factors will be discussed later in the chapter.

Occupancy

While practices vary substantially, day-care centers typically offer early education for children under 6 years old, with children often grouped by age and allocated to different grades. Normally, there are three categories: infants less than 1-year-old, toddlers between the ages of 1 and 3, and children older than 3 years. As over-crowded classrooms are associated with high indoor air pollutant concentrations, proper child/staff ratios and floor space per child are often a requirement of local governments/authorities (Table 1).

Table 1 Recommended child/staff ratio and floor space per child

Age	Maximum child: staff ratio		Indoor space requirements US ^a	UK ^b
	US ^a	UK ^b		
≤12 months	3:1	3:1	42 sq. ft (3.9 m^2) of usable floor space per child; 50 sq. ft (4.6 m^2) per child is preferred	$3.5\text{ m}^2/\text{child}$
1-year-olds	4:1	3:1		$3.5\text{ m}^2/\text{child}$
2-year-olds	4:1	3:1		$2.5\text{ m}^2/\text{child}$
3-year-olds	7:1	8:1		$2.3\text{ m}^2/\text{child}$
4-year-olds	8:1	8:1		$2.3\text{ m}^2/\text{child}$
5-year-olds	8:1	8:1		$2.3\text{ m}^2/\text{child}$

^bRecommended by Department for Education, UK

Typical operating hours of day-care centers are around 9:00 am to 3:00 pm, Monday to Friday except for holidays. Opening hours can vary for different day-care centers. Studies have demonstrated that occupants have a significant influence on IAQ. One study reported that the PM concentrations in a day-care center started to rise from the beginning of the occupancy period and started decreasing after the end of the occupancy period (Branco et al. 2014). Another study reported an average PM_{10} level of 97.0 $\mu\text{g}/\text{m}^3$ during the occupied period and 58.2 $\mu\text{g}/\text{m}^3$ during the unoccupied period, and the PM_{10} concentrations were much higher when children were entering or leaving the classroom (Alves et al. 2013). Based on their conclusions, the rise in indoor PM levels are most likely caused by resuspension (Resuspension is covered in depth in ► Chap. 12, “Resuspension,” in this book by Ferro) and other internal activities.

The activities in day-care centers, and the corresponding effects, need further study. The table below (Table 2) shows the arrangement of the school day of a typical day-care center in the UK. The time periods for different activities are comparatively shorter than for elementary schools or higher institutions. The high frequency of activity changes may make it difficult for researchers to trace the associations between occupant activities and change in indoor air quality.

Function/Uses of Space in Day-Care Centers

In general, the main spaces of a day-care center include baby home bases (4 months to 2 year-olds), toddler home bases (2–3 year-olds), pre-school home bases (3–4 year-olds), garden, toilets, kitchen, laundry, staffrooms, storage, reception,

Table 2 Typical schedule of a day-care-center in the UK

Time (AM)	Activity	Time (PM)
Half day		
8:30	Children Arrive	12:15
8:45	Free flow & focus activity inside/outside	12:30

9:30	Free flow and focus time	Tidy
10:55	Tidy	Snack within group
11:10	Group time	Group time
11:30	Children's lunch	Home time

manager's office, medical room, and external facilities (Dudek 2013). Home bases are the most commonly used space in the day-care center, where children spend most of their time. There are many functions of home bases, e.g., for sleeping, learning, and playing.

One thing that sets day-care centers apart from other education buildings is the predominance of sleeping as a daily activity. Day-care centers typically have either sleeping-only rooms or offer mattresses for children to sleep on in the classroom. In Poland, a study measured two classrooms in one day-care center and found the highest CO₂ concentrations were measured in the afternoon nap time at the classroom of younger children (Mainka et al. 2015a). A similar conclusion was also reported by a study in the USA. Ferng and Lee (2002) found a high CO₂ concentration in sleeping-only rooms (a closed space without enough ventilation). Additional analysis of the relationship between the CO₂ peaks and sleeping activity was not provided. However, one explanation is that windows tend to be closed during naptime to keep the noise level down which leads to insufficient ventilation. More research is needed to further explain these findings.

The age of occupants is another element that may affect IAQ performance. In general, classrooms with older children tend to have higher PM levels. In Portugal, a study concluded that classrooms occupied by older children had the highest PM concentrations due to their greater mobility (increasing PM resuspension) when compared with the classrooms of younger children (Branco et al. 2014). Another study with a similar conclusion reported that PM (PM₁, PM_{2.5}, PM₁₀, and TSP) concentrations were higher in older children's (5–6 years old) classrooms due to the intensive activities of older children (Mainka and Zajusz-Zubek 2015).

Children's activities during classes are also important sources of pollutants in day-care centers (PMs, VOCs, etc.). Activities like painting, sculpting, other arts and crafts activities, and the use of do-it-yourself products may have an effect on air quality (Morawska et al. 2009; Fonseca et al. 2014). Additionally, some staff activities should also be noted. For example, high PM concentrations were reported during cleaning and cooking activities (Alves et al. 2013; Branco et al. 2014). In Portugal, a study concluded that canteens had the highest ultra-fine particulate matter (UFP) concentrations (especially during the children's lunch time) as they were connected to the kitchens using gas-fueled appliances for cooking (Fonseca et al. 2014). Cleaning solvents may also be the source of air pollutants, e.g., toluene, xylenes, and other VOCs (Mainka et al. 2018).

Air Temperature and Relative Humidity

According to ASHRAE (American Society of Heating, Refrigeration and Air Conditioning Engineers), Standard 55-2017, the recommended indoor temperature range for buildings in general is around 19–27 °C, and the recommended indoor relative humidity is between 30% and 60% (EPA 2012). Several studies from across the globe have measured the indoor air temperature and relative humidity in day-care centers and compared the results with current guidelines. Temperature and relative

humidity in most day-care centers lie within the comfort range. However, some studies reported thermal conditions outside this range (Daneault et al. 1992; Ruotsalainen et al. 1993; Zuraimi and Tham 2008; Kamaruzzaman and Razak 2011; Roda et al. 2011; St-Jean et al. 2012; Branco et al. 2015a; Zender-Swiercz and Telejko 2019).

One study measuring four day-care centers in Portugal reported a situation with lower temperature and higher relative humidity values compared with the guidelines recommended by ASHRAE. These conditions may be due to a poorly constructed or ageing building (e.g., insufficient thermal insulation and water intrusion), and the inappropriate use of heaters or air conditioning systems (Branco et al. 2015b). Another study investigated 26 day-care centers in the western United States. They reported that 42% of the monitored day-care centers were outside of the temperature comfort zone (34.6% lower and 7.7% higher), and during naptime, 26.1% of the day-care centers had a higher relative humidity than the comfort zone (Ferng and Lee 2002). In Poland, a study found high indoor temperatures, ranging from 24.0 °C to 29.6 °C during the daytime. The author explained this situation as the overheating due to reduced heat loss following increased insulation (Zender-Swiercz and Telejko 2019).

In addition to collecting temperature and relative humidity data from day-care centers, researchers assessed the thermal comfort of the children. Fanger's model is typically used to evaluate thermal comfort in school classrooms (Fanger 1973). It includes two indices, which are: Predicted Mean Vote (PMV) and Predicted Percentage of Dissatisfied (PPD). Adaptive models have also been developed to evaluate naturally ventilated buildings. These models adjust for occupant behavior, physiological, and psychological factors (Conceição et al. 2012). However, studies addressing thermal comfort of children in day-care centers are scarce, and it is difficult to get accurate feedback from children using traditional methods like questionnaires and interviews. Children have higher metabolic rates than adults, and when they are dissatisfied with the thermal conditions, they do not necessarily behave like adults to adapt to the environment (e.g., take off/add clothes, open/close windows). One study did focus on the thermal comfort of day-care centers in winter and spring (Mendes et al. 2014). They reported PMV between "neutral" (0) and "slightly cool" (≤ -1), on the thermal sensation scale. In Japan, Yoshida et al. (2000) used an indirect method of assessment by administering a questionnaire to teachers and observing the thermal responses of disabled day-care center children. They reported that about 40% of the children had thermo-regulatory disorders. Another study reported that children prefer lower temperatures (about 3 °C lower) than adults and girls prefer temperature about 1 °C lower than boys of day-care center age (Yun et al. 2014).

In summary, temperature and humidity are important elements in the study of indoor air quality. It has been well demonstrated that temperature and humidity have a strong influence on the perception of indoor air quality and on volatilization of chemicals used indoors (Fang et al. 1998, 2004; Haghhighat and De Bellis 1998). Notably, according to the available studies, day-care centers generally performed within temperature and relative humidity guidelines.

Ventilation

Ventilation moves outdoor air into a space to replace indoor air. It can be categorized into three types: mechanical ventilation, natural ventilation, and hybrid (or mixed-mode) ventilation. Natural ventilation can provide a high air-change rates at a low cost, but it is affected by the outdoor environment and might introduce other problems, such as outdoor air pollution, noise, and security issues. With mechanical ventilation, temperature, relative humidity, and air flow rate can be easily controlled, but limitations are maintenance and energy use. In most reported studies, the classrooms in day-care centers were naturally ventilated, with mixed evidence on the advantages and dis-advantages of mechanically and naturally ventilated spaces. In Canada, a study investigated 21 day-care centers, and 18 of them had mechanical ventilation systems. They concluded that mechanical ventilation systems were significantly associated with lower indoor CO₂, formaldehyde, and acetaldehyde levels due to higher ventilation rates. However, in this same study, 85% of the classrooms had mean CO₂ levels that exceeded 1000 ppm, which indicated that many day-care centers have insufficient ventilation (St-Jean et al. 2012). In another study, 83 predominantly naturally ventilated rooms and 40 predominantly mechanically ventilated rooms in day-care centers were sampled. Here, indoor CO₂ and human-related bacteria levels were significantly lower in naturally ventilated rooms. The air exchange rates, O₃, and fungal concentrations were significantly lower in mechanically ventilated rooms (Zuraimi and Tham 2008).

The indoor concentration of CO₂ can be used as an indicator of ventilation rate and indoor air quality. However, it is a poor indicator of outdoor-associated pollutants (e.g., traffic-related pollutants and fungi species). Indoors, CO₂ is mainly produced by respiration of occupants. Several factors can affect the concentration of CO₂ in indoor environments, including the ventilation rate, occupant density, activity level of occupants, and the occupied time (BB101 2018). The ASHRAE Standard 62.1-2016 (Ventilation for Acceptable Indoor Air Quality) recommends that indoor CO₂ concentrations should not exceed 700 ppm above the outdoor concentration (typically around 400 ppm), and when mechanical ventilation is used, indoor CO₂ concentrations in schools should be maintained at/or below 1000 ppm according to UK guidelines for schools (BB101 2018). The guidelines do not specify a difference between schools and nurseries.

Studies commonly report that CO₂ concentrations in day-care centers are high. Published results from several studies found 75% (out of 6 schools), 89.3% (out of 28 samples) and 90% (out of 91 schools) of the measured indoor CO₂ concentrations exceeded 1000 ppm (Daneault et al. 1992; Stankevica and Lesinskis 2017; Rejc et al. 2019). In France, one study reported that 75% of monitored day-care centers had mixed-mode ventilation; mechanical ventilation and operable windows with an opening frequency at least one time per day. However, 46.4% of these day-care centers still had CO₂ concentrations that exceeded 1000 ppm (Roda et al. 2011). Across numerous studies (see Fig. 1), measured indoor CO₂ concentrations ranged from 377 to 2750 ppm (Daneault et al. 1992; Yang et al. 2009; Roda et al. 2011; Yoon et al. 2011; Kabir et al. 2012; St-Jean et al. 2012; Mendes et al. 2014;

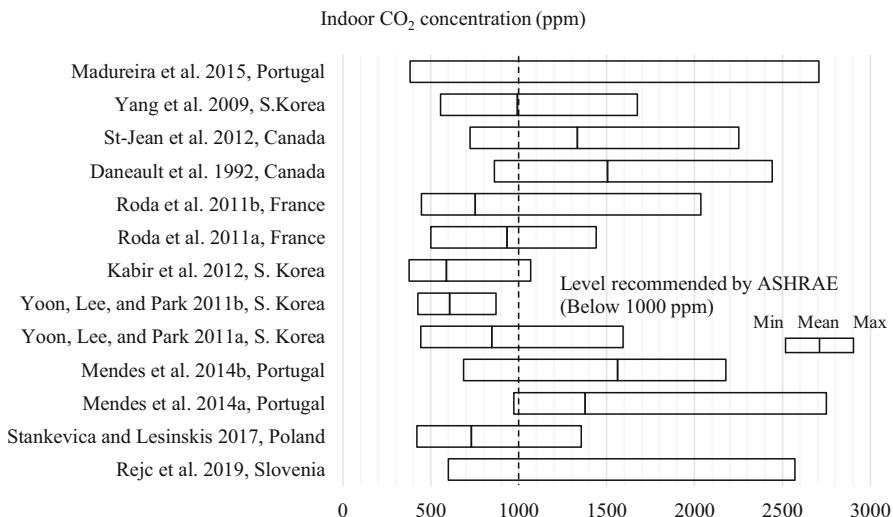

Fig. 1 Summary of reported indoor CO₂ concentration means and ranges (Zhang et al. 2021)

Madureira et al. 2015; Stankevica and Lesinskis 2017; Rejc et al. 2019). However, as monitoring methods (e.g., monitoring periods) used in the studies were different, comparing the results is tricky. Therefore, this range provides a snapshot of the CO₂ concentration published in the current research. As shown in Fig. 1, indoor CO₂ concentrations are relatively high in most studies. Canha et al. (2016) monitored seven day-care centers in France and reported a mean CO₂ concentration of 1200 ppm (Canha et al. 2016). However, low CO₂ concentrations (below 1000 ppm) do not guarantee acceptable indoor air quality. As one study done in South Korea reported, 41% of rural schools exceeded the South Korean IAQ standard for TVOC concentrations (400 µg/m³), even though the average CO₂ concentration was 607.8 ppm in these same day-care centers (Yoon et al. 2011).

Studies have reported that classrooms of younger children tend to have a higher CO₂ concentration than classrooms of older children. Additionally, higher CO₂ concentrations often occur during nap-time, about 104 ppm higher than non-nap-times (Ferng and Lee 2002; Mendes et al. 2014; Mainka et al. 2018). This finding was not explained, but could be due to less window opening, or higher occupant densities during nap times. The effect of inadequate ventilation on human health and performance includes: respiratory illnesses, allergies and asthma, sick building syndrome symptoms (SBS), reductions in performance and productivity and perceived air quality (Seppänen and Fisk 2004). Previous meta-analyses have reported that low ventilation rates might have adverse effects on the health of school children (Daisey et al. 2003). Sundell et al. (2011) and Smedje and Norbäck (2000) reported that increasing the outdoor air flow rate from 1.3 to 12.8 l/s·p (corresponding to a decreased mean indoor CO₂ concentration of 1050–780 ppm) and reduced asthma symptoms in pupils from 11.1% to 3.4% over a 2-year period. In addition to health

outcomes, a study in elementary and secondary schools reported that a 1000 ppm increase in indoor CO₂ related to a 10–20% increase in student absenteeism (Shendell et al. 2004). These studies were from school-age children, and work to confirm similar effects in younger children needs to be confirmed by more research.

Air Cleaning

There are three main approaches to improving indoor air quality: (1) eliminate sources of indoor air pollution, (2) improve ventilation, and (3) providing some form of air cleaning (Siegel 2016). Many studies attempted to track the sources of indoor air pollutants to suggest means of reducing the levels, and ventilation is recognized as an efficient method of diluting pollutants from indoor sources. However, these approaches are not always feasible, leaving air cleaning as an additional strategy to improve indoor air quality.

Air cleaners are designed to remove pollutants of different types. They may be integrated into the ventilation system to serve multiple spaces within a building, or they can be a portable or fixed (wall, window, or ceiling) device installed in one room or area. Current air filtration technologies were reviewed by Luengas et al. (2015) and Kelly and Fussell (2019), and are presented in ► Chap. 59, “Control of Airborne Particles: Filtration,” in this book by Stephens. The pollutants typically targeted in air cleaning are PM, VOCs, and bioaerosols. Studies reported efficient removal rates in many circumstances (Kelly and Fussell 2019). However, there are still limitations for each technology, including unwanted and potentially harmful by-products such as O₃, and NO_X. The literature review by Luengas et al. (2015) investigated various types of indoor air treatment and reported that “mechanical filtration is a simple and extensively used technique for removing suspended particles from indoor air.”

The use of air cleaning technology to reduce particulate pollutants in homes has been demonstrated to be effective in improving indoor air quality (Cooper et al. 2021). In the USA, a study found that an air cleaner intervention (using HEPA filtration) in homes substantially decreased the indoor PM_{2.5} levels, from 38 to 24 µg/m³ over a 12-month period (Eggelston et al. 2005). However, research on school and nursery environments is scarce, with relevant information from the few available studies in Table 3. One study selected 18 classrooms (9 control, 9 intervention) in 3 urban elementary schools. They reported that the PM_{2.5} levels in the intervention classrooms with HEPA filters were substantially reduced compared with control classrooms, with mean PM_{2.5} concentrations reduced from 6.2 to 2.4 µg/m³ (Jhun et al. 2017).

Two recent studies also reported the efficiency of air cleaners to improve indoor air quality in day-care centers. In South Korea, PM₁₀, PM_{2.5}, airborne bacteria, and fungi were measured for 5 days in ten nurseries before the use of air cleaners. The authors then took the same measurements with the air cleaners operating. The researchers reported that all pollutants were substantially reduced over the 3 weeks of air cleaner use. Concentrations dropped from 39.9 to 5.6 µg/m³ for PM_{2.5}, and

Table 3 Studies using air purifiers in day-care center environments

Study	No. of nurseries	Targeted pollutants	Filtration technology	Reference classroom	Outdoor levels	Study design	Conclusion/effectiveness
Rosén and Richardson (1999), Sweden	2	Particulate matter (0.3–7 µm)	Electrostatic Air Cleaning (EAC system)	No	Taken into consideration	Over 3 years, the EAC systems were turned on year 2, then turned off and left in place throughout year 3. Indoor particle counts were recorded for 24-h periods in one center only	Reductions of 78% for fine particles ($PM_{3.7}$) from outdoors. The very fine particles ($PM_{0.3-3}$) produced indoors were reduced by 45% compared with rooms without air cleaners, a substantial reduction from 428 to 232 particles/liter of air
Oh et al. (2014), S. Korea	10	$PM_{2.5}$, PM_{10} , airborne bacteria and fungi	Air purifier (LA-R119SWF, Korea)	No	Not taken into consideration	(1) $PM_{2.5}$, PM_{10} , airborne bacteria and fungi were measured with air purifier off (2) Air purifier was on for 5 days (3) Measured for 20 days. Concentrations compared before and after air purifier use	The concentration went from 39.9 to 5.6 $\mu\text{g}/\text{m}^3$ for $PM_{2.5}$ and from 81.3 to 15.0 $\mu\text{g}/\text{m}^3$ for PM_{10} . The bio-aerosol concentration went from 794.1 to 304.4 CFU/m ³ , and from 94.4 to 42.5 CFU/m ³ for airborne bacteria and fungi, respectively
Gayer et al. (2018), Poland	4	$PM_{2.5}$	HEPA filters	One in each nursery	Taken into consideration	In each of the selected classrooms where routine work was performed the air purifier was turned on for 24 h, 7 days a week, and in the other room the air purifier was turned off. Measurements of $PM_{2.5}$ concentration were taken over 5 days (3 working days and weekend)	Two classrooms were measured (one with an air cleaner and one without) in each nursery, the measured mean $PM_{2.5}$ concentrations were 20.9 and 33.0 $\mu\text{g}/\text{m}^3$; 13.3 and 7.3 $\mu\text{g}/\text{m}^3$; 17.8 and 8.4 $\mu\text{g}/\text{m}^3$; 17.1 and 13.0 $\mu\text{g}/\text{m}^3$ for the classroom with and without an air cleaner respectively

from 81.3 to 15.0 $\mu\text{g}/\text{m}^3$ for PM_{10} . The bio-aerosol concentrations decreased from 794.1 to 304.4 CFU/m^3 and from 94.4 to 42.5 CFU/m^3 for airborne bacteria and fungi, respectively (Oh et al. 2014). Another pilot study tested the efficiency of HEPA filtration in four day-care centers, they selected two classrooms (one with an air purifier and one without) in each nursery building. The measured $\text{PM}_{2.5}$ concentrations were respectively, nursery (A) 33.0 and 20.9 $\mu\text{g}/\text{m}^3$; nursery (B) 13.3 and 7.3 $\mu\text{g}/\text{m}^3$; nursery (C) 17.8 and 8.4 $\mu\text{g}/\text{m}^3$; nursery (D) 17.1 and 13.0 $\mu\text{g}/\text{m}^3$. Outdoor $\text{PM}_{2.5}$ concentrations were 35.5, 18.6, 26.9 and 21.9 $\mu\text{g}/\text{m}^3$, respectively. Although air cleaning appears to be an effective method of removing some indoor air pollutants, the links between their use and health improvements need further development (Gayer et al. 2018).

Indoor Air Pollutants

There are many kinds of indoor air pollutants, including PM, NO_2 , CO, and VOCs, and it is difficult to trace the sources of all indoor air pollutants. Pollutants can be from outdoor sources, via ventilation or infiltration, as well as from indoor sources, such as the use of cleaning products and emissions from building materials. Additionally, occupants may carry harmful pollutants from other environments into indoor spaces. This chapter presents common indoor air pollutants, including NO_2 , CO, O_3 , allergens, PM_{10} , $\text{PM}_{2.5}$, ultrafine particles, infectious diseases, fungi, VOCs, and radon.

NO₂

Compared to other indoor environments, day-care centers tend to have higher indoor NO_2 levels. Indoor levels are strongly influenced by outdoor levels associated with road traffic. For convenience, day-care centers are often located on the ground floor and close to main roads making them vulnerable to this pollutant (Roda et al. 2011; Villanueva et al. 2018). Reported indoor NO_2 levels in day-care centers (Fig. 2) ranged from below the limit of detection to 138.0 $\mu\text{g}/\text{m}^3$. Most studies did not report concentrations exceeding the previous annual mean value of 40 $\mu\text{g}/\text{m}^3$ recommended by the World Health Organization (WHO 2010), but the majority would now all exceed the latest annual limit (WHO 2021) of 10 $\mu\text{g}/\text{m}^3$ (Kamaruzzaman and Razak 2011; Roda et al. 2011; Villanueva et al. 2018). However, high indoor NO_2 levels in day-care centers in Portugal were reported with mean NO_2 concentrations in ten urban and five rural classrooms ranging from below the limit of detection to 136 $\mu\text{g}/\text{m}^3$ and 16.67–125.17 $\mu\text{g}/\text{m}^3$, respectively. The classroom with the highest NO_2 concentration was the one located on the ground floor with windows in the front (roadside) façade of the building (Nunes et al. 2016).

Contradictory findings have been reported for the relationship between occupancy and NO_2 concentrations. One study reported higher NO_2 levels in classrooms with more students (Villanueva et al. 2018). However, in another study, a classroom was measured both fully occupied and partially occupied for NO_2

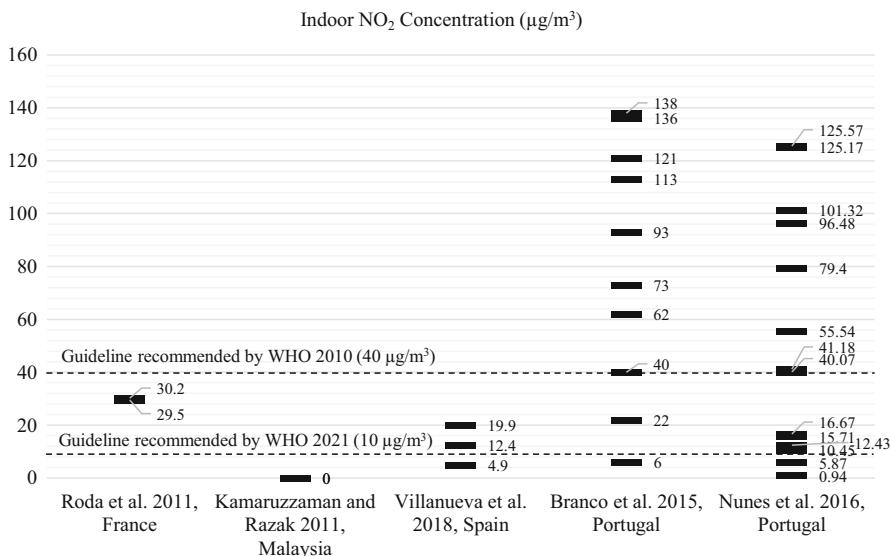

Fig. 2 Summary of reported indoor NO₂ concentration averages (Zhang et al. 2021)

concentrations, and the outcomes were 16.67 and 41.18 $\mu\text{g}/\text{m}^3$, respectively, indicating lower NO₂ levels with more students (Nunes et al. 2016). The relationship between indoor NO₂ levels and occupant density, or intermediately factors, warrants further exploration.

The health impact of NO₂ is primarily on the respiratory system, increasing the risk of lung infection and causing problems such as wheezing, coughing, colds, flu and bronchitis. A meta-analysis (the age range of children in the panel studies was 5–19 years) found that with an increase of 10 $\mu\text{g}/\text{m}^3$ of NO₂, there was an increase in asthma symptoms of 3.1% (Weinmayr et al. 2010). However, compared with other pollutants, the adverse impact of NO₂ on health may have a longer lag period, which contributes to the difficulty in studying the relationship between NO₂ exposure and health outcomes (Mukala et al. 1999).

Carbon Monoxide (CO)

One study in day-care centers reported that the CO found indoors was mainly from outdoor sources, and generally traffic related (Nunes et al. 2016). As a result, day-care centers located in urban and naturally ventilated buildings tend to have higher indoor concentrations (Zuraimi and Tham 2008; Nunes et al. 2016). However, there are still indoor sources that should be considered such as gas-fired heating systems, water heaters, dryers, and stoves as well as wood-burning stoves and fireplaces (Kabir et al. 2012).

Studies investigating CO levels in day-care center environments reported an average concentration range from 4.2 to 2786.0 $\mu\text{g}/\text{m}^3$ (Zuraimi and Tham 2008; Yang et al. 2009; Kabir et al. 2012; Cano et al. 2012; Alves et al. 2013; Mendes et al. 2014; Branco et al. 2015a; Oliveira et al. 2016). In Greece, a study investigated two elementary schools and one kindergarten in their research. They reported that during the heating season, one kindergarten that included kitchen facilities had an extremely high CO concentration of 4.2 ppm (approximately 4900 $\mu\text{g}/\text{m}^3$) (Kalimeri et al. 2016).

The health effects of breathing CO include headache, dizziness, vomiting, and nausea. If levels are high enough, people can become unconscious or die. The CO concentrations in the reviewed studies do not exceed the 6.1 ppm for 24-h exposure (approximately 7015 $\mu\text{g}/\text{m}^3$) set up by WHO (2010) guidelines. However, it should be noted that a study on elementary schools showed that with each 1.0 ppm increase in CO levels, the rate of absenteeism increased by 3.79% (Chen et al. 2000).

Ozone (O_3)

Indoor O_3 concentrations are mainly influenced by outdoor air. In most day-care centers indoor O_3 levels are significantly lower than outdoor levels because there are typically few indoor sources (e.g., printers, electronic air purifiers), and O_3 is highly reactive with products commonly used in nurseries (e.g., ozone/terpene reactions) (Kalimeri et al. 2016). One study investigated ten classrooms in four urban day-care centers, the mean O_3 concentrations in classrooms ranged from 9 to 24 $\mu\text{g}/\text{m}^3$. Higher mean O_3 concentrations ranging from 19 to 38 $\mu\text{g}/\text{m}^3$ in lunchrooms were reported, with no identifiable indoor sources. The author explained that this might be caused by the higher ventilation from outdoors in lunchrooms (Branco et al. 2015a). In another study, the authors compared O_3 levels in rural and urban day-care centers. Higher O_3 levels were reported in rural day-care centers, and the highest concentrations were associated with window opening (Nunes et al. 2016). They also concluded that O_3 concentrations were lower on weekends than on weekdays due to lower ventilation rates (less frequent window opening). In Singapore, a study focused on the difference between mechanically and naturally ventilated day-care center classrooms. Naturally ventilated classrooms had a mean O_3 concentration of 71.0 $\mu\text{g}/\text{m}^3$, which was significantly higher than the mechanically ventilated classrooms which had a mean concentration of 31.5 $\mu\text{g}/\text{m}^3$ (Zuraimi and Tham 2008).

A study from Portugal reported a mean O_3 concentration of 119 $\mu\text{g}/\text{m}^3$ (20–30 min sampling periods during mornings as well as in the afternoons for 5 working days) which exceeds the 100 $\mu\text{g}/\text{m}^3$ (over an 8-h period) recommended by WHO (2010). The outdoor mean O_3 concentration was 188 $\mu\text{g}/\text{m}^3$. The authors did not provide a reason for the high concentrations, but reported that the studied day-care center was located on streets with moderate levels of traffic (Oliveira et al. 2016). A list of studies and their reported findings on O_3 concentration can be found in Fig. 3. Based on the results of these studies, outdoor O_3 concentration and total

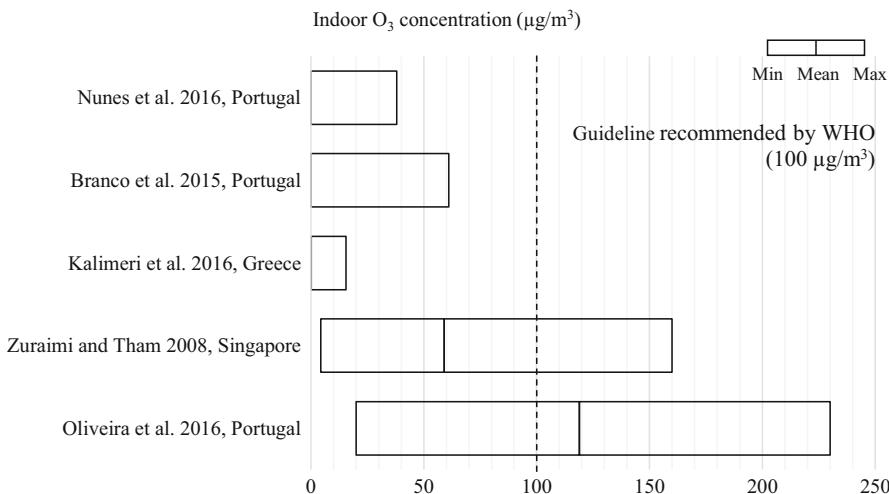

Fig. 3 Summary of study reported indoor O₃ concentration means and ranges (Zhang et al. 2021)

area cleaned are important elements that influence indoor O₃ concentration (Zuraimi and Tham 2008).

Exposure to O₃ is associated with various respiratory symptoms including coughing, wheezing, dyspnea, and other symptoms such as nausea and headaches (Carlisle and Sharp 2001). In Mexico, a study reported that when day-care center children were exposed for 2 consecutive days to relatively high O₃ levels (>0.13 ppm or 278.4 μg/m³), there was a 20% increased risk of respiratory illness (Romieu et al. 1992). Another study focused on primary schools estimated that an increase of 0.02 ppm (42.8 μg/m³) of O₃ was associated with an 82.9% increase in upper respiratory illnesses, 173.9% for lower respiratory illness with wet cough, and 62.9% for illness-related absence (Gilliland et al. 2001). A separate study, with similar outcomes, estimated that relative risks of illness-related absenteeism for O₃ were 1.08 (95% CI, 1.06–1.11) per 0.016 ppm (34.1 μg/m³) (Park et al. 2002).

Allergens

Studies have demonstrated that indoor allergens are common in day-care centers, and allergens can be different due to different geographic, climatic, and cultural factors (Salo et al. 2009). Higher concentrations of allergens were reported in the heating season than in the non-heating season (Roda et al. 2011). Most studies in day-care center environments reported a low concentration of allergens which did not exceed recommended levels; however, low levels of exposure still have the potential to cause allergic reactions (Grant et al. 2019).

Based on current studies, cat (*Fel d 1*) and dog (*Can f 1*) allergens were the dominant allergens found in day-care centers. Measured cat allergen (*Fel d 1*) ranged

from undetectable to 1.48 µg/g (Rullo et al. 2002; Instanes et al. 2005; Gülbahar et al. 2012; Cyprowski et al. 2013). Measured dog allergen (Can f 1) ranged from undetectable to 3.3 µg/g (Rullo et al. 2002; Instanes et al. 2005; Cyprowski et al. 2013). The concentrations of both dog and cat allergens were substantially higher on samples collected from mattresses and curtains than from pillows and soft toys. Cat allergens were reported up to 4.5 µg/g and dog allergens up to 10.0 µg/g on samples from mattresses (De Andrade et al. 1995; Instanes et al. 2005).

Dust mite (Der f 1 and Der p 1) and cockroach (Bla g 1 and Bla g 2) allergens were also detected in some studies. Dust mite allergens (Der f 1 and Der p 1) ranged from 0.13 to 5.40 µg/g and 0.05 to 21.8 µg/g (Fernández-Caldas et al. 2001; Roda et al. 2011; Gülbahar et al. 2012; Mendes et al. 2014). In Brazil, a study reported that dust mite allergens were greater than 2 µg/g in 67% of samples collected from day-care centers and preschools, and the highest levels were seen in a preschool bed with a mean Der 1 (Der p 1 + Der f 1) concentration of 6.3 µg/g (Rullo et al. 2002). Cockroach allergen levels were comparatively low or undetectable in other studies (De Andrade et al. 1995; Cyprowski et al. 2013).

The common reservoirs for allergens were carpeting, upholstered furnishings, and clothing (Salo et al. 2009). Animals were not allowed in almost all day-care centers, so the indoor allergens were mainly from the shedding of hair and clothing worn by occupants with pets at home. It should be noted that day-care center children are more likely to play on the floor than school children and therefore may be exposed to higher allergen levels. Cleaning was beneficial at reducing indoor allergens as reported by Smedje and Norback (2001).

Particulate Matter

PM is a complicated mixture of solid and liquid particles suspended in the air. It can vary continuously by location with a wide variety of physical and chemical characteristics (WHO 2013). Particulate matter is defined by its aerodynamic diameter, the USEPA (United States Environmental Protection Agency) has classified it mainly into two size categories: PM₁₀ and PM_{2.5}. Indoor PM is described in detail in the indoor air particles section of this book. Indoor PM concentrations are strongly influenced by outdoor sources (mainly from traffic emissions), and urban day-care centers tend to have higher PM levels than rural day-care centers (Oh et al. 2014; Nunes et al. 2015). There are also indoor determinants that strongly influence the PM level. In indoor environments, particles can be generated from human-related activities like cooking, activities of children (playing/walking), cleaning activities, shedding of skin cells, emission of clothing fibers, and from construction-related activities like renovation and reconstruction (Zuraimi and Tham 2008; Yang et al. 2009; Patel et al. 2020). Studies also find that higher indoor PM levels are associated with high occupant density and PM₁₀ concentrations are more sensitive to occupancy than PM_{2.5} (Alves et al. 2013; Branco et al. 2014; Rim et al. 2017). However, a small number of children in the classroom is enough to increase PM concentrations through re-suspension (Nunes et al. 2015). Indoor PM levels have been found to be

higher in the classrooms of older children, due to the high level of activity of older children (Branco et al. 2014; Mainka and Zajusz-Zubek 2015).

Particulate matter is a known cause of death and disability worldwide (Kim et al. 2015). Studies have demonstrated that PM has a negative impact on human health (e.g., respiratory and cardiovascular systems) and this impact is also true for children (McCormack et al. 2011; Kim et al. 2015). Particles can penetrate into the respiratory tract (Varghese and Gangamma 2009) posing a great threat to human health. Studies show that large-scale international or national interventions, as well as personal prevention approaches, might help to reduce particulate matter and improve indoor air quality (Kelly and Fussell 2019). In an example of one intervention study, two Swedish day-care centers used electrostatic cleaning systems, and reported reductions of 78% and 45% for fine particles (PM_{3-7}) and ultra-fine particles ($PM_{0.3-3}$), respectively. Additionally, illness-related absenteeism was reduced by 55% (Rosén and Richardson 1999).

PM₁₀

The reported PM₁₀ levels in indoor day-care center environments ranged from 6.8 to 216 $\mu\text{g}/\text{m}^3$ (Yang et al. 2009; Cano et al. 2012; Kabir et al. 2012; Oh et al. 2014; Mainka and Zajusz-Zubek 2015; Oliveira et al. 2016; Kaczmarek et al. 2017; Rim et al. 2017). As shown in Fig. 4, almost all the studies report indoor PM₁₀ levels that exceed the 50 $\mu\text{g}/\text{m}^3$ 24-h mean guidelines recommended by WHO (2013). Some studies find higher PM₁₀ concentrations during the heating season and lower concentration in the non-heating season (Oliveira et al. 2016; Kaczmarek et al. 2017). While others reported a higher PM₁₀ level in the non-heating seasons (Kabir et al. 2012; Mendes et al. 2014). In general, higher PM₁₀ levels in the heating season may be caused by solid fuel combustion and higher average outdoor concentrations. Higher PM₁₀ levels in the non-heating season might be influenced by increased

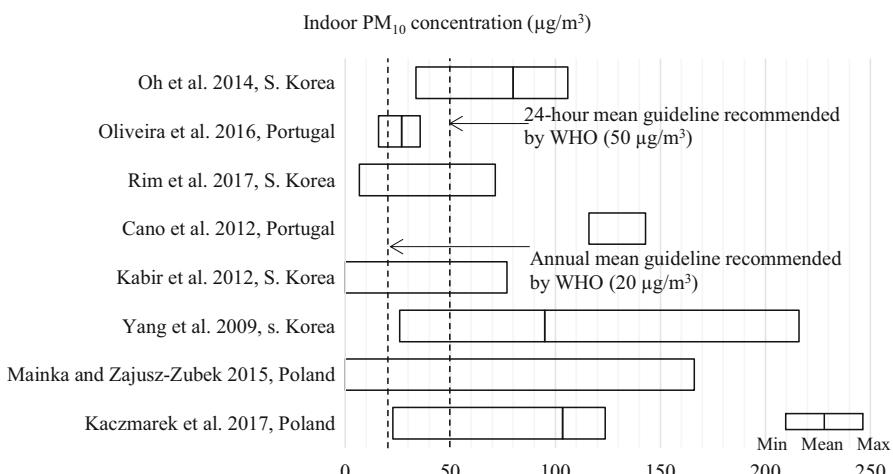

Fig. 4 Summary of reported indoor PM₁₀ concentration means and ranges (Zhang et al. 2021)

frequency of open windows (greater contributions from outdoor air). A meta-analysis reported that with an increase of $10 \mu\text{g}/\text{m}^3$ of PM_{10} , there was an increase of 2.8% in asthma symptoms and 1.2% in cough (Weinmayr et al. 2010). Exposure to air pollutants such as PM_{10} was associated with illness-related absenteeism in a 3-year study, with estimated relative illness-related absenteeism risks of 1.06 (95% confidence interval, 1.04–1.09) per $42.1 \mu\text{g}/\text{m}^3$ increase in PM_{10} (Park et al. 2002).

PM_{2.5}

The reported $\text{PM}_{2.5}$ levels in day-care center environments ranged from 3.2 to $177.2 \mu\text{g}/\text{m}^3$ (Zuraimi and Tham 2008; Wichmann et al. 2010; Oh et al. 2014; Mainka and Zajusz-Zubek 2015; Mainka et al. 2015b; Canha et al. 2016; Oliveira et al. 2016; Rim et al. 2017). The authors concluded that $\text{PM}_{2.5}$ was positively correlated with CO_2 levels and ventilation rates (the correlation were weaker for ventilation rates) (Canha et al. 2016). Outdoor $\text{PM}_{2.5}$ concentration (mainly derive from traffic emission), carpeted floor, presence of curtains and soft toys, recent renovation, shelf area, and fan cleaning are the key elements that could influence indoor $\text{PM}_{2.5}$ level (Zuraimi and Tham 2008).

$\text{PM}_{2.5}$ is a pollutant of significant concern worldwide due to its recognized association with negative health impacts such as cardiovascular disease and cancer. Due to the varied health risks of $\text{PM}_{2.5}$ exposure, WHO (2021) has established both long-term and short-term limit guidelines (5 and $15 \mu\text{g}/\text{m}^3$ respectively). As shown in Fig. 5, almost all the studies reported substantially higher indoor $\text{PM}_{2.5}$ levels than the $15 \mu\text{g}/\text{m}^3$. One study measured seven day-care centers and ten elementary schools and reported an average $\text{PM}_{2.5}$ level of $21.0 \mu\text{g}/\text{m}^3$ in day-care centers. In their research, all investigated classrooms exceeded the long-term limit of $5 \mu\text{g}/\text{m}^3$, and 31% of the classrooms exceeded the short-term limit. One study found that children exposed to an excess level of $\text{PM}_{2.5}$ have a greater risk of respiratory symptoms and reduced lung function (Gold et al. 1999). An epidemiological study

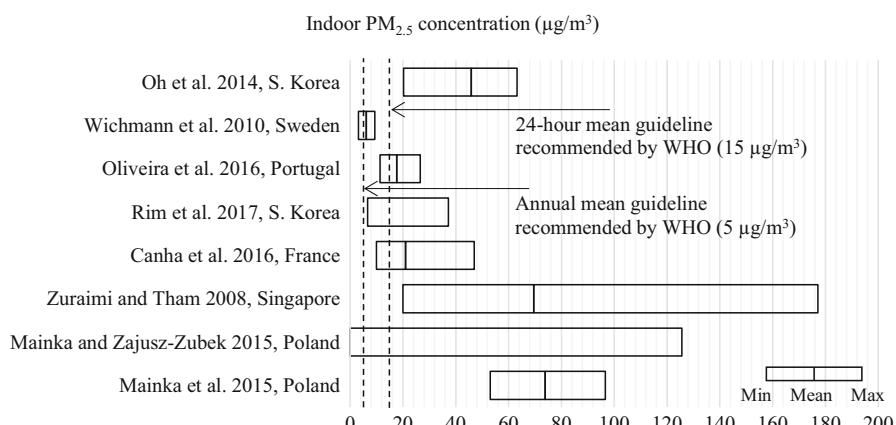

Fig. 5 Summary of reported indoor $\text{PM}_{2.5}$ concentration means and ranges (Zhang et al. 2021)

reported that a $10 \mu\text{g}/\text{m}^3$ increase in $\text{PM}_{2.5}$ was correlated with a 15% rise in hospital admissions for asthma (Tecer et al. 2008). Studies in school-aged children have found several health symptoms associated with $\text{PM}_{2.5}$, such as cough, eczema, dermatitis, headache, and nausea.

Ultra-Fine Particulates (UFPs)

Limited data are available on the concentration of ultrafine particles (particulate matter of nanoscale size; less than $0.1 \mu\text{m}$ or 100 nm in diameter) in day-care centers. The main elements influencing UFP level are summarized as: children's activities during classes (e.g., painting and other arts and crafts activities), combustion sources (e.g., candles on a birthday cake), and classroom cleaning (e.g., dusting and wood polishing) (Morawska et al. 2009).

In Portugal, a study investigated three day-care centers and reported a mean concentration of 1.82×10^4 and $1.32 \times 10^4 \text{ particle}/\text{cm}^3$ in urban day-care centers, and $1.15 \times 10^4 \text{ particle}/\text{cm}^3$ in a rural day-care center. They concluded that canteens have the highest UFP level, likely because they were directly connected to a kitchen with a gas stove. Also, they mentioned that UFP levels in playrooms were about two times higher than in school classrooms. During two activities (candles burning on a birthday cake and clay grinding), the concentrations were 13 times higher than the estimated mean value (Fonseca et al. 2014). Due to the small size of UFPs, they can penetrate biological membranes and translocate into the systemic circulation, and eventually get into organ systems including the brain and nervous system. Studies about independent health effects of UFP are scarce. A review study identified 85 studies and reported that there were inflammatory and cardiovascular changes associated with short-term UFP exposure (Ohlwein et al. 2019).

Infectious Diseases

Children who attend day-care centers may have increased infectious diseases risks. Infections like enteric infection (e.g., diarrhea, hepatitis A), respiratory tract infections (e.g., pharyngitis, pneumonia), invasive bacterial disease (e.g., *Hemophilus influenzae* type b, *streptococcus pneumonia*), herpesvirus infection (e.g., cytomegalovirus, varicella zoster) and other types of diseases should be noted (Holmes et al. 1996). Although guidelines (e.g., caring for our children-CFOC, USA) have been developed to help protect children from infectious diseases, eliminating these risks is impossible. A birth cohort study reported a rapid increase of respiratory infections after children started to attend day-care center with 3.79 mean sick days/month before the start of day-care to 10.57 mean sick days/month during the second month of attendance (Schuez-Havupalo et al. 2017).

During the COVID-19 pandemic, indoor air quality has become even more critical. Qian et al. (2020) investigated 318 outbreaks in China and reported that they all occurred in indoor environments. Respiratory droplets (generally $>5 \mu\text{m}$) and aerosol droplets (generally $<5 \mu\text{m}$) that can carry the SARS-CoV-2 virus (the causative agent for COVID-19) are the means of airborne transmission of

COVID-19 (Christopherson et al. 2020). Respiratory droplets deposit on the ground or surface rapidly, but aerosol droplets may remain suspended in indoor air for one or more hours. Knibbs et al. (2011) suggested that increased air exchange rates could decrease the risk of airborne disease transmission through dilution with outdoor air. In addition to, or in lieu of, increased ventilation, air filtration could also be used to help reduce the transmission risk by reducing the concentration of virus-laden droplets. One recent review reported that air purifiers with HEPA filters which have a high removal rate for indoor particles larger than $0.3\text{ }\mu\text{m}$, may be an effective method for reducing viral load in hospital environments (Mousavi et al. 2020). Previous experiments on SARS-CoV-1 (the causative agent of the SARS outbreak) demonstrated the efficacy of HEPA filters in the “capture and containment of diseases of similar particle size” (Schentag et al. 2004). However, since no direct studies have been conducted to validate this assumption, more specific studies on the impact of using air purifiers on indoor viral load of SARS-CoV-2 are needed (Christopherson et al. 2020).

Studies about indoor airborne bacteria in day-care centers mainly focused on the total bacterial concentrations. It is difficult to determine if indoor bacteria have a specific influence on health, because of a lack of speciation information. However, long exposure time in an environment with high levels of bacteria was shown to have adverse health effects (Daisey et al. 2003). It is worth noting that day-care centers tended to have higher bacterial concentrations compared with other indoor environments that were tested. These high levels may be due to higher occupancy densities, activities of children, and poor ventilation. A study in South Korea focused on bacteria levels in public buildings found the highest concentrations in a kindergarten in a hospital, a kindergarten, an elderly welfare facility, and a postpartum nursing center that were tested (Kim and Kim 2007). A study done in Portugal investigated four environments including homes, child day-care centers, primary schools, and elderly care centers. They reported the highest bacterial concentration with a median of 3870 CFU/m^3 in 50 rooms of 9 day-care centers, and found that children have at least two times the dose rates of bacteria than older people (Madureira et al. 2015).

Most studies reported significantly higher indoor total bacterial concentration than outdoor, with results that ranged from 1596 to 4630 CFU/m^3 (Cano et al. 2012; Mendes et al. 2014; Mainka et al. 2015a, 2018; Carreiro-Martins et al. 2016). Based on these higher indoor concentrations, the main airborne-bacteria sources are likely from indoors. Human oral and respiratory droplets emitted during coughing, sneezing, talking, breathing, and skin shedding are likely sources (Carreiro-Martins et al. 2016).

The reported bacteria concentrations were much lower in some locations. Researchers in South Korea studied 43 child care facilities and the mean total suspended bacteria was 418 CFU/m^3 (Kabir et al. 2012). Another study in South Korea reported that the mean concentrations of total and respirable airborne bacteria were 931 and 358 CFU/m^3 in childcare centers (Kim and Kim 2007). The indoor concentrations they reported were lower than outdoor concentrations, and the I/O ratios were below 1.0. The author concluded that the primary bacterial contamination was of outdoor origin. The explanation they provided was that the measuring

periods of their study were spring and autumn, which are the highest periods of outdoor concentrations of airborne bacteria.

In addition to studies of total bacteria concentrations, a few studies focused on determining the size distribution and the genera of indoor bacteria in day-care center environments. One study reported that *Staphylococcus spp.*, *Micrococcus spp.*, *Corynebacterium spp.*, and *Bacillus spp.* were the dominant genera and accounted for over 95% of the total airborne bacteria (Kim and Kim 2007). In Poland, a study investigated one urban day-care center and identified *Micrococcus spp.* as the dominant indoor bacteria. They also analyzed the size distribution of bacterial aerosols and concluded that small particles ($<4.7\text{ }\mu\text{m}$) contributed up to 85% of the total bacterial aerosols in indoor air. In this study, they developed a day-care center exposure dose equation and reported that the highest inhaled values happen in the winter (Brągoszewska et al. 2016).

For the determinants that influence indoor bacterial concentration, studies have concluded that increased indoor bacteria levels were associated with high occupant densities, low ventilation rates, and irregular floor cleaning, but frequent table cleaning frequencies (table cleaning activities resuspend bacteria from surfaces) (Zuraimi and Tham 2008; Cano et al. 2012; Mendes et al. 2014).

Dampness and Mold

Issues of moisture and mold damage in structures have been reported in many countries. An increase in fungal levels in the indoor environment is associated with mold/water damage in the building structure. Exposure to fungi can cause adverse human health effects from three aspects: immune response, infection by the organism, or toxic-irritant effects from by-products of mold (mycotoxins, MVOCs, etc.) (Bush et al. 2006). It has also been reported that mold and other fungi are sources of VOCs (Bennett and Inamdar 2015). However, little is known about the relationship between inhalation and response, and there are no unified sampling or analytical methods for mold exposure (Salonen et al. 2015).

Studies in South Korea and Portugal reported that day-care centers tend to have higher fungi concentrations compared to homes, hospitals, postpartum nursing centers, primary schools and elderly care centers (Kim and Kim 2007; Madureira et al. 2015). The fungi found in the indoor environment were mainly from outdoor sources. *Penicillium* and *Cladosporium* were the two main fungi genera found in indoor environments (Aydogdu and Asan 2008; Roda et al. 2011; Madureira et al. 2015; Rejc et al. 2019). Studies investigating total indoor fungi concentrations reported results ranging from 69.2 to 707 CFU/m³, with a higher concentration in summer (Kim and Kim 2007; Roda et al. 2011; Cano et al. 2012; Mendes et al. 2014; Madureira et al. 2015; Carreiro-martins et al. 2016; Mainka et al. 2015a, 2018).

In tropical countries, the indoor fungi concentrations in day-care centers tended to be much higher. In Singapore, a study reported that the total fungi concentration was 1424.2 CFU/m³ on dry days and 2930.5 CFU/m³ on rainy days (Zuraimi et al. 2009). They also reported that most of the indoor airborne culturable fungi had a size range

between 1.1 and 3.3 μm . However, another study reported a dominant size range of 3.3–4.7 μm (Kim and Kim 2007). Further studies are needed to explain this inconsistency. In addition to outdoor air (the main determinant), occupant density, cleaning, pets, plants, plumbing systems, heating, ventilation, air-conditioning systems, mold and dust resuspension all had an impact on the fungi concentrations indoors (Zuraimi and Tham 2008; Rejc et al. 2019).

VOCs

In many studies on the indoor air quality of day-care centers, total VOCs (TVOCs) are used to report the indoor organic chemical compounds level. As shown in Fig. 6, reported indoor TVOCs ranged from below the limit of detection to 6440 $\mu\text{g}/\text{m}^3$ (with mean concentrations that ranged from 114 to 642.11 $\mu\text{g}/\text{m}^3$). Some high TVOC peaks are included in this range, but further studies that may explain those high peaks have not been conducted (Ruotsalainen et al. 1993; Yang et al. 2009; Yoon et al. 2011; Cano et al. 2012; Mendes et al. 2014; Oliveira et al. 2016).

Some detailed research on indoor concentrations of specific VOCs in day-care center environments has been conducted, with BTEX (benzene, toluene, ethylbenzene and xylenes) some of the most commonly reported compounds. The ranges of reported mean concentrations for benzene (1.4–2.93 $\mu\text{g}/\text{m}^3$), toluene (2.2–7.9 $\mu\text{g}/\text{m}^3$), ethylbenzene (0.6–2.2 $\mu\text{g}/\text{m}^3$), m,p-xylenes (1.6–5 $\mu\text{g}/\text{m}^3$), and o-xylenes (1.3–1.6 $\mu\text{g}/\text{m}^3$). As reported in the UK school guidance document, BB101 (2018), trichloroethylene, tetrachloroethylene, naphthalene, and d-Limonene are also important chemicals in indoor environments. However, there is limited information about indoor concentrations of those pollutants in day-care center

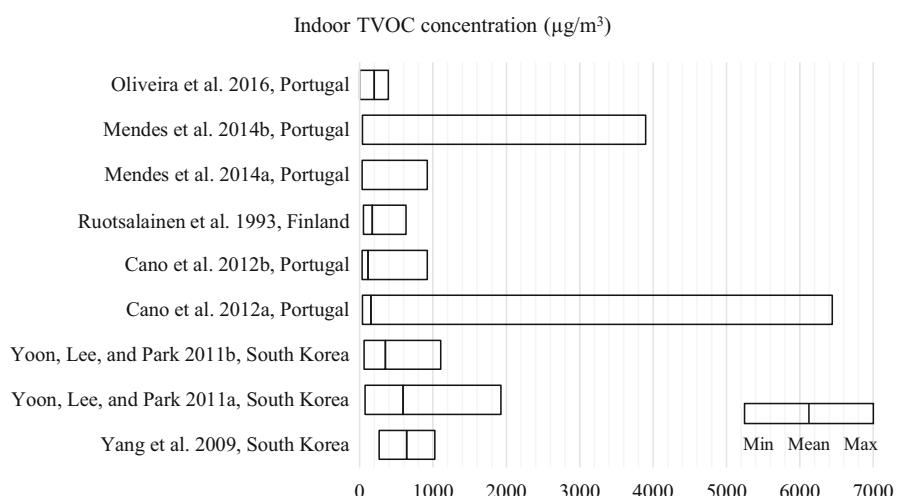

Fig. 6 Summary of reported indoor TVOC concentration means and ranges (Zhang et al. 2021)

environments. One study investigated seven day-care centers and ten primary schools in France and reported a mean trichloroethylene concentration of $2.3 \mu\text{g}/\text{m}^3$ with a range of $0\text{--}28.3 \mu\text{g}/\text{m}^3$ and mean tetrachloroethylene concentrations of $1.1 \mu\text{g}/\text{m}^3$ with a range of $0\text{--}11.5 \mu\text{g}/\text{m}^3$ (Canha et al. 2016). Two studies reported a naphthalene concentration that ranged from 0.3 to $3.1 \mu\text{g}/\text{m}^3$ (St-Jean et al. 2012; Mainka et al. 2015a). Studies on indoor d-Limonene levels in day-care centers were not found.

Due to the relative complexity of individuals' susceptibilities to TVOCs, only indicators of sensory effects are reported (Chatzidiakou et al. 2012). The complex mixture of chemicals in TVOCs can cause eye, nose, and throat irritation, shortness of breath, headaches, fatigue, nausea, dizziness, and skin problems. Higher concentrations may cause irritation of the lungs, as well as damage to the liver, kidney, or central nervous system. The estimated change in the odds ratio for chronic lower respiratory symptoms associated with a $2 \mu\text{g}/\text{m}^3$ change in process-related (industrial) compounds was 1.08 (95% CI 1.02–1.14) (McCloskey 1996).

Since indoor materials can emit formaldehyde including plywood, particleboard, carpets, and foam insulation that are frequently used indoors, many studies focus on the indoor level of this compound (Gilbert et al. 2008). As shown in Fig. 7, mean indoor formaldehyde levels reported are relatively low. However, high concentration peaks were reported in many studies. One study found those peaks corresponded

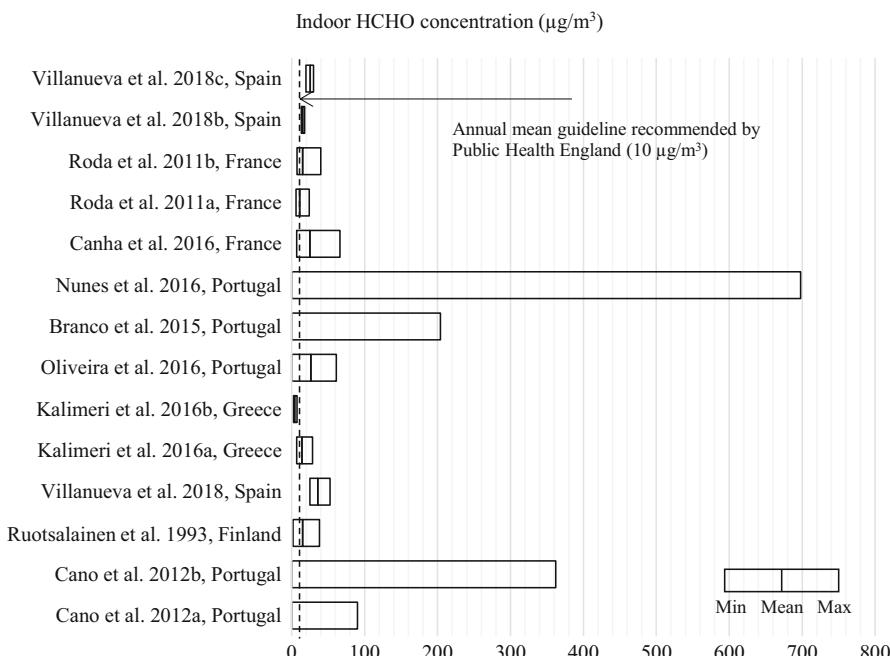

Fig. 7 Summary of reported indoor formaldehyde (HCHO) concentration means and ranges (Zhang et al. 2021)

with poor ventilation and the activities of cleaning and moving furniture (i.e., scraping the floor) (Ramalho et al. 2015; Nunes et al. 2016). Most studies report high formaldehyde during the hot/non-heating season (Kabir et al. 2012; Ramalho et al. 2015; Kalimeri et al. 2016). It is worth noting that there was a strong correlation between benzene and CO with formaldehyde, which could suggest they may occur from common sources (Kabir et al. 2012; Ramalho et al. 2015).

Radon

Radon is a naturally occurring radioactive gas produced from the decay of uranium in soil and rocks. It can penetrate buildings through cracks in the foundation. When its decay products are inhaled, they can release ionizing radiation that damages tissue (National Research Council 1999; WHO 2009).

Most studies that looked at the radon levels in day-care center environments reported acceptable average indoor values, below the 100 Bq/m³ recommended by WHO (Planinić et al. 1993; Al-Ghamdi et al. 2011; Bem et al. 2013; Jónsson et al. 2015). Other studies reported ranges of 100–300 Bq/m³ recommended by ICRP (The International Commission on Radiation Protection) (Kullab 2005; Fojtikova and Navratilova Rovenska 2014; Ivanova et al. 2014; Sousa et al. 2015; Branco et al. 2016).

However, in some high radon areas, relatively high levels were reported. In Slovenia, a study investigated ten high radon level kindergartens. The average indoor air radon concentration ranged from 264 to 1700 Bq/m³ (Vaupotič 2002). Studies have reported high radon levels in other countries (Italy; Slovenia; Bulgaria), with results ranging as following: 50–1047 Bq/m³ (Trevisi et al. 2012); 145–794 Bq/m³ (Vaupotič et al. 2012); 104–1761 Bq/m³ (Vuchkov et al. 2013). Although in many places radon is not a serious pollutant, in high-risk locations, radon should be taken into consideration in the indoor environments of day-care centers. Mitigation systems, such as active soil depressurization that remove the radioactive gas from the soil below the structure are recommended when radon levels are high.

Emerging Hazards

Recently, semi-volatile organic compounds (SVOCs) have drawn the attention of researchers, as they may have adverse effects on human health. The endocrine and respiratory systems of humans could be affected by SVOCs that are used in buildings, such as phthalic acid esters (phthalates or PAEs), polycyclic aromatic hydrocarbons (PAHs) and polybrominated diphenyl ethers (PBDEs). SVOCs have a higher molecular weight and boiling point temperature and are more stable than VOCs and therefore can remain in the indoor environment for years. There are three routes of exposure to SVOCs: inhalation, dermal and oral (Wang et al. 2010).

In day-care center environments, the presence of phthalates has been reported in many studies. Phthalates are used as a plasticizer in many consumer products and

industrial goods. Many studies have revealed an association between phthalate exposure and reproductive and developmental effects, and it is one of the risk factors for atopic diseases in children. Flooring, wire, cables, toys and children's products are reported as main sources of indoor phthalates. Di(2-Ethylhexyl) phthalate (DEHP), Di-isobutyl phthalate (DiNP), and Di-n-butyl phthalate (DnBP) are the most commonly reported phthalate esters (Fromme et al. 2005; Kim et al. 2013; Gaspar et al. 2014).

Measurable levels of a number of SVOCs, or their metabolites, have been found in children. One study noted that phthalates are rapidly absorbed and metabolized after inhalation or oral administration (Kavlock et al. 2006). Higher concentrations of phthalate metabolites in children compared with their parents and day-care center teachers have been reported (Koch et al. 2004). In Germany, a study investigating 63 day-care centers, collected indoor air samples, indoor dust samples, and urine samples of children. For some phthalates, they reported "significant correlations between the concentrations in the indoor air and dust and their corresponding metabolites in the urine specimens," and mentioned that a further reduction in phthalates exposure is necessary (Fromme et al. 2013). Additional studies are needed to better understand the sources, transportation, intake, and exposure risks of SVOCs in day-care center environments.

Conclusions

This chapter focused on indoor air quality in day-care center environments. The current research on IAQ in day-care centers includes a wide range of building types, activities, and occupancy. In addition, context changes drastically between countries, climates, and education systems. These differences pose a challenge when trying to assess the indoor air quality in a comprehensive and cohesive way, and many of the published findings are contradictory or inconsistent. As a result, more comprehensive studies considering building typologies and characteristics are needed. The overall evidence indicates that the indoor air quality in day-care centers is poor, and poor indoor air quality can lead to negative health outcomes. Key findings are as follows:

- Regarding thermal conditions in day-care centers, most reported temperature and relative humidity levels were within the comfort range. However, both lower and higher temperatures occurred due to poor building facilities. HVAC systems should be properly operated and maintained, which may require appropriate training or additional personnel. Also, it was reported that children prefer lower temperatures than adults, and that there is a difference between the preferences of boys and girls. The methods of collecting accurate feedback on the thermal comfort of children, and guidelines based on the needs of children warrants further development.
- Ventilation in many studied nurseries appears inadequate based on CO₂ concentrations which commonly exceeded recommended standards (mean

concentrations: 377–2750 ppm). The main reasons for high CO₂ levels were overcrowding and poor ventilation of the classrooms. Higher ventilation rates, reducing occupant density, and additional mechanical ventilation are recommended. Additionally, sleep time and sleeping-only rooms should be of special consideration because higher CO₂ concentrations were often reported during naptime.

- Particulate matter of both indoor and outdoor origin was reported in studies. PM levels in day-care centers often exceeded current guidelines. Air cleaning systems, such as HEPA filtration, may be useful in improving indoor air quality. High intensity activities of children, as well as activities that produce indoor particles (e.g., cooking, burning candles, clay grinding), should be considered in the design and operation of day-care centers.
- Indoor NO₂, O₃, and CO levels were generally influenced by outdoor levels, and although limited information was available, most measurements exceeded the 2021 WHO guidelines (10 µg/m³). Urban day-care centers, or day-care centers adjacent to high traffic areas, should be aware of these pollutants. When ambient air quality is not ideal (e.g., during peak traffic periods), ventilation from outdoor air without adequate filtration may not be advisable.
- High peaks in VOC concentration were reported in most studies, the mean concentrations, however, were generally low. The effect of short-term exposures to VOCs on children's health needs further study. Construction materials, interior decoration, cleaning and office products should be carefully selected and used in areas with proper ventilation.
- Bioaerosols like allergens, fungi species and bacteria were reported in some studies. Day-care centers could be potential important sources of exposures to those contaminants. Low levels of exposure might still cause adverse health outcomes. Well-defined thresholds, as well as methods for cleaning or removal, of biological contaminants are needed.
- In areas known to be at high-risk for radon, indoor levels should be measured, and appropriate remediation actions taken if standards are exceeded.
- Air purifiers may be a useful tool to help improve indoor air quality when source control and ventilation alone cannot achieve the necessary levels. The filtration technology should be carefully selected as some air cleaning technologies produce unwanted by-products. Currently, HEPA filters are recommended as one of the best options (especially for reducing PM levels). However, it should be noted that the costs of purchasing and maintaining air purifiers could exacerbate existing health inequalities (Cheek et al. 2020).

Studies reported in this review originate from different countries with different climates. Also, the methods used were different, for instance, monitoring devices, monitoring periods, and monitored parameters varied in different studies. It is therefore difficult to directly compare results, and we can only gain a general understanding about the current IAQ performance in day-care center environments. More comprehensive studies with longer monitoring campaigns and more considered confounders are needed to help us further understand the issues.

Additionally, more research from developing countries, where approximately 70% of the world's population lives, is needed. Studies have found that poor indoor air quality in homes in developing countries has a fundamental impact on health (Bruce et al. 2000; Gall et al. 2013). However, it is noteworthy that most of the studies cited in this chapter were from developed countries, and yet the overall IAQ performance was unacceptable. The authors express concern, therefore, that the air quality in nurseries in developing countries may be even more precarious, especially where outdoor pollution is high, and the structural fabric of buildings is poor.

The present chapter highlights the poor indoor air quality in day-care center and its potential effect on the health of children. When it comes to day-care centers, designers should take ambient pollution levels, ventilation, filtration, decoration and construction materials, and occupant density and activities into consideration to design for healthier indoor environments in the future.

Abstract

Schools are tasked with providing a safe and healthy place in which children can learn and grow, and it is very important that schools do not contribute to children's exposure to air pollution. Not only do children spend much of their time in school classrooms, but they are also more vulnerable than adults to airborne pollutants because of their developing lungs, narrower airways, and greater air breathed to body weight. Childhood exposure to air pollution can result in reduced lung function that is persistent into adulthood, and may lead to greater susceptibility to respiratory and cardiovascular diseases as adults. Additionally, exposure to poor indoor air quality can lead to increased absenteeism and poorer cognitive or academic performance. Studies from around the world have demonstrated that many schools fail to provide adequate indoor air quality in terms of particulate matter (PM), volatile organic compounds (VOCs), and ventilation rates to reduce indoor generated pollutants.

Introduction

What Is Unique About Schools?

The primary purpose of schools is to provide a safe and healthy place in which children can learn and grow. Schools present a unique and complex building type for several reasons. First, outside of the home, children spend most of their time indoors at school, roughly 30% of the time. Second, occupant densities are typically higher than for other building types. Third, there are a wide range of pollutant types associated with the wide range of activities common in schools (e.g., arts, gym). Finally, children's different physiologies and developing bodies may make them more vulnerable to different environmental exposures than adults. Specifically, children breathe more air relative to their body weight, have narrower airways, and their actively developing lungs, and other organs, may be less able to repair

themselves from injury (Bateson and Schwartz 2008). Failure to respond appropriately to indoor air quality (IAQ) problems can lead to long- and short-term health problems for the occupants, negatively impact the attendance and performance of students, and impair staff performance. Therefore, it is important to provide optimal indoor air conditions that support the education, health, and well-being of children.

Over the past few decades, problems with the indoor air in schools have come to the attention of both researchers and the public. Issues that affect the quality of air in schools include: increasingly airtight building envelopes, reduced ventilation rates, an increase in the use of harmful compounds in products such as pesticides and cleaning products employed indoors, and the use of synthetic building materials, finishes, and furnishings. This chapter introduces some of the key factors associated with the indoor air quality in schools. First, the chapter will provide a brief review of some of the common school building typologies and influences. Second, there is an introduction to key IAQ variables and monitoring studies in schools. Then the chapter will review what has been reported about IAQ in schools and the health and cognitive performance of students. Next, some of the most commonly occurring indoor air pollutants will be discussed, including existing levels in classrooms from recent studies, and finally a synthesis of the evidence and a discussion of the current knowledge gaps will be provided.

Review of the School Building Archetypal Forms

Understanding the drivers that encourage persistence or change of the school archetypal forms requires a consideration of the historical context of educational activities. Examples of drivers are technological, scientific, and social advances, and crucially through perception of the functional failure or success. The perception of failure or success of a building, and the criteria for this evaluation evolve through research, which influences guideline documents and practice. The emergence, persistence, or replacement of different building typologies are influenced in multiple ways by factors that include interpretation of emerging evidence, and of architectural trends that change the criteria for the evaluation of the success or failure of buildings. Another factor is advancement in construction technology that influences the construction methods and ultimately the different characteristics of buildings. These are reflected in building practice and building standards and regulations. Conversely, these regulations and performance targets can drive technological advances and innovation. Funding streams and procurement methods are traditionally also recognized as a factor. These are historically linked to the evolution of the education system, current pedagogy, and curriculum. In addition to these, in some places, listing and heritage value criteria continue to shape today's school building stock.

From an IAQ perspective, existing literature recognizes building design as an overarching determinant (Ashmore and Dimitroulopoulou 2009; de Gennaro et al. 2014). Factors such as airtightness, air exchange rates, and materials of construction can all contribute to improved or poor air quality.

Emerging evidence is likely to influence building characteristics on a wide scale, leading to new typologies directly and indirectly, through guidelines, changes in building regulations, large-scale adoption of voluntary standards, and guidance documents. An example is the requirement for energy efficient and low-carbon school building structures, e.g., through standards such as Passivhaus or the European Union's Energy Performance of Buildings Directive (EPBD). Additionally, a changing climate will require that our buildings be more resilient and adaptive to new ambient environmental conditions. Most recently, knowledge on how the indoor environment impacts children's health and performance is leading to changes in design guidelines.

Classroom IAQ

IAQ Variables

Acceptable levels for IAQ in classrooms are determined through criteria, ranges, and limits/thresholds for different variables in existing standards and guidelines. These are based on available evidence on their likely effect on health, comfort, and academic or cognitive performance. Indoor air quality in the classroom is directly indicated by the measured indoor air pollutant concentrations or by proxy measures such as ventilation rates.

Indoor air quality variables, investigated because of their relevance to health, include:

- (i) Temperature and thermal comfort indices
- (ii) Ventilation rates and CO₂ levels, and indoor air pollutants including:
 - (a) Particulate matter (PM_x)
 - (b) Nitrogen dioxide (NO₂)
 - (c) A range of volatile organic compounds (VOCs)

Not all known contaminants are presented in this chapter, which focuses instead on pollutants listed in the ambient air quality regulations (PM_x, NO₂, and VOCs), and pollutants with potential indoor sources in classrooms (for example, PM₁₀ and the VOCs formaldehyde, limonene, α-pinene, and toluene). Uncertainty around the chemical composition of the indoor air matrix of pollutants means that variables relevant to IAQ are not fixed and are not universal for all buildings. This result is especially true for VOCs and the chemical components of PM_x in indoor air.

Empirical Evidence and Key Monitoring Studies

Empirical evidence from monitoring studies in schools is important for research in order (i) to identify correlations between IAQ variables in indoor air and health

outcomes, (ii) to link building characteristics to levels of IAQ variables, and (iii) to include more potentially harmful chemical IAQ variables, achieving a holistic assessment of IAQ.

Comprehensive IAQ studies reviewed in this section are included with other indoor environmental studies in schools in Table 1. Among the key IAQ monitoring studies in schools was the comprehensive SINPHONIE study (Schools Indoor Pollution and Health Observatory Network in Europe) with monitoring in 2010–2012 in 114 schools, in 23 countries (Csobod 2014); the SEARCH study (School Environment and Respiratory Health of Children) between 2006–2009 and 2010–2013 in 10 countries (Csobod 2014); and the AIRMEX study (Geiss et al. 2011) which included other building types focused on VOCs. The SEARCH project (2006–2009) explored the relationship between school environments and health with the aim of drafting recommendations. Other review studies include the European Commission's Pilot Indoor Air monitoring study (Kephalopoulos et al. 2014) and the French six cities project (Annesi-Maesano et al. 2013a).

Health Outcomes and Limits

The influence of IAQ in classrooms on children's health, well-being, comfort, attendance, academic achievement, and productivity was explored in a number of studies. The classroom indoor environment was shown to be important for children's health again and again (Bakó-Biró et al. 2012; Mendell and Heath 2005; Wargocki and Wyon 2007) and is noted in regulatory and guidance documents (Kephalopoulos et al. 2014; WHO 2015). The adverse health effects from exposure to poor indoor air quality in classrooms can be both short- and long-term since children spend a large amount of time in the school classroom. The wealth of the available evidence and the complexity of the involved parameters are evident from a series of literature review studies on the correlation of health symptoms to poor IAQ in school classrooms (Annesi-Maesano et al. 2013a; Bluyssen et al. 2018; Daisey et al. 2003; de Gennaro et al. 2014). The review by Daisey et al. (2003) investigated the correlations between a set of IAQ parameters in schools (including ventilation rates, CO₂ concentrations, and concentrations of indoor air pollutants including VOCs, formaldehyde, microbiological factors, and allergens) and a number of adverse health effects on children: asthma, acute and chronic irritation symptoms, and cancer.

Another review (Mendell and Heath 2005) focused on the influence of IAQ and thermal conditions on academic performance and attendance of children in schools. It found evidence to link higher nitrogen dioxide (NO₂) levels to reduced school attendance and inadequate ventilation rates to reduced performance. The study suggested asthma and respiratory infections associated with dampness and microbiological factors are likely influencing performance and attendance. Key studies that investigated the correlation between classroom indoor environment and cognitive or academic performance are summarized in Table 2.

Table 1 Key monitoring studies of indoor environmental quality in schools in different countries

Study name and reference	Sample (country, numbers), years	Monitored parameters
The AIRMEX study Geiss et al. (2011)	Included school buildings, monitoring between 2003 and 2008 In nonresidential buildings: including schools, public buildings and offices, in EU cities	Monitored parameters VOCs
EXPOLIS-UK Lai et al. (2004)	1998–2000, Oxford, UK Measured locations: home indoor, home outdoor, work indoor concentrations, and personal exposure	NO ₂ , CO ₂ , CO, PM _{2.5} , 37 elements in PM _{2.5} , 30 VOCs
WHO Schools Survey WHO (2015)	2012–2014, monitoring in Croatia, Albania, Latvia, Estonia, and Lithuania, 233 schools	NO ₂ , CO ₂ , CO, formaldehyde, benzene, ventilation rates, mold
SEARCH (School Environment and Respiratory Health of Children) Csobod (2014)	2006–2009 (phase I), monitoring in 6 countries: Albania, Bosnia and Herzegovina, Hungary, Italy, Serbia, and Slovakia 2010–2013 (phase II) In 10 countries in addition: Belarus, Kazakhstan, Tajikistan, and Ukraine	CO, CO ₂ , NO ₂ , formaldehyde, benzene, toluene, xylenes, PM ₁₀
HESE (Health Effects of the School Environment) Csobod (2014)	2004–2005, monitoring in 21 schools, 5 European countries (Italy, France, Norway, Sweden, Denmark)	Ventilation, lighting, PM, NO ₂ , CO ₂ , O ₃ , formaldehyde, dust/air allergens, molds, bacteria.
SINPHONIE Csobod (2014)	2010–2012, monitoring in 114 primary schools across 23 countries in Europe Countries included the UK	CO, NO ₂ , CO ₂ , O ₃ , PM ₁₀ , PM _{2.5} , dust allergens, dust/air bacteria, mold, formaldehyde, benzene, α-pinene, D-limonene, naphthalene, trichloroethylene, tetrachloroethylene, PAHs (B[a]P)
SINPHONIE-UK Chatzidiakou, Mumovic, Summerfield, Hong, and Altamirano-Medina (2014)	5 primary schools and 1 nursery, UK	PM, NO ₂ , O ₃ , TVOCs monitored over 5 consecutive days
BRE-ODPM Ajiboye, White, Graves, and Ross (2006)	8 primary schools, England, UK. Post-1995 buildings 2 classrooms in each school, duration 1 working week Measurements September 2002–February 2003 and October–November 2003	Monitored over 2 weeks in each school: air exchange rates, temperature, RH, CO ₂ , VOCs, TVOCs, CO, NO ₂ , PM ₁₀ , PM _{2.5} , aldehydes, fungi and bacteria, dust mites

(continued)

Table 1 (continued)

Study name and reference	Sample (country, numbers), years	Monitored parameters
CEHAP-E-WHO-Austria Wallner et al. (2012)	Elementary schools, Austria 2 classrooms per school, both seasons, 1-week periods	34 pollutants Temperature, RH, CO ₂ , PM Chemical groups: alcohols, chlorinated hydrocarbons, aliphatic hydrocarbons, terpenes, aldehydes, other including NO ₂ , VOCs in PM/dust, perfumes, phenols, phthalates, trisphosphates, PAHs, PCBs, and other Spirometry on children
Zhong, Su, and Batterman (2017)	144 classrooms in 37 conventional and high-performance schools recently built or renovated (last 15 years) in the USA. Monitoring took place in 2015–2016.	Temperature, RH, CO ₂ , PM, noise. Indoor and outdoor concentrations of 94 VOCs were determined (using thermal desorption, gas chromatography-mass spectroscopy) Only those compounds, 24 were detected in over 15% of the samples were included in the analysis. Duplicates in 3 schools
PRIMEQUAL Blondeau, Iordache, Poupard, Genin, and Allard (2005) Poupard, Blondeau, Iordache, and Allard (2005)	France 8 primary schools 1 classroom in a MV school. 5 classrooms total. 2-week periods, repeated in winter and in summer	O ₃ , nitrogen oxides (NO and NO ₂), PM, temperature, RH, CO ₂ concentration
EC ISAAC II Annesi-Maesano et al. (2013a), Annesi-Maesano et al. (2012) (International Survey of Asthma and Allergy in Childhood)	France, 6 cities, 108 schools, 401 classrooms	PM _{2.5} , formaldehyde, NO ₂ , O ₃
Stranger, Potgieter-Vermaak, and Van Grieken (2008) reported on a subset in Belgium of the ISAAC III Project schools in 56 countries ISAAC monitoring took place in 2001	Antwerp, Belgium, in 2001, 27 primary schools, children ages 6–7 and 13–14 years (older than primary school ages in the UK) Heating (December 2002 and non-heating season (June 2003)	PM _{2.5} (elemental content of PM) NO ₂ , SO ₂ , O ₃ BTEX
de Gennaro et al. (2014)	8 school buildings, both middle and elementary, Southeast Italy	The study provided quantitative information on 14 compounds including formaldehyde

(continued)

Table 1 (continued)

Study name and reference	Sample (country, numbers), years	Monitored parameters
Rovelli et al. (2014)	7 schools (of which 3 primary schools), Milan, Italy, three classrooms in each school, monitoring over a week in winter, 2011–2013. Naturally ventilated only	PM, CO ₂ , temperature
Sofuoğlu, Aslan, Inal, and Sofuoğlu (2011)	3 primary schools, Turkey	The method was optimized for quantitative determination of 51 compounds, and an average of 16 compounds were found in the samplers. Active sampling, repeated 6–9 times each season, repeated in fall, winter, and spring. Monitoring in a classroom, a kindergarten, and outdoor playground site
Ye, Won, and Zhang (2017)	A practical method and its applications to prioritize volatile organic compounds emitted from building materials based on ventilation rate requirements and ozone-initiated reactions	List of priority VOCs and assessment based on combined effect
Kim et al. (2007)	8 primary schools, Sweden	Plasticizers MVOCs
Fromme et al. (2013) LUPE 2 study	Germany, 14 classrooms over 20 consecutive days, 1 classroom over 83 days	PM, endotoxins, CO ₂

Ventilation Rates

Effect on Health and Academic Performance

Many studies have found a positive correlation between ventilation rates and measures of academic, cognitive performance and productivity. The following provides some of the key findings.

Wargocki and Wyon (2013) found that numerical test performance (in terms of speed) increased with ventilation rates and in the same paper proposed a dose-response relationship between classroom ventilation rates and student performance. An earlier study, by the same authors (Wargocki and Wyon 2007), reported on findings from the investigation of the influence of outdoor airflow rate on academic performance and found significant improvements in the speed of completing tasks with increased outdoor airflow.

Table 2 Existing evidence on effects of classroom IEQ on health, comfort, academic and cognitive performance of children

Study	Method	Sample	Environmental variable	Health or performance variable	Nr/ages of children	Findings/limitations
Wyon (1970) from review	Intervention study		Temperature (20, 27, 30 °C)	School exercises: Numerical (addition, multiplication, number checking) Language (reading and comprehension, supplying synonyms and antonyms)	9–10-year-old 3 classes	Numerical exercises, a decrease in speed was seen with higher temperatures. Reading comprehension as well as reading speed was reduced. Significant changes in afternoon not in morning.
Schoer (1973) from reviews	Timed with stopwatch, maximum effort conditions		Temperature	19 tests from simple-repetitive tests to school exercises	10–12-year-old, 2 groups, over 6–8 weeks	Finding: cooler classroom, higher performance Limitations: increasing difference between groups with time
Wargocki and Wyon (2007)	Field intervention experiments, summer, double crossover, 1 week	Denmark, 1 school, 2 classrooms	Air temp. and Air temp. plus outdoor air supply	Timed tests for academic performance Language and numerical, incorporated in normal lesson	10–12-year-old	
Petersen, Jensen, Pedersen, and Rasmussen (2016)	Field intervention, double-blind crossover	Denmark, 2 schools, 4 classrooms	Ventilation rates (measured through CO ₂ concentration)		10–12-year-old	
Haverinen-Shaughnessy, Moschandreas, and	Intervention, monitoring 1 day, closed conditions, winter/spring months	USA south west, 104 classrooms /schools	Ventilation rates from CO ₂ levels	Academic achievement, standardized tests, curriculum aligned	Fifth grade 10–11 years	A correlation was found between ventilation rates and percentages of children passing the math and reading tests

(continued)

Table 2 (continued)

Study	Method	Sample	Environmental variable	Health or performance variable	Nr/ages of children	Findings/limitations
Shaughnessy (2011)						
Twardella et al. (2012)		6 schools MV, 20 classrooms, 417 children, Germany	Median CO ₂ levels	Concentration, using a test	9–10 years	Accuracy decreased when median CO ₂ concentration increased but concentration was unaffected
Hutter et al. (2013)	Monitoring, 1 week winter one in summer	9 primary schools, 436 children, in Austria	Semi-volatile organic compounds (including phosphorganic compound TCEP) and CO ₂	Cognitive performance of children, using SPM tests	6–8 years	A negative correlation was found between CO ₂ and concentrations of CO ₂ and a SVOC and a PAH with cognitive performance in children
Wallner et al. (2012)	LuKi Study: Air and Children					
Bakó-Biró et al. (2012)	Field intervention		Ventilation rates (1 l/s/p to 9 l/s/p)	VisCoPe tests on laptops: Simple reaction time, choice reaction time, color word vigilance, addition reaction time, digit span memory, digit classification, digit symbol matching, picture memory	200 pupils 53 groups of children in 8 school	Faster and more accurate responses for choice reaction, color word vigilance, picture memory, word recognition at higher ventilation rates

A study in the USA explored correlations between classroom ventilation rates and student academic achievement (Haverinen-Shaughnessy et al. 2011). The authors measured ventilation rates in 104 schools (one fifth-grade classroom in each school) in the southwestern USA. Academic achievement was assessed using the national multiple choice standardized tests aligned with the curriculum for that year for subjects of mathematics, reading, social studies, science, and writing. The study concluded that ventilation rates explained an additional 3–6% of the variation of academic achievement (in addition to other explanatory variables including race/ethnicity, type of school, home environment). Within the ventilation range $0.9\text{--}7.1\text{ l s}^{-1}$ per person, an increase of 1 l s^{-1} per person corresponded to an additional 2.9% and 2.7% children passing the math and reading tests, respectively.

A double-blind two-by-two intervention experiment in Denmark, which took place in two schools and four classrooms, investigated the effect of ventilation rate as indicated by CO₂ levels on schoolwork performance (short-term concentration and logical thinking) for children aged 10–12 years (Petersen et al. 2016). The study found an increase in correct answers (but not an increase in wrong answers) as the ventilation rate increased from an average 1.7 l s^{-1} per person to 6.6 l s^{-1} per person (Petersen et al. 2016).

A study in England explored ventilation rates and performance of school children in a field intervention study in 8 primary schools involving 200 pupils (Bakó-Biró et al. 2012; Clements-Croome et al. 2008). Two classrooms in each school (a total of 16 classrooms) were monitored over 3 weeks, and ventilation rates were increased from 1 l s^{-1} per person to 8 l s^{-1} per person while the temperature was maintained within acceptable levels. The study used tests to assess 9–10-year-old children's performance. The results showed improved performance in terms of speed and accuracy for tasks requiring attention, vigilance, memory, and concentration, when ventilation rates increased.

Ventilation Rates Requirements and Limits

Required ventilation rates in classrooms are determined both through performance-based criteria (that is, requirements are based upon how the building, or building systems, meets measurable outcomes) and prescriptive criteria. The prescribed methods, however, should be derived from performance-based considerations.

The 2018 UK guidance for schools (BB101, 2018) requires a minimum 3 L s^{-1} per person and a minimum daily average 5 L s^{-1} per person. The occupants should be able to achieve a recommended 8 L s^{-1} per person in mixed mode ventilation or naturally ventilated school buildings. The UK guidelines suggest that ventilation levels above the minimum may be determined necessary based on the CO₂ requirements (ESFA 2018). Ventilation levels equivalent to 8 L s^{-1} per person, regardless of ventilation strategy, were associated with levels below 1000 ppm (Santamouris et al. 2008).

Similarly, the ANSI/ASHRAE Standard 62.1 2016 requires a minimum of 5 L s^{-1} per person and a 0.6 L per m^2 floor area in primary school classrooms occupied by

children. For a classroom of typical floor area 60 m^2 , and 30 occupants, this amounts to 6.2 L s^{-1} per person (ANSI/ASHRAE 2016).

The Australian building regulations require a 7.5 L s^{-1} per person to achieve acceptable levels of CO₂ concentration (Luther et al. 2018). This value is a steady state estimation, suggesting that it corresponds to the daily average. In Sweden, regulatory requirement of ventilation in schools requires $0.35 \text{ L s}^{-1} \text{ m}^{-2}$ plus 7 L s^{-1} per person.

While mainly based on office buildings, an outdoor air supply rate of 10 L s^{-1} per person is recommended for occupant health, also satisfying the 8 L s^{-1} per person to limit odor dissatisfaction due to bio-effluent emissions when entering an occupied space. These requirements may not suffice for addressing “occasional occupant controlled” sources of pollution such as cleaning and painting. Ventilation per occupant for limiting CO₂ levels to below 1000 ppm may not be adequate to limit other pollutants (Apte 2000; Daisey et al. 2003). A summary of requirements in standards and guidelines for rates of ventilation in schools is found in Table 3.

Ventilation Rates: Levels

Ventilation rates in primary school classrooms vary greatly with studies finding many classrooms do not achieve the recommended rate, which is typically about

Table 3 Requirements for ventilation rates in classrooms in standards and guidance

Standard or guidance document	Required ventilation rates
BB101 U.K. (ESFA 2018)	Minimum ventilation rate: 3 L s^{-1} per person Minimum average ventilation rate: 5 L s^{-1} per person Achievable ventilation rate (and for bio-effluents): 8 L s^{-1} per person
ADF U.K. (HM Government 2010)	For human health: 10 L s^{-1} per person
ANSI/ASHRAE Standard 62.1 2016 for classrooms with children (ANSI/ASHRAE 2016)	5 L s^{-1} per person plus 0.6 L s^{-1} per m^2 floor area $= 6.2 \text{ L s}^{-1}$ per person (assuming 60 m^2 classroom 30 occupants)
Australian Building Code (Luther et al. 2018)	7.5 L s^{-1} per person
BS EN ISO 16798-1: 2019 (BSI 2019)	10 L s^{-1} per person plus $1 \text{ L s}^{-1} \text{ m}^{-2}$ floor area (Cat. 1) 7 (Cat. 2.) 4 (Cat. 3) Minimum during occupancy 4 L 4, 7, or 10 L per person Plus 1 , 0.7 , or 0.4 L per m^2 Total 12 , 8.4 , 4.8 L per person

8 L s⁻¹ per person average (Blondeau et al. 2005; Chatzidiakou et al. 2012, 2015a, b, c; Daisey et al. 2003; Fromme et al. 2007). A number of studies estimated or measured ventilation rates under normal operation of the occupied classroom or under controlled conditions during interventions for the evaluation of infiltration and purge/maximum achievable ventilation rates, and found them to be inadequately ventilated (e.g., Chatzidiakou et al. 2014; Mendell et al. 2016).

A European study calculated ventilation rates from monitored CO₂ levels (Csobod 2014). The study found average ventilation rates of 1.8 L s⁻¹ per person, and a minimum to maximum range of 0.1–13.3 L s⁻¹ per person, highlighting that the large majority (86%) of the classrooms achieved less than 4 L s⁻¹ per person, which was cited as the minimum required average. The UK, Belgium, Germany, France, and Austria were among those countries for which even lower ventilation rates were reported (average 0.9 L s⁻¹ per person, range 0.2–2.9 L s⁻¹ per person).

A study of schools in Greece reported ventilation rates from a database generated from a literature review across different countries that included over 1,000 classrooms. Median ventilation rates were 8.3 L s⁻¹ per person for mechanically ventilated school buildings and 3.0 L s⁻¹ per person for naturally ventilated schools in the database (Santamouris et al. 2008). According to the review, 81% of the naturally ventilated and 45% of the mechanically ventilated classrooms failed to achieve ventilation levels at or better than the recommended minimum of 8 L s⁻¹ per person.

In the UK, Chatzidiakou et al. (2014) estimated infiltration, usual, and purge ventilation rates in 18 primary school classrooms in the UK and reported these as air changes per hour and L s⁻¹ per person, and found higher typical ventilation rates in the non-heating season. The usual ventilation rates during occupancy in the heating season ranged from 2.3 to 5.1 L s⁻¹ per person and in the non-heating season ranged 2.8–6.3 L s⁻¹ per person (Chatzidiakou et al. 2014). The average ventilation rate requirement of 5 L s⁻¹ per person (per UK regulations) was not achieved in most classrooms.

Studies in mild to warm climates found higher ventilation rates than studies in colder climates under normal operation, which could be due to more frequent window opening as well as design and construction characteristics allowing for larger opening areas. Santamouris et al. (2008) measured ventilation rates in 61 classrooms in naturally ventilated schools in Greece. The infiltration rates, determined with closed windows, were on average about 1.5 L s⁻¹ per person, increasing to 4.5 L s⁻¹ per person (range 2–11 L s⁻¹ per person) during teaching and further increasing during breaks, with a median of 7 L s⁻¹ per person and a range of 2–20 L s⁻¹ per person. The study found that ventilation rates were consistently higher in Greek schools during teaching hours, and that ventilation rates were highly variable during both teaching and break periods. In California, USA, Mendell et al. (2016) investigated the influence of ventilation rates in primary school classrooms on children's performance on standardized tests. The study estimated daily ventilation rates in 150 classrooms of 28 schools from measured occupant generated CO₂ concentrations over equilibrium periods, over a 2-year period. The sample consisted of naturally ventilated, mechanically ventilated, and air-conditioned mechanically ventilated classrooms. The ventilation rates were compared to the requirements in

California, of 7.1 L s^{-1} per person and the now superseded ASHRAE 62 Standard $6.7\text{--}7.4 \text{ L s}^{-1}$ per person (ANSI/ASHRAE 2013). The study found median school-year ventilation rates of 6.8 L s^{-1} per person for naturally ventilated schools, 7.7 L s^{-1} per person for mechanically ventilated schools, and 2.9 for air-conditioned classrooms. The averages and standard deviation (σ) were respectively $7.0 (2.4) \text{ L s}^{-1}$ per person, $8.0 (2.2) \text{ L s}^{-1}$ per person, and $3.3 (1.7) \text{ L s}^{-1}$ per person. Findings from Mendell et al. are not consistent with the wide differences between naturally ventilated and mechanically ventilated schools found in Santamouris et al. (2008) but revealed that air-conditioned classrooms were likely to experience lower ventilation rates.

Mumovic et al. (2009) monitored 18 classrooms in 9 contemporary secondary schools in England, UK. The study found that ventilation rates under normal operation in the heating season in secondary classrooms were lower in naturally ventilated classrooms compared to four mechanically or mixed mode ventilation classrooms. Average ventilation rates in 12 naturally ventilated classrooms were 3.3 L s^{-1} per person, and 7.2 L s^{-1} per person in 4 classrooms with mechanical ventilation. The 8 L s^{-1} per person was only achieved through window opening even in mechanically ventilated classrooms. Higher natural ventilation rates were observed in classrooms with cross and stack airflow or fully openable windows.

Across the reviewed studies, average ventilation rates during usual operation were 4.9 L s^{-1} per person. A summary of findings from investigations in ventilation in classrooms can be found in Table 4.

The Assessment of IAQ

Existing guidelines and standards, regulatory documents, and academic studies provide different interpretations of the definition of good indoor air quality, which are reflected in the assessment procedures and relevant criteria.

The ANSI/ASHRAE standard provides a comprehensive procedure for the assessment of indoor air quality and the provision of measures, such as ventilation, for providing acceptable indoor air quality without adverse health effects for occupants. More specifically, compliance with requirements is assessed with one of, or a combination of, the three procedures: the *Ventilation Rate Procedure* and the *IAQ Procedure* for the mechanical ventilation systems, and the *Natural Ventilation Procedure* for the natural ventilation systems of a building. The “*IAQ Procedure*” includes identification of main sources for contaminants of concern and determination of individual contaminant concentration limits. This method is a knowledge-based approach, not only relying on source identification but also suggesting that exhaustive IAQ assessment is required. It also suggests that the IAQ indicators need to reflect a different list of contaminants in each building, thus any comparison cannot rely on individual contaminant concentrations but on a cumulative metric, e.g., a version of the total VOC metric. In the following sections, the most common indoor pollutants, their effects, sources, and influencing factors are explored in greater detail.

Table 4 Monitoring studies which investigated classroom air exchange and ventilation rates in schools

Study	Country	Length of monitoring	Sample size	Conditions of operation	Ventilation rates (units vary)
SINPHONIE (Csobod et al. 2014)	European countries including the UK	One week in each season	300 primary schools	Normal operation	Average 1.8 L s^{-1} per person, range $0.1\text{--}13.3 \text{ L s}^{-1}$ per person
Santamouris et al. (2008) database from literature review	International database			Mediannally ventilated schools	Mediannally ventilated schools Median 8.3 L s^{-1} per person in mechanically ventilated schools Median 3 L s^{-1} per person in naturally ventilated schools
Chatzidiakou et al. (2014)	UK, primary schools	One week in each season	18 primary school classrooms	Normal operation, usual	Range $2.3\text{--}6.3 \text{ L s}^{-1}$ per person
Mendell et al. (2016)	California, USA	Longitudinal, average daily VRs, average of 30 days, medians over 2 years	150 classrooms, 28 schools	Heating season average 3.8 L s^{-1} per person Non-heating season average 5.2 L s^{-1} per person	

Carbon Dioxide

Effects of CO₂ on Health and Cognitive/Academic Performance

Existing literature provides evidence on correlations between increased CO₂ levels and health and cognitive performance of adults and children. High CO₂ levels were associated with several metrics for asthma, absenteeism, and poor cognitive performance in children (Annesi-Maesano et al. 2013a; Daisey et al. 2003). Azuma et al. (2018) found that exposure to indoor CO₂ levels influenced health and psychomotor performance. The correlation between CO₂ and attendance and academic performance was investigated by Gaihre et al. (2014) in Scottish primary schools. The study found a negative correlation between CO₂ levels and attendance records, but found no correlation between CO₂ concentrations and measures of academic performance. An increase of 100 ppm in CO₂ concentration was associated with a 0.2% drop in attendance, which is equivalent to 1 half day per year. From the Csobod et al. (2014) investigation of the effect of indoor air on attention and concentration levels, increased CO₂ levels were found to have a negative correlation with performance in morning logical tests as well as with attendance, with asthma being the most common reason for missing school among chronic diseases. Increased CO₂ levels were associated with reduced cognitive performance in children according to Hutter et al. (2013) in a study in Austrian schools.

Since CO₂ levels in classrooms are strongly correlated with ventilation rates and other occupant-related pollutants (Chatzidiakou et al. 2015a, b, c), some studies have challenged the implied causal relationship between exposure to CO₂ and health effects due to confounding effects from covariates (Azuma et al. 2018; Carreiro-Martins et al. 2014). Zhang et al. (2017) suggested that bio-effluents, rather than CO₂, were responsible for effects on performance tasks. Addressing these concerns around methodological limitations of existing studies, a review by Azuma et al. (2018) concluded that CO₂ exposure can have effects on health and physiological performance. Nevertheless, further research is required to understand the effects of a wide range of CO₂ levels (500–3000 ppm) on children who may be more susceptible than adults (Azuma et al. 2018).

Limits for CO₂ and Required Ventilation Rates in Schools

Since CO₂ is generated by the occupants through exhaled air, its concentration in indoor air is often used for the performance-based determination of ventilation requirements in classrooms. This approach is in addition to sufficient ventilation for satisfying cooling requirements and for limiting pollutants from indoor sources other than occupants.

Slight variations in guidance exist between countries, and a summary of several standards can be found in Table 5. Azuma et al. (2018) reported that upper limits for indoor CO₂ concentrations are set at 1000 ppm in a number of countries including Germany, Norway, South Korea, Japan, and Canada. In Portugal, the

Table 5 Recommended limits for indoor CO₂ levels in nonresidential buildings in existing standards

Standard/publication year	Category/description	CO ₂ levels limit or target value (ppm)	CO ₂ levels assuming outdoor levels 400 ppm
ANSI-ASHRAE 62.1 Standard (ANSI/ASHRAE 2016)	Maximum Limit	Outdoor +700	1100
2018 BB101 (ESFA 2018)	Achievable levels most of the occupied time in new buildings	Outdoor +800	1200
	Achievable levels most of the occupied time in existing buildings	Outdoor +1350	1750
BS EN ISO 16798-1: 2019 (BSI 2019)	Category 1	Outdoor +550	950
	Category 2	Outdoor +800	1200
	Category 3	Outdoor +1350	1750

limit for average CO₂ concentration in classrooms is higher at 1250 ppm. The national regulations for school buildings in the Netherlands, according to Teeuwen et al. (2015), require a maximum 95th percentile of 1200 ppm, allowing for the limit to be exceeded up to 5% of the time while defining three bands of performance. The performance is acceptable if the 95th percentile is between 1000 and 1200 ppm, good if between 800 and 1000 ppm, and very good if less than 800 ppm. The influential American National Standard Institute (ANSI) Standard *ANSI/ASHRAE 62.1 2016 Ventilation for Acceptable Indoor Air Quality* recommends concentrations of CO₂ not to exceed 700 ppm over outdoor levels (1,100 ppm, assuming outdoor levels 400 ppm) (ANSI/ASHRAE 2016). The World Health Organization recommended levels of 1,000 ppm above outdoor levels, while a study found 25% predicted percentage of dissatisfied (PPD) at these levels (~1,400 ppm) (Luther et al. 2018).

In the UK, the regulatory requirements for CO₂ concentrations in classrooms are intertwined with ventilation rate requirements in the Approved Document F Ventilation of the UK Building Regulations (HM Government 2010) and the supplementing guidance document Building Bulletin 101 (BB101) Guidelines on ventilation, thermal comfort, and indoor air quality in schools (ESFA 2018). The CO₂ concentration requirements were differentiated for schools that operate on mechanical/mixed and natural ventilation modes. Therefore, two different thresholds are given for maximum daily averages (1000 ppm and 1500 ppm) and for 20-min-long peaks (1500 ppm and 2000 ppm) for mechanically ventilated and naturally ventilated classrooms, respectively. In new naturally ventilated school buildings, BB01 states that concentrations below 1200 ppm (assuming outdoor concentrations at 400 ppm) must be achievable for most of the occupied hours. Similarly, BB101 recommends that mechanical ventilation set points should be set to achieve levels of CO₂ less than 1000 ppm.

CO₂ Levels from Existing Studies

As carbon dioxide is considered as a proxy for indoor air quality in classrooms, it is among the most monitored and investigated pollutants in classrooms. It should be noted, however, that CO₂ may not be a useful proxy for all indoor air pollutants, particularly those from traffic-related sources. Studies that report results from continuous monitoring of CO₂ concentrations in school classrooms generally focus on assessing ventilation rates, indoor air quality, and correlations of CO₂ to pollutants and other variables of environmental performance and children's health or attendance.

A literature review of CO₂ levels in classrooms collated results from studies from several countries (Santamouris et al. 2008). Their literature review of 36 papers reported median levels across naturally ventilated schools of approximately 1420 ppm and for mechanically ventilated schools 910 ppm. Average concentrations exceeded 1500 ppm in 46% of the naturally ventilated schools and 15% of the mechanically ventilated schools. The exceedance percentages over 1000 ppm were 75% and 48%, respectively. Finally, exceedance percentages over 2000 ppm were 18% and 5%, respectively. The study did not distinguish between seasons and primary or secondary schools. Results of this comprehensive review by Santamouris et al. are often used as a reference across studies.

Carbon dioxide concentration levels monitored under the SINPHONIE framework in primary school buildings in Europe were collated in the final report (Csobod et al. 2014). The average CO₂ concentration across the 300 primary school classrooms was 1433 (σ : 856) ppm and the median was 1257 ppm. However, classrooms which featured mechanical ventilation (11% of the classrooms) averaged considerably lower concentrations at 1087 ppm. This compares to the average for naturally ventilated classrooms of 1500 ppm (Csobod et al. 2014). In 20 countries out of a total of 22 participating in the SIPHONIE study, the reported overall median CO₂ concentrations exceeded 1000 ppm (1490 ppm), with the exceptions of Sweden and Norway (with 657 ppm and 686 ppm, respectively). The SINPHONIE study provided a comparison between countries, highlighting that occupancy densities in different countries can play a significant role.

Several studies in the UK have found similar CO₂ levels to those found in the SINPHONIE project. Bako-Biro et al. (2012) monitored CO₂ levels in 16 classrooms in 8 schools for 1 week before an intervention that increased ventilation rates to investigate potential correlations with children's health and cognitive performance. Average CO₂ concentrations during occupied hours ranged from 644 ppm to 2833 ppm (average 1426 ppm, σ : 624). Peaks reported averaged 3132 ppm and reached the 5000 ppm limit. In another UK study, Korsavi et al. (2020) investigated the influence of occupants on indoor air quality and monitored CO₂ levels in 29 classrooms in 8 naturally ventilated primary school buildings. Of these classrooms, 14 were monitored over a day in the heating season and 15 over a day in the non-heating season in 2017–2018. The study found average CO₂ levels of 1208 (σ : 427) ppm in the heating season and 1050 (σ : 444) ppm in the non-heating season (values referred to nominal occupied hours). A summary of some of the studies investigating CO₂ levels in classrooms can be found in Table 6.

Table 6 Monitoring studies which investigated classroom CO₂ levels in schools

Study with continuous monitoring of CO ₂ in classrooms	Country	Length of monitoring	Year of monitoring	Sample size	Seasons	Results on CO ₂ levels (ppm)
SINPHONIE Csobod et al. (2014)	European countries including the UK	One week in each season	2012–2013	300 primary schools	Heating and non-heating	Average 1433 ppm, median 1257 ppm
Bako-Biro et al. (2012)	UK	Week (before intervention)	2006–2008	8 primary schools, 16 classrooms	Mix of seasons	
Korsavi, Montazami and Mumovic (2020)	UK, England	One day, random	2016–2017	29 classrooms in 8 schools, 14 in the heating season, 15 in the non-heating season	Heating and/or non-heating	
Gaihre et al. (2014)	UK, Scotland	3–5 days	2010	60 classrooms, 30 primary schools, Aberdeen	Non-heating, May–June	Median of daily averages: 1086 ppm Median of peak values: 2167 ppm
Dorizas et al. (2018)	UK, London, England	Long-term monitoring over 15 months and seasonal week-long monitoring	2006–2007	1 primary school, 2 classrooms, naturally ventilated with Monodraught	Heating and non-heating	
Beisterner and Coley (2003)	UK	Continuous at 5 min intervals over 1 week approximately	2002	4 classrooms, 2 primary schools	Non-heating: May and June Heating	Non-heating: average during occupied period 1570 ppm, maximum 3750 ppm Heating: average during occupied period

(continued)

Table 6 (continued)

Study with continuous monitoring of CO ₂ in classrooms	Country	Length of monitoring	Year of monitoring	Sample size	Seasons	Results on CO ₂ levels (ppm)
Fromme et al. (2007)	Munich, Germany	One day (during occupied hours), 1 min interval	2004–2005	64 schools, 92 classrooms in winter, 75 classrooms in summer	Heating, non-heating	1957 ppm, max over 4000 ppm
WHO-CEHAPe, Lukis Study Air and Children, Austria (Wallner et al. 2012; Hutter et al. 2013)	Austria	1-week period per season		18 classrooms, 9 primary schools	Autumn and spring	Daily average: from 500 to 1400 ppm Median: 850 ppm Maximum of 1 h moving average: 3300 ppm
Teeuwen et al. (2015)	The Netherlands	Continuous monitoring, 1 week, mechanically ventilated school buildings including 2 Passivhaus schools		4 schools	Heating season	Average 1066 (300) Norm. average 1655 (467) 95th percentile averaged at 1281 (412), 90th percentiles ~2300 ppm

Rovelli et al. (2014)	Italy, Milan	Naturally ventilated only	7 schools (of which 3 primary schools), 3 classrooms in each school	Over a week in winter, two monitoring campaigns 2011–2013.	Averages from two campaigns: 1423 (σ : 562) 1428 (σ : 609) Medians: 1333, 1271
Pegas et al. (2011)	Lisbon, Portugal	Primary schools. 1 day per season	3 classrooms in 3 primary schools (one classroom per school)	Spring, autumn, and winter	Average 1109 (σ : 499) ppm
Heudorf, Neitzert, and Spark (2009)	Germany	2 schools, 4 classrooms	February	1 week of normal operation	Average 1437 (994) ppm Median 1100 ppm Max 4840 ppm
Fronnme et al. (2013) LUPE 2 study	Germany	14 classrooms over 20 consecutive days, 1 classroom over 83 days.			Mean 1329 ppm, median 1211 ppm Range 267–4247 ppm Daily medians ranged 423–3135 ppm

Influencing Factors and Correlations

From the previously listed studies, factors affecting CO₂ concentrations in the classroom included:

- Number of occupants
- Occupant metabolic rates (occupant activities)
- Air exchange rates
- Ventilation type (natural ventilation vs. mechanical or mixed move ventilation)
- Ventilation rate control type (fixed rate vs. dynamic control).

Nitrogen Dioxide

NO₂ Limits, Link to Health

Nitrogen dioxide is one the few selected pollutants in the 2010 WHO Guidelines for indoor air due to its recognized impacts on health (WHO 2010). The recommended limits for both short- and long-term exposure to indoor air NO₂ are listed in Table 7. WHO Air Quality Guidelines (2021) recommended a short-term limit of 25 µg m⁻³ (13.3 ppb) for hourly average concentrations. This recommendation was based on evidence presented in the systemic review by Orellano et al. (2020). A chronic exposure limit at 10 µg m⁻³ (5.3 ppb) is recommended for annual average concentrations. The long-term limit was based on a systematic review by Huangfu and Atkinson (2020). The guidelines, however, acknowledge that there is a lack of

Table 7 Levels of NO₂ in schools in existing literature

Study	Levels (µg m ⁻³)	HRQ, level-over-limit ratios (WHO 2010) long-term limit of 40 µg m ⁻³	IORs
SINPHONIE, Csobod et al. (2014)	Average 14 µgm ⁻³ (7.5 ppb), median 11 µg m ⁻³ (5.9 ppb) (range: below detection limit – 88 µg m ⁻³)	<1.0	
Chatzidiakou et al. (2015d)	Averaged over 2 weeks. Heating season: 23.0 (9.7) Non-heating season: 14.7 (5.4) Urban heating season: 31.2 Suburban heating season 14.9 Urban non-heating: 19.1 Suburban non-heating: 10.2	Long-term limit: >1.0 (except suburban in the non-heating season)	>1
Wichmann et al. (2010) Sweden			Average ~ 1 (0.96) Range 0.44–2.17
Blondeau et al. (2005)			0.88–1.00

evidence on the exposure-response effect for NO₂, and the certainty of the evidence from the review was only considered moderate (Huangfu and Atkinson 2020).

Exposure to NO₂, mainly from outdoor sources in schools, is associated with respiratory health effects, and high concentrations can affect lung growth in children and low attendance rates in schools (Annesi-Maesano et al. 2013a; WHO 2006). The WHO guidelines note that an increase of 28 µg m⁻³ over 15 µg m⁻³ associated with indoor sources led to an increase by 20% of respiratory health risk in children. Exposure to indoor air NO₂ was consistently linked to respiratory symptoms, and respiratory infections resulting from impaired immune response, bronchoconstriction, increased bronchial reactivity, and airway inflammation (Kephalopoulos et al. 2014).

NO₂ Levels from Existing Studies

The WHO Schools Survey including more than 150 schools across 5 countries found that median NO₂ levels in classrooms were below the 40 µg m⁻³ annual average WHO limit. The SINPHONIE-EU study average classroom indoor concentration ($n = 300$) was 14 µg m⁻³ (SD = 8), with a range from below the detection limit to 88 µg m⁻³. Only a few classrooms exceeded the annual exposure limit as outlined by the 2006 WHO guidelines, with 90% of the classrooms below 26.4 µg m⁻³ (Csobod et al. 2014). However, more than half of the classrooms exceeded the revised WHO guideline of 10 µg m⁻³ annual average (50th percentile, 11.4 µg m⁻³).

The PRIMEQUAL study covered eight schools in France and found that NO₂ indoor to outdoor ratios (IORs) were within the range of 0.88–1.00, suggesting that little removal of the pollutant from outdoor air introduced to the building occurs (Blondeau et al. 2005). The ventilation type and airtightness were not found to correlate with NO₂ infiltration.

Nitrogen dioxide concentrations were monitored with passive sampling over 2 weeks in the UK primary school classrooms by Chatzidiakou et al. (2015b, c). Average classroom concentrations in the heating season were 23.0 (σ : 9.7) µg m⁻³ and 14.7 (σ : 5.4) µg m⁻³ in the non-heating season. The difference is influenced by ambient concentration variation across the seasons. Twofold higher concentrations were observed in urban environments and in schools close to major roads in both seasons (Ferguson et al. 2021). Urban outdoor concentrations in Chatzidiakou et al. (2015d) ranged from 40.2 to 49.4 µg m⁻³ and were higher than ambient concentrations in suburban school locations. The authors reported IORs ranging from 0.3 to 0.5 in more airtight buildings and from 0.6 to 0.8 to leakier buildings in the heating season. Higher IORs were observed in the non-heating season, ranging from 0.8 to 0.9, commensurate with more window opening.

Time-averaged NO₂ levels monitored with passive samplers over occupied hours ranged from 2.9 to 47.0 µg m⁻³ with an average of 17.3 (σ : 12.5) µg m⁻³ and a median of 14.1 µg m⁻³ in Swedish schools with IORs ranging 0.44–2.17 and averaging 0.96 (σ : 0.36). (Wichmann et al. 2010). Levels found in the literature are summarized in Table 7.

Influencing Factors

Nitrogen dioxide in schools is primarily introduced from the external environment and is associated with traffic-related sources and proximity to roads. Therefore, average classroom NO₂ concentrations in schools are primarily influenced by outdoor levels (Chatzidiakou et al. 2015d; Poupart et al. 2005). However, potential indoor sources, such as school kitchens, should be noted.

The relationship between NO₂, ventilation rates and building airtightness is complicated. An intervention study by Rosbach et al. (2013) introduced CO₂ controlled ventilation in naturally ventilated classrooms, increasing ventilation rates during occupied hours, reflected in the reduced CO₂ concentrations, but found that NO₂ levels remained the same before and after the intervention.

In an effort to investigate the effect of school building airtightness on indoor air pollutants, Poupart et al. (2005) monitored eight naturally and mechanically ventilated school buildings in France. The investigation of the correlation between indoor and outdoor concentrations of the nitrogen oxides (NO and NO₂) showed that indoor concentrations followed outdoor concentrations, but this was not influenced by the building envelope airtightness levels. The IORs of NO₂ were consistently close to 1, suggesting that an airtight envelope does not protect from outdoor NO₂.

Findings from IORs investigations in Chatzidiakou et al., however, contradicted the Poupart et al. findings, suggesting that infiltration of NO₂ to the indoor environment was influenced by the airtightness of the building envelope (Chatzidiakou et al. 2015d). A study by Wichmann et al. (2010) on personal microenvironments, school, and home NO₂ and PM_{2.5} concentrations in Sweden found that indoor and outdoor NO₂ concentrations were strongly correlated. They reported that ventilation type and air exchange rates did not influence the infiltration rate of NO₂. More evidence is required from continuous real-time monitoring to investigate these differences.

Particulate Matter (PM)

PM_x Limits, Link to Health

Particulate matter (PM) includes all suspended solid and liquid phase material in the air. PM can be grouped into subcategories by size (particle aerodynamic diameter) and can vary in terms of chemical composition depending upon the sources (WHO 2021). Both size and chemical composition matter in terms of the toxicity of PM. Chemical composition grouping of ambient PM is comprised of sulfates, nitrates, diesel smoke, and soil/road dust (a more comprehensive discussion of which can be found in the ► Chap. 8, “Introduction to Particles in Indoor Air”). There are relationships between particle size and chemical composition categories. For example, diesel smoke particles are likely smaller than nitrate particles and soil dust or road dust. Exposure limits are differentiated by broad size categories for PM_{2.5} and PM₁₀ (Table 8).

Table 8 Acceptable concentrations of PM_{2.5} and PM₁₀ according to existing standard and guidelines

Air pollutant	Upper limit, criterion ($\mu\text{g m}^{-3}$)	Type of exposure	Based on outcomes	Reference
PM _{2.5}	5	Long-term, mean annual exposure	Cardiovascular and respiratory functions	WHO Ambient Air Quality Guidelines (2021)
	15	Short-term exposure, 24-h mean	Cough, eczema, dermatitis, headache, and nausea	WHO Ambient Air Quality Guidelines (2021)
	25	Long-term, mean annual exposure		EU Ambient Air Quality Directives
	12	Long-term, annual average (primary)		USEPA NAAQS
	35	Short-term, 24- h average (98th percentile, averaged over 3 years)		USEPA NAAQS
PM ₁₀	15	Long-term, mean annual exposure		WHO Ambient Air Quality Guidelines (2021)
	45	Short-term exposure, 24-h mean		WHO Ambient Air Quality Guidelines (2021)
	40	Long-term, mean annual exposure		EU Ambient Air Quality Directives
	150	24-h maximum (not to be exceeded more than once per year on average over 3 years)		USEPA NAAQS

Oeder et al. (2012) reported that the chemical composition, particle numbers, and particle mass concentration for the coarse size fraction in indoor air are typically different compared to outdoor air. The study found that indoor PM₁₀ levels were not only higher (six times higher in this study) than outdoor levels but could also be qualitatively different (more biologically active), causing stronger health effects per unit concentration. Oeder et al. found that particle bound endotoxin and polycyclic aromatic hydrocarbons (PAHs) were higher in classroom air than outdoor air due to the presence of indoor sources. Investigating the chemical composition of different size fractions can further support the source apportionment of PM in indoor air. Some studies argue that PM_{2.5} in schools is introduced substantially through outdoor sources (e.g., road traffic), primarily due to lack of well-defined indoor sources in

schools. However, in other indoor environments, particles are reported to arise from human-related activities such as cooking, resuspension of particles from the activities of occupants (e.g., walking), cleaning, shedding of skin flakes, and from construction projects (Zuraimi and Tham 2008; Patel et al. 2020). Studies also find that indoor PM levels are associated with occupant density, with PM_{10} concentrations more sensitive to occupancy than $\text{PM}_{2.5}$ (Alves et al. 2013; Branco et al. 2014; Rim et al. 2017). Even a small number of children in the classroom is enough to increase PM concentrations through resuspension (Nunes et al. 2015). Indoor PM levels have been found to be higher in the classrooms of older children, due to higher activity levels (Branco et al. 2014; Mainka and Zajusz-Zubek 2015). Other sources include secondary formation from ozone and terpenes for smaller sizes (Madureira et al. 2016; WHO 2021; Morawska et al. 2009).

Exposure of children to $\text{PM}_{2.5}$ and PM_{10} has been demonstrated to be associated with adverse health effects by many studies (e.g., Annesi-Maesano et al. 2012; Daisey et al. 2003; Morawska et al. 2013). Both long- and short-term exposure to $\text{PM}_{2.5}$ are of concern to health according to the United States Environmental Protection Agency (USEPA) and the WHO. Annesi-Maesano et al. (2012) found that asthma prevalence in school children increased with exposure to $\text{PM}_{2.5}$ levels over $17.5 \mu\text{g m}^{-3}$. $\text{PM}_{2.5}$ in classrooms is associated with several health symptoms such as cough, eczema, dermatitis, headache, and nausea (Annesi-Maesano et al. 2013b). The long-term exposure limit for $\text{PM}_{2.5}$ of $5 \mu\text{g m}^{-3}$ aims at protecting against effects on cardiovascular and respiratory function (WHO 2021). PM_{10} concentrations were associated with lung disorders and reduced lung function. Madureira et al. (2016) investigated indoor air quality in schools and its relation to childhood respiratory health in Portugal. The study found that $\text{PM}_{2.5}$ and PM_{10} were positively correlated to increased risk for asthma-like symptoms, such as wheezing and irritating cough. PM_{10} showed a stronger association than $\text{PM}_{2.5}$ to this short-term health effect.

PM_x Levels from Existing Studies

The levels of fine particulate matter ($\text{PM}_{2.5}$) exceeded the long-term limit for annual average concentration of $5 \mu\text{g m}^{-3}$ as well as the $15 \mu\text{g m}^{-3}$ for 24-h average set out in WHO Ambient Air guidelines (WHO 2021) in primary school classrooms across European countries participating in the SINPHONIE study. $\text{PM}_{2.5}$ concentrations averaged $43 \mu\text{g m}^{-3}$ (median of $37 \mu\text{g m}^{-3}$) and ranged from 4 to $185 \mu\text{g m}^{-3}$. Levels of PM_{10} were reported by country average in the WHO Schools Study; country averages ranged between 28 and $102 \mu\text{g m}^{-3}$ (WHO 2015). A review of PM levels in classrooms in several countries found average PM_{10} concentrations in classrooms across northern Europe and the USA of $23 \mu\text{g m}^{-3}$ (Fischer et al. 2015).

In a study of six schools in Munich, Germany, PM_{10} concentrations were higher in classrooms than in both dwellings and outdoor air (Oeder et al. 2012). Oeder et al. found indoor classroom PM_{10} concentrations of $117 \pm 48 \mu\text{g m}^{-3}$ and outdoor concentrations were at least five times less at $21 \pm 15 \mu\text{g m}^{-3}$. In a study in French primary school classrooms, Tran et al. (2014) found PM_{10} during occupied hours between 70 and $99 \mu\text{g m}^{-3}$, although $\text{PM}_{2.5}$ concentrations were lower at less than $25 \mu\text{g m}^{-3}$.

Continuous measurements by Fromme et al. (2007) in classrooms in 64 schools in Munich in winter and summer 2004–2005 found daily median concentrations from the classroom were $19.8 \mu\text{g m}^{-3}$ in winter and $12.7 \mu\text{g m}^{-3}$ in summer. Median PM_{10} concentrations were $91.5 \mu\text{g m}^{-3}$ in winter and $64.9 \mu\text{g m}^{-3}$ in summer. Gravimetrically determined $\text{PM}_{2.5}$ median concentrations were slightly higher than from continuous measurements, $36.7 \mu\text{g m}^{-3}$ in winter and $20.2 \mu\text{g m}^{-3}$ in summer. Wallner et al. (2012) determined $\text{PM}_{2.5}$ and PM_{10} averages in spaces adjacent to 18 Austrian classrooms, using gravimetric measurements. They found PM_{10} concentrations of a median of $29 \mu\text{g m}^{-3}$ while $\text{PM}_{2.5}$ concentrations had a median of $12 \mu\text{g m}^{-3}$. A summary of study findings of PM levels in schools can be found in Table 9.

Influencing Factors

Resuspension of particles in classrooms is an important factor in the concentration of PM in classrooms. Larger particles are especially influenced by occupancy and resuspension, as they deposit more quickly on surfaces (Blondeau et al. 2005; Chatzidiakou et al. 2015a). Occupant density has been found to influence indoor levels of PM_{10} (Chatzidiakou et al. 2015b, c). The influence of occupancy is confirmed by findings in Tran et al. (2014), again reporting much lower PM_{10} concentrations during unoccupied hours, a difference that could not be explained by a much smaller decrease in outdoor concentrations across unoccupied periods. In line with these findings, higher occupant densities were associated with increased median PM_{10} concentrations in Fromme et al. (2007). Similarly, Fischer et al. (2015) found that larger particles concentrations increased when children were in the classroom due to resuspension of material deposited on surfaces leading to marked peaks. Resuspension of PM_{10} is consistent with findings in Wallner et al. (2012) where indoor $\text{PM}_{2.5}/\text{PM}_{10}$ ratios were higher than the outdoor ones. Primary schools and classrooms with younger children have higher PM levels compared to secondary schools (Fischer et al. 2015). This finding was attributed to activity types and levels of younger children. Resuspension related PM_{10} peaks can be addressed by cleaning. Fischer et al. (2015) suggest that cleaning in the morning before the start of the day reduces PM levels and that surface cleaning frequency and thoroughness may play a role in reducing PM concentrations. However, cleaning during occupied hours was found to increase fine and coarse PM during occupied hours through resuspension (Chatzidiakou et al. 2015d).

Smaller particles, including PM_1 , are heavily influenced by generation from occupants, including skin flakes, squalene, and other reactive hydrocarbons and secondary formation (Weschler 2004). For example, the ozonolysis of terpenes is likely to cause the secondary formation of ultrafine PM (PM_1) (Blondeau et al. 2005; Fischer et al. 2015; Morawska et al. 2009). This process is influenced by ventilation rates. Increasing ventilation rates lowers terpene concentrations but introduces ozone in indoor air. Fischer et al. found that further increasing ventilation rates could prevent this process, but that intermittent ventilation could increase the efficiency of PM_1 production through the ozonolysis of terpenes. The presence of terpenes in classroom indoor air is influenced by cleaning activities (terpenes are often used in cleaning products) but

Table 9 Levels of $\text{PM}_{2.5}$ and PM_{10} in schools

also fruit consumption. Citrus fruit pealing during breaks led to peaks of PM₁, through the secondary process described above (Fischer et al. 2015).

Poupard et al. (2005) reported that the building envelope airtightness did not have an effect on the correlation between indoor and outdoor PM₁ levels or fine PM (2–3 um). Poupard et al. also noted IORs for PM₁ decreased with increasing outdoor concentrations, hypothesizing that an increase of outdoor PM₁ levels at night coincided with decreased indoor generation from occupancy. Fischer et al. (2015) reported that when mechanical ventilation is on, infiltration through the building envelope had a proportionately small effect on indoor concentrations of PM.

Seasonal variations investigated in Fromme et al. (2007) showed that a significant decreases of indoor PM_{2.5} and PM₁₀ concentrations is likely to occur in summer. The seasonal variation was attributed to different ventilation practices and therefore, different primary sources in winter and in summer. Chatzidiakou et al. (2015d) also found that classroom PM_{2.5} and PM₁₀ levels were higher in the heating season compared to the non-heating season, commensurate with ambient concentrations. However, lower air exchange rates with outdoor air in the non-heating season means that indoor sources are likely still important (Morawska et al. 2017).

Madureira et al. (2016) found PM₁₀ levels were influenced by the number of windows open during the heating season (with levels reducing with more open windows). Similarly, Chatzidiakou et al. (2015d) noted inadequate ventilation rates correlated with higher PM concentrations in classrooms. Chatzidiakou et al. also found that lower wind-driven natural ventilation rates (wind direction parallel to classroom window wall) were associated with higher PM levels. The location of air intake for mechanical systems is also an important factor as they are often located near loading docks, or areas where school buses or other vehicles idle, leading to the contribution of diesel exhaust to indoor PM concentrations.

In terms of internal finishes, higher PM_{2.5} were found in classrooms with carpet compared to classrooms with hard flooring material (Shaughnessy et al. 2002). This finding is consistent with those in laboratory studies (Tian et al. 2014) and more recent findings in the UK; Chatzidiakou et al. (2015d) found considerably higher indoor coarse and fine PM in classrooms with carpet flooring versus classrooms with hard flooring. Other indoor sources of PM in schools included visible damp spots and mold growth (Madureira et al. 2016), and in schools which prepare meals, cooking of hot food for lunches (Weichenthal et al. 2008).

VOCs

VOC Limits, Link to Health

Adverse health effects from inhalation of the wide range of indoor air VOCs are known to result in acute and chronic adverse health effects including irritation of the mucous membrane and lower respiratory irritation, neurological, allergic, developmental, reproductive, and carcinogenic effects. The presence of VOCs in indoor air

has been specifically associated with discomfort, sensory irritation, and cancer (Sofuoğlu et al. 2011).

A number of studies investigated the influence of VOCs on children specifically. One study found there was a correlation between levels of a semi-volatile organic compounds (SVOCs) and children's concentration performance (Hutter et al. 2013). The VOCs formaldehyde and benzene were found to have a negative correlation with morning and afternoon mathematical test results by Csobod et al. (2014). Additionally, Csobod et al. (2014) found that attendance was negatively influenced by increased concentrations of the VOCs limonene and naphthalene in classrooms. Reduced school attendance is considered to negatively impact academic performance.

A few studies discussed the relationships of total VOC (TVOCs) in indoor air and health (e.g., Daisey et al. 2003). Predictors of TVOCs include cleaning products, fleecy materials, and occupancy density. Common sources include paints, furniture, and air fresheners. Exposure to increased TVOCs was associated with an increased risk of asthma in children in a study in primary schools in Portugal (Madureira et al. 2016).

The influence of levels of SVOCs in dust in primary schools and the cognitive performance of children, aged 6–8 years was investigated in the Austrian LuKi study: "Air and Children" which included nine schools (Hutter et al. 2013). The study found a negative correlation between cognitive performance and indoor concentrations of the semi-volatile organic phosphor-organic compound (POC), tris(2-chlorethyl)-phosphate (TCEP) in dust and air samples. POCs are used as flame retardants, plasticizers, and floor adhesives. TCEP is a carcinogenic substance of very high concern due to its reproduction toxicity. In addition, cognitive performance of children was found to have a negative correlation with the polycyclic aromatic hydrocarbon (PAH), phenanthrene.

Limiting values for indoor air concentrations of different lists of individual compounds have been developed by different organizations in various countries. Additionally, studies reported on current efforts to derive limiting values for 95 more compounds (Harrison et al. 2011; Ye et al. 2014). Limits for indoor air concentrations of VOCs applicable to all building types from both building regulations and the WHO Guidelines are listed in Table 10. The compounds are listed in hierarchical order as they appear in documents in hierarchical order. On an international level and applicable to all four building types, the WHO guidelines for indoor air quality: selected pollutants (WHO 2010) provide limiting values for VOCs including benzene, formaldehyde, naphthalene, trichloroethylene (T3CE), tetrachloroethylene (T4CE), 1,3-butadiene, polycyclic aromatic hydrocarbons (PAHs) and their indicator benzo[a]pyrene (BaP). A number of additional air pollutants for which exposure limits were not determined due to insufficient evidence are also listed in the WHO Guidelines and include acetaldehyde, biocides and pesticides, flame retardants, glycol ethers, hexane, phthalates, styrene, toluene, and xylenes.

Limiting values for all indoor air pollutants, including VOCs, take into consideration toxicological and epidemiological data, the levels of exposure linked to adverse effects on health, and the likelihood of presence of indoor sources and current levels. Despite the well-established health risks of specific air pollutants

Table 10 WHO and UK DEFRA limits for VOCs in primary school building classrooms

Pollutants	WHO	UK Air Quality Objectives (DEFRA, 2007)

found in classrooms, and the guidelines addressing these, there is currently little evidence available on the actual levels in classrooms, as collecting it can be complex, expensive, labor intensive, and time consuming, and requires technical expertise. Evidence that is available is described in the following section.

VOC Levels from Existing Studies

There are several comprehensive indoor air quality studies in school buildings identified in Csobod et al. (2014). The reviewed studies, de Gennaro et al. (2013) in Italy, Zhong et al. (2017) in the USA in 2015–2016, and Sofuoğlu et al. (2011) in Turkey, are summarized in Table 11 and further described below.

A sample of 144 mechanically ventilated classrooms in 37 school buildings in a 2015–2016 air quality monitoring in US school classrooms in Ohio, Indiana, Michigan, and Illinois reported concentrations of the 94 most frequently detected (detection frequency over 15%) VOCs (Zhong et al. 2017). All schools were built or renovated between 2001 and 2012 and were Energy Star and LEED-certified. Most of the detected compounds were aromatic hydrocarbons, alkanes, and terpenes. Benzene, toluene, xylenes, n-tetradecane, and n-limonene were found in most classrooms. While formaldehyde, methyl-cyclohexane, methylene-chloride, and n-limonene had the highest median concentrations.

A monitoring study in classrooms of eight naturally ventilated middle and elementary school buildings in southeastern Italy determined concentrations for different classes of VOCs, including alkanes, aliphatic hydrocarbons (alkanes, cycloalkanes), aromatic hydrocarbons, terpenes, ketones, aldehydes, alcohols, and

Table 11 Comprehensive indoor air quality studies that determined a range of VOC concentration levels in school buildings

Study	Sample	Method/limitations	Key findings
Zhong et al. (2017)	144 classrooms in 37 conventional and high-performance schools recently built or renovated (last 15 years) in the USA Monitoring took place in 2015–2016.	Indoor and outdoor concentrations of 94 VOCs were determined (using thermal desorption, gas chromatography-mass spectroscopy) Only those compounds detected in more than 15% of the samples were included in the analysis (24 VOCs in total)	24/94 compounds with a detection frequency >15%. Most of the detected VOCs fell into classes of aromatic hydrocarbons, alkanes, and terpenes. Average concentrations below 5 µg m ⁻³ .
de Gennaro et al. (2013)	8 school buildings, both middle and elementary, South each Italy	The study provided quantitative information on 14 compounds including formaldehyde	Passive sampling using radial samplers over a week, in 3 classrooms and an outdoor site. Limonene, pinene, and toluene were at highest concentrations in schools in Italy (of 14 compounds measured)
Sofuoğlu et al. (2011)	3 primary schools, Turkey	The method was optimized for quantitative determination of 51 compounds, and an average of 16 compounds were found in the samplers. Active sampling, repeated 6–9 times each season, repeated in fall, winter, and spring. Monitoring in a classroom, a kindergarten, and outdoor playground site	Benzene, toluene, and formaldehyde were the most abundant compounds with 95th percentile indoor air concentrations of 29, 87, and 106 µg/m ³ , respectively

halocarbons as reported by de Gennaro et al. (2013). de Gennaro monitored VOCs in three classrooms and one outdoor site in each school building using passive sampling. The most abundant compounds were determined to be *a*-pinene, *D*-limonene, and toluene. The study discussed potential sources and health-risk associated limits of specific compounds.

Concentrations of VOCs and formaldehyde in three primary school buildings in Turkey were evaluated in Sofuoğlu et al. (2011). Benzene, toluene, and formaldehyde were confirmed as the most abundant compounds in indoor classroom air with 29, 87,

and $106 \mu\text{g m}^{-3}$ 95th percentile concentrations, respectively. The importance of indoor sources is highlighted in Sofuođlu et al. (2011) since results showed greater variation between urban schools compared to variation between urban and suburban schools. A summary of key pollutants, and their target levels, in schools can be found in Table 12.

Influencing Factors

Likely sources of commonly targeted VOCs have been identified in the literature. Madureira et al. (2016) found that 21% of the variation of indoor VOC concentrations were explained by factors including: main flooring material, number of windows open in the cooling season, number of windows usually open before the start of teaching, and the presence of graphic arts materials in the classroom. Surface materials are important influencing factors of indoor air quality in classrooms as they function as primary indoor sources, sinks, and secondary sources of pollution. Poulhet et al. (2014), in a source apportionment study in eight primary schools in France, showed that a surface material with high loading factor can be responsible for 87–98% of the formaldehyde emissions in classrooms even though 29 different sources of formaldehyde were identified (see ► Chap. 2, “Very Volatile Organic Compounds (VVOCs)”). Temperature, relative humidity, and air exchange rates influence the emission rates of compound/source couples. Other processes also play a role, including deposition and chemical reactions.

Many VOCs have strong indoor sources, including T3CE, limonene, and pinene with the last two mainly from cleaning products (Chatzidiakou et al. 2015d; de Gennaro et al. 2013, 2014). Toluene is emitted from traffic as well as being a solvent, and therefore both indoor and outdoor sources can be present. Benzene is predominantly traffic related but can also be emitted from art supplies (Chatzidiakou et al. 2014). As with particulate matter, if the air intake for mechanical HVAC systems is located near areas where vehicles stand idling (such as in bus queues or loading docks), the exhaust can contribute substantially to indoor VOC concentrations. Formaldehyde is mainly emitted from furnishing and construction materials containing resins and adhesives. Emissions from these sources are persistent and gradually decline over the years. Sources of α -limonene and α -pinene are cleaning products and fragrances, and sources of 2-butoxyethanol include latex paints, paint thinners, and varnishes. Many compounds were found to have significant indoor sources including: α -limonene, hexanal (I/O ratio 14.3), formaldehyde, acetone, 1-butoxy-2-propanol, acetaldehyde, propanol, 1-butanol, *n*-undecane, methylcyclohexane, and *n*-dodecane (Geiss et al. 2011).

Compounds with high IORs in the AIRMEX monitoring study in offices, public buildings, and schools included: formaldehyde, hexanal, α -limonene, α -pinene, 2-butoxyethanol, acetaldehyde, acetone, 1-butoxy-2-propanol, *n*-undecane, propanol, methyl-cyclohexane, *n*-dodecane, and 1-butanol. Ye et al. (2017) created a priority list of VOCs that were most likely to contribute to ventilation rate requirements that included pinene, hexanal, and 2-ethyl-1-hexanol (but not formaldehyde or phthalates).

^aWHO guidelines for indoor air quality: selected pollutants (2010)

Higher ventilation rates were associated with lower TVOC concentrations in classrooms (Madureira et al. 2016). Increasing ventilation levels to 7–10 L s⁻¹ per person was found to reduce TVOC concentrations in classrooms to acceptable levels (Daisey et al. 2003) and in the review by Luther et al. (2018).

Summary and Conclusions

The Evidence Gap

More empirical evidence from classrooms is needed for assessing IAQ in schools. Modelling approaches for determining indoor air pollution from building characteristics and sources are limited by the many unknowns in complex physicochemical processes and cannot substitute for monitoring (Poupard et al. 2005). Analysis of monitoring results using statistical modelling techniques can help identify and verify potential relationships between building physical and operational characteristics that influence indoor air quality. These techniques can facilitate determination of population-level environmental exposures of children to be used for policymaking and school building design. There is a need for a holistic understanding of actual indoor air quality in school classrooms and the role of heating, cooling, and ventilation systems, as well as finishing and furnishing materials, on air quality of classrooms. Comprehensive indoor air pollution monitoring evidence is limited in schools. Despite their importance for the determination of health risks, the chemical composition of PM and qualitative description of the matrix of VOCs in schools is understudied. This information is greatly needed since the types of VOCs present in indoor air is heavily influenced by indoor sources, which can vary between countries, and building types.

Influencing Factors and Correlations

The physical characteristics that distinguish the indoor environment from the outdoor environment are (as listed in the review by Abbatt and Wang (2020)): air exchange rates and mixing rates, volume to surface ratios, sunlight, limited temperature and relative humidity variation, absence of moisture deposition, and occupancy density. The processes that determine indoor concentrations, and thus exposure to pollutants, are indoor primary sources, infiltration, and secondary processes (generation or depletion). Indoor sources are linked to design and delivery decisions (building materials), cleaning and occupancy, and can be pulse or continuous, persistent or transient. Infiltration of outdoor sourced compounds relate to the building envelope and the age of air (air infiltration, air exchange rates and patterns) and can be influenced by different factors for different pollutants.

IAQ is evaluated with many different methodologies. The investigation of proxies of IAQ demonstrate that existing proxies such as CO₂ and ventilation rates are not likely to provide a holistic description of IAQ in classrooms. Therefore, IAQ

studies with comprehensive monitoring of IAQ are important. As school building characteristics evolve with changes in building practices and building regulations, in particular high-performance buildings and retrofits, a better understanding of IAQ is increasingly important.

Ventilation Strategy

The ventilation strategy, broadly classified as natural ventilation only, mechanical ventilation only, and mixed mode ventilation, was found to influence average ventilation rates in school classrooms. Santamouris et al. (2008) found that median ventilation rates in classrooms in naturally ventilated schools were considerably lower compared to those in mechanically ventilated school ($3.0 \text{ vs. } 8.3 \text{ L s}^{-1} \text{ p}^{-1}$). This is corroborated by findings in Mumovic et al. (2009) that average heating season ventilation rates under normal operation in 12 naturally ventilated classrooms were lower compared to 4 mechanically or mixed mode ventilation classrooms ($3.28 \text{ vs. } 7.15 \text{ L s}^{-1} \text{ p}^{-1}$). In addition, while mixed mode ventilated schools have wider fluctuations than mechanical ventilation, similar to naturally ventilated schools, on average they provide higher ventilation rates than naturally ventilated schools (Mumovic et al. 2009).

Air Exchange Rates

Air exchange rates in school classrooms are often estimated from CO_2 concentration as these variables are strongly and inversely correlated. While increasing ventilation rates will reduce CO_2 concentrations in the occupied classroom, this is not the case for the concentrations of all other pollutants. Evidence from several monitoring studies agreed that increasing ventilation rates during occupied hours decreased indoor PM_{10} classroom concentrations. Findings on the relationship between ventilation rates and $\text{PM}_{2.5}$ were contradictory, and more work needs to be done to reach consensus on the relationship between $\text{PM}_{2.5}$ and ventilation rates. NO_2 has no indoor sources in schools, and a number of studies suggested that higher ventilation rates increased NO_2 levels in classrooms. However, in at least one study, increasing ventilation rates with a CO_2 control system in a classroom did not influence NO_2 . A number of studies found that higher ventilation rates were associated with lower TVOC.

Building Envelope Airtightness

Infiltration, due to leakage through the building envelope, has a smaller impact on overall air exchange rates the higher the ventilation rates are, and in densely populated classrooms, required ventilation rates are quite high. Findings from existing literature reviewed in this chapter found that airtightness influenced indoor thermal conditions and air quality parameters in classrooms, as follows.

The literature reviewed in this chapter identified contradictory findings with regards to the influence of building envelope air permeability on classroom NO₂ concentrations, but that NO₂ IORs did not appear to be influenced by outdoor concentration levels.

Airtightness was not found to influence the correlation between indoor and outdoor PM. Indoor followed outdoor concentrations no matter the airtightness. However, it is noted that findings mostly represent PM₁ particle size fraction.

Classroom Occupancy

The role of occupants in the generation of pollutants is a significant factor in the concentration of, and exposure to, indoor air contaminants in schools. Occupants shed skin flakes, and produce squalene, which contributes to PM. Occupants also (especially active children) play a major role in the resuspension of particles through activities such as walking and playing. They also produce a number of bio-effluents, including CO₂ and VOCs, that impact indoor air quality (Béko et al., 2020). It is, therefore, critically important to consider both occupant density and activities in the evaluation and assessment of air quality in classrooms.

The lower limits of 1.5 m² per child and 2 m² per child (or equivalent upper limits of 0.7 and 0.5 children per m²) are set in the SINPHONIE final report as associated with increased CO₂ levels (above 1500 ppm) and associated risk for health and academic performance. Additionally, smaller classroom volumes per occupant were associated with increased median PM₁₀ concentrations.

Seasonal Effects

Several parameters that define the classroom air quality are found to vary across the heating (cold) and non-heating (warm) seasons. A considerable decrease of classroom ventilation rates during occupied hours, and CO₂ levels from winter to summer is a frequent finding. Lower ventilation rates are anticipated in cold weather in naturally and mixed mode ventilated schools. While NO₂ IORs are lower in the heating season compared to the non-heating season (due to its correlation with ventilation rates), indoor classroom concentrations are not lower in summer than winter. This result is because ambient NO₂ concentrations are lower in summer compared to winter. Higher ventilation rates also contributed to lower concentrations of terpenes in the warm season compared to the cold season. Higher ventilation rates increased the reaction of terpenes with O₃.

Building Better Schools

Current practices for building design optimization in both new construction and retrofit projects involve iterative processes (optioneering) for meeting targets of

environmental and energy performance. These targets are regulatory requirements or optional requirements from guidance documents. Within these limits, there is room for prioritization of certain criteria through trade-offs. In school buildings, designing for the minimization of energy use and the optimization of the indoor environment involves such trade-offs. Bernardo et al. (2018) investigated the issues that influence energy performance of school buildings in a methodological framework for multi-criteria decision analysis.

As discussed in the “Influencing Factors” section of this chapter, different physical and operational features of the building (airtightness, surface materials, ventilation strategy and rates) and surrounding area can impact IAQ. Several of these may also impact other outcomes: energy efficiency, carbon footprint, and cost of the building. It is worth noting also that there is little evidence for the IAQ impact of new net-zero and other high-performance building types. Furthermore, IAQ is linked to a number of outcomes including health and academic performance. From these correlations, the building/classroom characteristics are indirectly linked to the health and performance outcomes (for example, this is directly studied in Bluyssen et al. (2018)). A building performance assessment that takes into consideration these outcomes for children, in a comparable manner, can help decision-making beyond the existing regulatory framework where conflicts and requirements for trade-offs can arise in the procurement process.

Abstract

Since multiple studies have addressed IAQ and associated exposure-related symptoms in office workers, a careful assessment and management of indoor air quality (IAQ) in office-like environments is important for the protection of human health and to ensure optimal comfort and well-being for office workers. For this purpose, the development of appropriate monitoring strategies is crucial to properly characterize the chemical and physical complexity of IAQ dynamics and subsequent potential impacts on office occupants. To obtain comprehensive and representative conclusions about IAQ problems in office-like environments, and to prioritize the order of management interventions, a multilevel approach should be implemented. The assessment process should include a general survey of the building and of the offices, occupants' questionnaire surveys (concerning

IAQ, symptoms, and psychosocial working aspects), and environmental measurements. IAQ monitoring and assessment, combined with source identification and control and adjustment of ventilation rates, has been recognized as the prioritized strategy for improving IAQ in office-like environments and reducing the combined health risks associated with indoor exposures.

IAQ · Indoor air pollutants · Office-like environments · Comfort · Symptoms

Introduction

Background

Indoor environmental quality (IEQ), which is related both to indoor air quality (IAQ) and to other environmental characteristics (such as temperature, noise, and light), may affect occupants' health, comfort, and well-being (Wolkoff 2013). The IAQ of confined nonindustrial environments is considered as a priority interest for both the general population and for a large part of the workforce. Indoor air contains a wide variety of physical (e.g., alpha ionizing radiation deriving from radon), biological (e.g., fungi, bacteria, mites, algae, etc.), and chemical contaminants (e.g., volatile organic compounds (VOCs), formaldehyde, ozone (O_3), particulate matter (PM), asbestos and man-made fibers, environmental tobacco smoke), arising from several sources, and presenting wide spatial and temporal variations. The sources of pollution consist mainly of infiltration of air from outdoors, heating, ventilation, and air-conditioning (HVAC) systems, humidifiers, building materials, furniture and furnishings, electronic equipment (including computers and photocopiers), and activities carried out by the occupants and the occupants themselves, who represent a source of many bioeffluents (e.g., skin flakes, carbon dioxide (CO_2), squalene, acetaldehyde). Overall, the contribution of IAQ to personal exposure to pollutants could be more relevant than the contribution of outdoor exposure. The indoor concentration of some pollutants is often equal to (e.g., for PM_{2.5} and nitrogen oxides (NO_x)) or much greater than (formaldehyde, radon, fungi) the corresponding outdoor concentrations, but the duration of exposure indoors is far greater than that outdoors. Overall, indoor chemical air pollutants can be divided into two general categories: (1) pollutants most commonly associated with occupant discomfort or acute illness (e.g., carbon monoxide (CO), formaldehyde, petroleum-derived solvents, halogenated solvents, and a variety of other VOCs) and (2) pollutants that can also cause chronic or carcinogenic illnesses (some VOCs, NO_x , airborne fibers, and airborne PM). There are also physical agents relevant to the field of IAQ assessment such as alpha ionizing radiations, emitted mainly by radon and its decay products. Radon exposure is the most relevant source of exposure to ionizing radiations in the general population and the primary risk factor for lung cancer in never smokers, with an almost linear increase in risk with increasing long-term exposure in indoor

spaces. Specific regulatory measures have therefore been adopted in various countries for preventive purposes (e.g., in Europe, the 2013/59/EURATOM directive laying down basic safety standards for protection against the dangers arising from exposure to ionizing radiation). Further, a mixture of biological pollutants can be present in indoor living and working environments. Viruses, bacteria (and their endotoxins), fungal spores, mites, algae, amoebas can proliferate in hydraulic and HVAC systems and in furnishings (carpets, upholstered furniture, rugs, wallpaper). High humidity and temperature facilitate the growth of molds and fungi and their presence is quite common and affecting, according to some estimates, between 18% and 50% of buildings. Biological agents can cause allergic diseases (e.g., rhinitis and conjunctivitis, bronchial asthma, hypersensitivity pneumonias) and infectious diseases (e.g., “Legionnaires’ disease,” Pontiac fever, Q fever), including viral diseases and miosis (Menzies and Kreiss 2006). HVAC systems can facilitate both the spread of infectious agents (influenza viruses, measles viruses, bacteria, fungi) and their proliferation, since they often represent a good growth environment. The World Health Organization has defined that exposure to mold in indoor environments involves an increased risk of respiratory symptoms for occupants (cough, wheezing), respiratory infections, new asthma onset, and exacerbations of preexisting bronchial asthma. There is also clinical evidence of an increased risk of less common diseases such as hypersensitive pneumonia, chronic rhinosinusitis, and allergic sinusitis.

Problem Statement: IAQ in Office Buildings

Overall, IAQ has been identified as a major concern in terms of its potential impact on human health: indoor exposures have been estimated to cause a substantial loss of health (Asikainen et al. 2016). The burden of disease is dominated by airborne PM, but also includes a contribution from long-term exposure to the most common air pollutants (e.g., nitrogen dioxide (NO_2), volatile organic compounds (VOCs) – this last group also include aldehydes which, however, are often named separately from other VOCs). Exposure to these indoor air pollutants (IAPs), even at low concentrations, may affect human health, causing or aggravating diseases, such as sensory irritation, cardiovascular diseases, chronic obstructive pulmonary disease, allergic and asthma symptoms, and lung cancer (Carrer et al. 2015). Overall, multifactorial causality of IAQ-related symptoms have been found, suggesting that a given symptom may arise from a combination of individual, occupational, and environmental risk factors (Wolkoff 2013, 2017). On the other hand, some relationships have been found between building characteristics and self-reported health complaints (Bluyssen et al. 2016). Generally, diseases and uncomfortable situations mainly reported in office workers find their origin in a condition of nonoptimal IAQ, especially if associated with unfavorable microclimatic conditions. Further, other factors such as the exposure to noise, the prolonged use of equipment with monitor (especially for some workers such as designers, journalists, brokers, computer scientists, web designers, graphic designers, etc.), inadequate working space and a

tight work organization can take on considerable importance in specific cases (Steinemann et al. 2017).

From these considerations and considering that people spend approximately 90% of their time indoors, IAQ may considerably affect human health and well-being (World Health Organization 2010). In this context, nonindustrial built work environments such as offices are of particular concern, as they represent the most common occupational environment in developed countries. In industrialized countries, about 67% of the employed population works in environments in the tertiary sector and in offices (while 27% and 6% are employed in industry and agriculture, respectively). In developing countries, about 46% of the employed work in the tertiary sector (while 19% work in industry and 35% in agriculture). Different sources may emit pollutants in office indoor environments directly (e.g., emissions from consumer products, building materials, office equipment, indoor combustion sources, etc.) or indirectly (i.e., primary pollutants may react with each other, with pollutants from other sources, or with surface materials, creating secondary compounds) (Trantallidi et al. 2015). IAQ in office buildings can be affected by several parameters such as inappropriate selection of indoor materials, emissions from electronic equipment and performance of the heating, ventilation, and air-conditioning (HVAC) systems, the use of carpets as floor covering, recently painted walls, and is related with other workplace conditions (crowded offices and presence of unpleasant odors, dust, and dirt). Further, office environments involve some other specific characteristics leading to the presence of typical pollutants sources (e.g., printers and photocopiers, computers, solvents, adhesives, cleaners, air fresheners, etc.). Finally, office employees spend a significant part of their time in environments that in recent years are typically characterized by complex building systems (e.g., mechanical, electrical, plumbing, controls, and fire protection systems) designed to reduce energy costs through controlled indoor environment conditions. Beside central control, a certain degree of personal control (local thermostats, windows, personal lights etc.) over the indoor environment should be allowed to office occupants, since personal control has a crucial role in achieving a healthy, comfortable, and productive environment (Sakellaris et al. 2019).

In summary, also considering the specific peculiarities of office environments, inadequate IAQ in office building could influence the perceived IAQ, comfort, health, but also indirectly impacts office work performance (Wyon 2004; Wolkoff et al. 2021).

Strategic Considerations

A careful assessment and management of IAQ in offices is important for the protection of human health and to ensure optimal comfort and IAQ perception for office workers. For this purpose, the development of appropriate monitoring strategies is crucial to properly characterize the chemical and physical complexity of the IAQ dynamics. Chemical and physical transformation of the pollutants can occur with high spatial and temporal variability. A proper IAQ assessment strategy should

consider the wide variety of indoor pollutants, as well as their temporal and spatial inhomogeneity. Further, several of monitoring methods and techniques are available, and the choice of the most appropriate method must be based on both the target constituent and the objective of field investigation. The aim of this chapter is to provide insight to carry out a comprehensive and accurate assessment of IAQ in a general office exposure scenario. Obviously, when considering a given specific scenario, further insights (which are impossible to report here extensively) should be considered. Independently of the methods of the evaluation, it is generally important to develop a multidisciplinary evaluation process based on a manifold know-how of air sampling, analytical chemistry, occupational hygiene, and toxicology and occupational medicine. It is also crucial to properly inform and interact with the employer, HSE (health, safety, and environment) and/or building managers, and last but not least workers and building occupants.

Indoor Air Pollutants of Concern for Offices

When setting up an IAQ study, the selection of proper parameters to be evaluated is of fundamental importance and needs to be aligned with traditional risk assessment paradigms whose first step is “hazard identification.” This choice clearly depends on the specific objectives of the study to be conducted, but in general, the aim should be to identify the chemical, biological, and/or physical agents that represent the highest priority for research, surveillance, or intervention due to their potential risks for occupant health (Sérafin et al. 2021). Among the most important and most widely considered reference documents, the World Health Organization (WHO) published IAQ-specific guidelines for the protection of public health from risks due to exposure to selected pollutants commonly present indoors and in particular, O₃, NO₂, PM (PM_{2.5} and PM₁₀), sulfur dioxide (SO₂), CO (World Health Organization 2021) and benzene, formaldehyde, naphthalene, benzo[a]pyrene, radon, trichloroethylene, and tetrachloroethylene (World Health Organization 2010). These are known to have indoor sources, can be found indoors in concentrations of health concern, and are considered of key importance due to their hazardous nature. These guidelines are certainly useful, but they refer to a limited number of key pollutants, compared to those that can be identified in indoor environments. Thus, some studies have considered different pollutants or have sought to define prioritization criteria for a wider number of air pollutants monitoring in indoor environments (Logue et al. 2011). As an example, in the OFFICAIR study (Mandin et al. 2017), a combination of physical (temperature, relative humidity, air change rate) and chemical parameters were measured. These parameters included PM_{2.5}, O₃, NO₂, aldehydes (formaldehyde, acetaldehyde, acrolein, propanal, benzaldehyde, glutaraldehyde, hexanal), and VOCs (benzene, toluene, xylenes, ethylbenzene, n-hexane, trichloroethylene, tetrachloroethylene, α -pinene, d-limonene, 2-butoxyethanol, 2-ethylhexanol, styrene). These selected chemicals were chosen since most of them were known to be emitted from building materials, cleaning products, and office equipment, and had potential

associations with adverse health outcomes (e.g., sensory irritation symptoms, cardiovascular and pulmonary effects) (Wolkoff 2013).

A WHO publication (World Health Organization 2020) also provides a list of most common chemical pollutants of indoor air in public settings for children, as they are also considered of particular concern (priority pollutants) for the assessment of risk of combined exposure in indoor environments. The same document also lists other common pollutants of indoor air in public settings that should be measured for the control of IAQ.

A method was developed to identify priority IAPs in office buildings (Sérafín et al. 2021) using both a chronic risk assessment approach and a hazard classification method based on carcinogenic, mutagenic, reprotoxic, and endocrine disruptive effects. The study evaluated 342 chemicals for which indoor air concentrations had been previously measured in office buildings and identified 71 of these as priority pollutants. These were further divided into five priority classes, ranging from “non-priority” or “unclassifiable” to “very high priority.” Among these, 16 pollutants (i.e., formaldehyde, acetaldehyde, glutaraldehyde, acrolein, benzene, dichloropropane, 1,2,4-trichlorobenzene, NO₂, SO₂, PM_{2.5}, PM₁₀, antimony, nickel, cadmium, manganese, and chlorine) were considered as pollutants of particular concern. Interestingly, 123 additional chemicals are proposed for future monitoring surveys to update the prioritization of IAPs in offices, since these could be present in office indoor air but could not be assessed with the proposed criteria due to the lack of measured data in the scientific literature (Sérafín et al. 2021). Table 1 presents a list of chemical pollutants considered as being of relevance for IAQ assessment in office buildings. However, there is no definitive consensus concerning the prioritizing method for IAPs based on health concerns and as knowledge of health hazards evolves, both well-known and emerging pollutants may present potential risks for building occupants. Thus, regular assessment and prioritization of indoor pollutants is essential to guide research, policies, IAQ surveys, and product development.

Sources and Determinants of IAPs in Offices

IAP concentrations are affected by several factors, including infiltration from the outdoors, indoor emission rates, indoor reaction and deposition dynamics, air change rates, room volume, and indoor temperature and humidity. In countries where effective anti-smoking policies have not been promulgated, environmental tobacco smoke (ETS) could be a significant source of indoor pollutants. Further, due to the presence of these sources and the confined air volume, indoor air concentrations in some indoor environments, such as offices, can be higher than in the outdoor air (Katsoyiannis et al. 2012). This problem is especially true for modern buildings, which have very different characteristics from traditional ones, such as energy-efficient structure and the interior fittings’ design and construction (i.e., the growing adoption of nonsmoking policies, “low-emitting” materials, synthetic heat-insulating and sound-absorbing materials, electronic equipment, air-conditioning and mechanical ventilation systems, and open-plan offices in place of cellular

Table 1 List of chemical pollutants to be considered as of relevance for IAQ assessment in office buildings

Reference	Guideline/project	Relevant pollutants
World Health Organization (2010)	WHO guidelines for indoor air quality: selected pollutants	Benzene, CO, formaldehyde, naphthalene, NO ₂ , polycyclic aromatic hydrocarbons (especially benzo[a]pyrene), radon, trichloroethylene, and tetrachloroethylene
Mandin et al. (2017)	OFFICAIR Project	PM (PM _{2.5} , O ₃ , NO ₂ , aldehydes (formaldehyde, acetaldehyde, acrolein, propanal, benzaldehyde, glutaraldehyde, hexanal), and VOCs (benzene, toluene, xylenes, ethylbenzene, n-hexane, trichloroethylene (TCE), tetrachloroethylene (PCE), α -pinene, d-limonene, 2-butoxyethanol, 2-ethylhexanol, styrene)
World Health Organization (2020)	Methods for sampling and analysis of chemical pollutants in indoor air	Priority pollutants: Oxygenated VOCs – aldehydes (formaldehyde and acetaldehyde); VOCs (aromatic hydrocarbons (benzene, ethylbenzene, o-xylene, m,p-xylenes, styrene, toluene, 1,2,3-trimethylbenzene and 1,4-dichlorobenzene), esters (butyl acetate), terpenes (limonene and α -pinene), chlorinated hydrocarbons (tetrachloroethylene and trichloroethylene)); SVOCs (PAHs (naphthalene and benzo(a)pyrene); inorganic compounds (NO ₂)) Other pollutants: PM, O ₃ , CO, phthalates, musks, BFRs, organophosphate flame retardants (OPFRs), and chlorinated paraffins (CPs)
Sérafin et al. (2021)	Indoor air pollutant health prioritization in office buildings	$n = 71$ priority pollutants [of which $n = 16$ pollutants of particular concern (formaldehyde, acetaldehyde, glutaraldehyde, acrolein, benzene, dichloropropane (DCP), 1,2,4-trichlorobenzene, NO ₂ , SO ₂ , PM _{2.5} , PM ₁₀ , antimony nickel, cadmium, manganese, and chlorine)] $n = 123$ chemicals are proposed for future monitoring surveys
World Health Organization (2021)	WHO global air quality guidelines	PM (PM _{2.5} and PM ₁₀), O ₃ , NO ₂ , SO ₂ , and CO

offices) have resulted in temporal changes of the factors driving the presence of IAPs and the resulting IAQ. Microclimatic conditions can affect IAQ differently: high temperatures and humidity affects volatile species emissions including the emissions

of VOCs from building materials and furnishings. Humidity may also influence aerosol formation by condensation and coagulation processes, as well as its chemical composition. Ventilation (i.e., the rate of air exchange with outdoor air) has a strong relationship with the concentrations of indoor pollutants. High concentrations of VOCs are generally related to low air exchange rates. Nevertheless, some pollutants are associated with outdoor sources (e.g., vehicular traffic). Thus, high air exchange rates may lead to higher indoor concentrations due to higher infiltration from outdoor but depending on the effectiveness of the HVAC system's filtration system. IAP concentrations can also significantly vary in different locations of the same indoor environment. This variation can be due to (i) the different types of sources and sinks in various locations, (ii) different activities performed by occupants in different locations (and at different times), and (iii) the effect of ventilation and air flows (mechanical and natural) that distribute contaminants from a given emission point throughout the indoor environment. A non-negligible temporal variability in concentrations can be also observed in office indoor environments, reflecting the intermittent nature of their sources (e.g., for contaminants associated to specific activities, such as printing, cleaning, etc.), interferences, and/or incursion of outdoor air or other temporal dynamics. Since emissions from construction materials and furnishings are important sources for indoor pollutants, newly constructed, remodeled, or furnished environments are expected to produce highly contaminated indoor air (Baek 2011). Seasonality could also play a major role in defining IAPs, with particular emphasis on VOC emissions from building materials (Campagnolo et al. 2017) and O₃-related indoor chemistry, which plays a major role in the summer period. The greater ultraviolet radiation, higher temperatures, and higher biogenic VOC emission rates in summer cause high O₃ concentrations outdoors that after infiltration, leads to the formation of oxidation products from O₃-initiated reactions involving common VOCs such as limonene and squalene (Nørgaard et al. 2014). Primary sources (traffic emissions, indoor product emissions, cleaning products, transport from other microenvironments, and air fresheners) of 30 target VOCs in residential interiors and workplace microenvironments were defined in the EXPOLIS study (Edwards et al. 2001). Two studies, conducted as part of the Officair project, were aimed at the source identification (Campagnolo et al. 2017) and assessment of IAP determinants (Spinazzè et al. 2020) specifically in office buildings, accounting also for seasonal variability. The dominant source of chemical IAPs in both summer and winter periods was linked to the infiltration of contaminated outdoor air into indoor environments, which was particularly relevant for benzene, toluene, ethylbenzene, xylenes, and n-hexane (Campagnolo et al. 2017). The other identified sources were individually attributed to wooden-based material emissions (α -pinene, formaldehyde, acetaldehyde, propanal, and hexanal), flooring emissions (α -pinene, 2-butoxyethanol, 2-ethylhexanol, and propanal), and printer emissions (styrene). In summer, O₃-initiated oxidation reactions were identified as important sources of formaldehyde and acetaldehyde. Further, sources directly linked to paint emissions (acrolein and benzaldehyde) and cleaning products (2-butoxyethanol) were defined for the winter period. Beyond these identified sources, several associations between IAPs concentrations and buildings' structural characteristic or

occupants' activity patterns were identified. Aldehydes and VOCs determinants in office buildings include building and furnishing materials, indoor climate characteristics (room temperature and relative humidity), the use of consumer products (e.g., cleaning and personal care products, office equipment), as well as the presence of outdoor sources in the proximity of the buildings (i.e., vehicular traffic) (Spinazzè et al. 2020).

Assessment Methods and Strategies for IAQ in Offices

A prerequisite for the assessment of IAQ and associated conditions in offices and office-like environments should be a detailed knowledge of building characteristics and possible pollution sources as well as the indoor activities, which are often collected by trained personnel making use of checklists. Besides those lists developed on a building-level basis, checklists at room level and time-activity diaries coupled with real-time measurements of IAPs allow the collection of higher-level information to gain a more detailed picture of the microenvironmental characteristics and exposure determinants (Spinazzè et al. 2020). The methods and strategies for the assessment of IAQ and associated factors in offices can vary substantially depending on the purposes of IAQ surveys. For instance, source identification and apportionment of IAPs are of great relevance to develop risk management strategy and to steer the choice of technological controls for IAQ improvement. For this purpose, a large number of repeated measurements with proper temporal resolution are typically needed to make inferences about the relationship between the monitored IAPs and continuous emission sources rather than intermittent or sporadic emission events. In parallel, reliable methods to assess IAQ or occupants' exposures should be thoughtfully identified based on the reference periods upon which IAQ guideline values are defined and to ensure good data quality. Although offices are classified as workplaces from the legal point of view, the traditional air sampling methods and occupational exposure limit values developed for occupational risk assessment are not directly applicable in office environments.

IAQ experts can be asked for advice on a problem building or building area in which there is a high prevalence of complaints or reported health symptoms by office workers. In this case, the reason behind the study is the identification of the causal agents and their sources for evidence-based and effective risk management. Thus, a recommendable study design is first to perform an assessment of symptoms and IAQ perception by standardized questionnaires followed by an IAQ monitoring campaign specifically focused on some targeted IAPs. As an example, a high prevalence of mucous membrane irritation and itching can be indeed associated with high concentrations of O₃ and some VOCs such as ethylbenzene and n-hexane (Sakellaris et al. 2021). Possible interventions must be focused on their possible emission sources or increasing air change rates, although the impact of the latter option can be somewhat overestimated (Rackes and Waring 2016).

In some other cases, a periodic IAQ assessment can be required by occupational risk prevention programs planned by the management system of private companies

or required by public authorities. If that is the case, the focus should be on the identification of priority IAPs to be monitored for an IAQ assessment based on testing the compliance of measured concentrations against guideline values. This should include, as a complement, an assessment of other IEQ stressors that could impact on occupants' health, comfort, and well-being.

A new frontier in this context is the application of sensor networks allowing a real-time monitoring of IAPs with good spatial coverage for an immediate and efficient energy, risk assessment, and risk management (Kumar et al. 2016).

IAQ Monitoring Approaches

There are many aspects of IAQ that have a potential impact on the sampling and analysis strategies adopted for its assessment. IAQ is determined by a complex series of processes, and thus, no single sampling and analysis system is completely appropriate for all the constituents of IAQ. For this reason, the monitoring protocol must be optimized to consider different compounds and classes of pollutants (Spinazzè et al. 2021). The constituents of IAQ components comprise gases and lower molecular weight organic compounds, which reside predominantly in the vapor phase, and higher molecular organic species and inorganic PM constituents that can be found predominantly in the particulate phase. Therefore, a sampling protocol for many IAQ constituents that emphasizes only the vapor or the particle phases could result in an incomplete understanding of the ambient levels of the target components. IAPs concentrations vary both spatially and temporally to a large extent relative to common outdoors pollutants. This variation is due to the large variety of sources, the intermittent operation of some of these sources, and the different types and quantities of sinks present at various locations. Mechanical ventilation and atmospheric diffusion tend to distribute contaminants from a given source throughout the indoor environment. By way of example, the high temporal variability in concentrations of combustion products reflects the intermittent nature of their sources. Thus, the time resolution and duration of sampling is a key factor affecting the concentrations and variability found in any study (Baek 2011).

The sampling strategy design is a fundamental step in IAQ assessment surveys to ensure representativeness of the assessment. A proper IAQ monitoring strategy should be based on several preliminary critical choices. First, the compounds to be investigated should be selected based on their possible impacts on human health or if they are known to be prominent substances emitted in the office environment by specific sources. Some insights were previously reported in *this chapter*. A prerequisite for the assessment of IAQ in offices and office-like environments should be a detailed knowledge of building characteristics. A preliminary step is a general survey of the building and of the office environments to allow the collection of technical information and to obtain a detailed picture of the environment (Spinazzè et al. 2020). All factors that may affect IAQ should be identified, analyzed, and reported, including activities in offices, HVAC systems, furnishings, fittings, cleaning routines, cleaning products, and potential outdoor sources of pollutants

(Kalimeri et al. 2016). Recommendations about the information to be recorded during indoor air measurement can be found in ISO 16000-1 (2004).

As said, the methods and strategies for the assessment of IAQ and associated factors in offices can vary substantially depending on the reasons for and purposes of the IAQ surveys; however, an overview of potentially useful approaches and instrumentation is reported in Spinazzè et al. (2021). Generally, for each building, the field campaigns should consist of multiple measurements performed in different indoor locations and, possibly outdoors for a proper period. An outdoor sampling site is optional but could be useful to identify the contribution of outdoor sources to the indoor air pollution. Outdoor samplers should be located close to the investigated building but no closer than 1.0 m (ISO 16000-1:2004 2004), protected from direct sunlight and precipitation and, when possible, from people; distance sources of emissions should be recorded for outdoor sampling site. If the building has a HVAC system, ambient air should be sampled close to the air intake (World Health Organization 2020).

Any sampling equipment should allow office workers to perform their work without being affected by the ongoing IAQ monitoring, also in terms of productivity and ability to stay focused. Thus, compact and silent methods using portable equipment should be preferred. In some cases, an effective noise reduction can be achieved using noise-reducing enclosures.

The number of sampling locations per building should be a compromise between extensive IAQ characterization for the whole building, the budget, and other feasibility issues (power supply, accessibility, etc.). The indoor locations should be selected as diverse as possible to represent IAQ at different workplaces in the building. Thus, for example, the locations should be selected on different floors and their position on each floor could be defined to have different orientations (North, South, East, and West). Moreover, if the office building had both types of working spaces, measurement should be performed in both in open-plan and cellular offices. The samplers should be placed in the center of each room, not close to the wall, at the height of the breathing zone of seated occupants (i.e., approximately 110 cm); ventilation channels and heating sources, including the sun, should be avoided. ISO 16000-1 (2004) recommends placing samplers in the center of a room. If this is not possible, the sampler should be placed 1.0–2.0 m from a wall and 1.0–1.5 m from the floor.

The general principles for IAQ monitoring in offices are similar to those already defined for the assessment of IAQ in the general living environments. The monitoring of IAPs in office building is typically carried out using active or passive samplers and/or real-time monitors placed in a fixed position (in the center of the room) away from door and windows. IAQ problems have multifactorial causes, and multi-pollutant measurement systems are generally used to account for the different chemical, biological, and physical agents, and quantify their contamination levels in indoor air. For this reason, multipollutant IAQ monitoring stations have also been developed and used in IAQ research studies (Spinazzè et al. 2021; Villanueva et al. 2021). Besides the already mentioned interaction between microclimatic parameters and IAPs, T and RH should also be monitored because of their possible influence

(e.g., uptake rates of passive samplers) or interference with air sampling (e.g., electrochemical sensors).

Concerning monitoring strategies, ISO 16000-1 (2004) provides recommendations about sampling of IAPs (i.e., duration, period, and location of sampling) with parallel measurements of concentrations of outdoor air pollutants. Basically, two different approaches can be considered for sampling duration: (i) 24-h measurements for 5 consecutive working days (24 h/5 days) and/or (ii) measurements during periods when workers are physically present indoors (typically 5–8 h for the workday). The first option may result in overestimation of exposure to certain pollutants which typically have indoor sources and could accumulate during the night (due to windows closed and mechanical systems turned off). Obviously, the contrary could be observed for pollutants typically emitted outdoors or IAPs having short atmospheric lifetimes. For example, a study outlined that by including unoccupied periods in the sampling interval, some VOC concentrations were overestimated (namely acetaldehyde, formaldehyde, tetrachloroethylene), while other VOCs were underestimated (i.e., toluene, ethylbenzene, xylenes, styrene, 1,2,3-trimethylbenzene, and 1,4-dichlorobenzene). In another case, an underestimation of formaldehyde concentration was observed when unoccupied periods were included (Mishra et al. 2015). Measuring during periods when workers are present in offices requires measurement techniques that can be activated or deactivated at specific times, and/or direct-reading measurements methods. Overall, passive sampling over a 5-working day (i.e., a working week) can be recommended for assessing combined exposure to chemicals in indoor air. In practice, different measurement techniques could be combined with each other to optimize the monitoring strategy based on pollutants characteristics and for the specific aims of the study. For example, the SINPHONIE and Officair projects applied this strategy in schools and offices, respectively. The SINPHONIE project applied different approaches for different pollutants: samples of PM ($PM_{2.5}$) were collected for gravimetric analysis for 8 h/day (due to the relationship between $PM_{2.5}$ and occupancy density and for reasons of detection limit). CO was continuously measured by a low-cost direct-reading instrument (short-term assessment is more suitable since CO causes acute health effects). CO_2 was measured by direct-reading instruments to calculate ventilation rates. $PM_{2.5}$ and PM_{10} were measured by optical light scattering (Kalimeri et al. 2016). In the OFFICAIR study, sampling was carried out over 5 days from Monday morning (approximately 9 a.m.) to Friday afternoon (approximately 5 p.m.) at four locations in each building, except for $PM_{2.5}$ (one location per building). The duration of the sampling was a compromise between the interest in characterizing the average concentrations in office buildings to assess long-term worker exposure and technical feasibility. Both passive and active sampling techniques were adopted for measurement of VOCs, aldehydes, NO_2 , O_3 , and $PM_{2.5}$ over the work-week period (Mandin et al. 2017), but also short-term active sampling and direct-reading methods were adopted for specific measurement (Nørgaard et al. 2014).

Further, concentration of some pollutants (e.g., emissions of formaldehyde from materials and products) can vary significantly, depending on the season and on several other factors (i.e., temperature, relative humidity, ventilation rate). For this

reason, analysis of indoor air pollution in the cold (“heating”) season (November to March in the northern hemisphere) would likely find higher levels for certain compounds, such as benzene, NO₂, and D-limonene (Mandin et al. 2017). To evaluate the seasonal variation of pollutant concentrations in indoor air, measurements during both in the cold (heating) and in the warm (non-heating) season are highly recommended, with periodicity and periods to be defined depending on the geographical location of the country (World Health Organization 2020).

In most cases, samples for IAQ investigations are collected in the field and returned to the laboratory for subsequent chemical analysis. However, for some IAPs, real-time monitors can be also used. Active sampling involves drawing air into a collection media by means of a pump, whereas passive sampling places a material that irreversibly adsorbs, absorbs, or immobilizes the chemical of interest in the target substrate. Active sampling is used to sample large volumes of air or to sample small volumes of air over short durations. Passive sampling is primarily used to sample small volumes of air over long periods of time. Passive systems offer the advantages of being relatively simple and inexpensive without pumping apparatus. Being noiseless and low cost are other advantages. Passive sampling has some disadvantages, for instance, it can be affected by ambient humidity. However, active sampling requires the mass transport of material to the collection device, thus requiring a sampling pump and electric power, and making the monitoring systems more complex (Baek 2011).

A WHO publication (World Health Organization 2020) discusses the advantages and drawbacks of some methods for sampling and analysis that have been used to characterize chemical pollution of indoor air. The methods were selected from among (i) those recommended by the International Organization for Standardization (ISO) and (ii) the most commonly used for sampling and analysis of IAPs in public settings. The document presents both passive (also called diffusive) and active sampling method. These are discontinuous methods: the pollutants are collected on a filter or sorbent for further analysis in a laboratory. Laboratory analysis usually consists of extraction, clean-up (when necessary), and the chemical characterization using appropriate analytical equipment. The extraction can be carried out using thermal desorption or solvent extraction. Analysis can be performed by means of different analytical systems depending on the pollutant to be analyzed (such as gas chromatography (GC) and liquid chromatography (LC) coupled to different detectors and an ultraviolet-visible (UV-Vis) spectrophotometer or mass spectrometer) (World Health Organization 2020).

Other than those mentioned above, the number of instrumental systems commercially available for the real-time measurement of IAPs has increased considerably. In many cases, a given constituent can be determined by a variety of instrumental techniques. The choice of the best approach can be a complex decision, which is influenced by several factors, including cost, system portability, selectivity and sensitivity, and the number and influence of potential interferences. Direct-reading instruments could provide substantial benefits (including lower efforts at lower cost) when applied in IAQ monitoring compared to traditional exposure assessment methods, which rely on active or passive sampling, collection substrates (e.g.,

sampling filters, adsorbent substrates), and offline analyses (e.g., gravimetric determination, chemical characterization, microscopic analysis). More in detail, one of the advantages of direct-reading techniques is to provide new insights on exposure dynamics due to their ability in collecting data at high spatiotemporal resolutions (Gao et al. 2015). Further, direct-reading instruments can report and process the data as soon as they are collected and while the instrument is still deployed (i.e., near real time analysis). Then, due to their features (reduced cost, ease of deployment, potential to be used in wireless networks), newer direct-reading sensor technologies (i.e., placeable, wearable, and implantable devices) (Howard et al. 2022) represent new ways of collecting and sharing environmental and occupational exposure information. For these reasons, not only the need for accurate evaluation of exposure to airborne pollutants is confirmed and reiterated, but a step forward is required as regards the methods, the techniques, and the technologies to be used for this purpose. Despite the advantages related to the use of newer direct-reading sensor technologies, these are generally less reliable (in terms of accuracy, sensitivity, precision, and specificity to the chemical/variable of interest) if compared to high-end devices (Fanti et al. 2021; Howard et al. 2022) and should be carefully evaluated before use. Overall, newer direct-reading sensors are being successfully used complementary to reference device monitoring, but they are not yet validated as alternative techniques for (or to replace) reference instruments (especially for purposes of mandatory monitoring). Further, unlike what happens for reference-grade instruments that are subjected to comprehensive regulatory standards and processes for evaluation and certification, only few standards exist for direct-reading techniques (Williams et al. 2018). Further, biases in the acquisition and interpretation of the data obtained with direct-reading techniques can derive from different sources of measurement error and interference, which arise once operating in the field and which cannot be completely covered in the development and calibration phases carried out in the laboratory. For these reasons, direct-reading techniques should be operated applying rigorous quality assurance and quality control protocols.

IAQ Perception and Health Symptoms

Complaints about deteriorated air quality that may be related to the building or a part of it are common in office workers (Rios et al. 2009). The existence of excessive complaints related to IAQ can be temporary and related to building renovation or adaptation. However, some buildings can be affected by long-term problems that require ad-hoc mitigation measures. In parallel, a high prevalence of complaints about health symptoms is commonly found in office buildings but it is not generally possible to attribute them to single causal factors.

Sick building syndrome (SBS) is somehow a semantically incorrect and outmoded wording used to describe work-related nonspecific symptom complexes occurring in buildings in which more than 20% of occupants report one or more symptoms that may be associated with IEQ and to the time spent by subjects in the building (Wolkoff 2013). SBS symptoms include mental fatigue and headache,

nausea and dizziness, eye, nose, and throat symptoms (i.e., dryness and irritation of the eyes, upper and lower airways symptoms, high frequency of airway infection, respiratory irritations, difficulty in breathing, coughing, tight chest, wheezing, etc.), skin symptoms (e.g., erythema, dry skin sensation, itching), and nonspecific hypersensitivity (World Health Organization 1983, 1986). The most common symptoms reported by office workers fall within the categories of mucosal irritation in eyes and upper airways, lower respiratory symptoms, central nervous system symptoms, and fatigue (Wolkoff 2013). These symptoms are characterized by multiple causality and IAQ is only one of them. SBS symptoms causes are not always known, but a common feature is that the majority of the occupants reports relief soon after leaving the building. SBS symptoms can be influenced by both personal (e.g., age, gender, allergy medical history, smoking status, anxiety, interpersonal conflicts, type of occupation, amount of work, and psychosocial work stress) and environmental factors (Azuma et al. 2015). The SBS symptoms are also related to physical environment and to IAQ. More in detail, among the causes of SBS in offices, chemical and biological contamination as well as poor ventilation (Finnegan et al. 1984; Hedge et al. 1989) were recognized as of primary importance since the early studies, but later on it became mostly regarded as a multifactorial health problem (Norback et al. 1990) viewed as a medical, psychological, and social phenomenon (Thörn 2000).

The assessment of perceived IAQ is typically based on questionnaire surveys. In the Audit project, questions were rated on seven-point scales and were focused on the perception of air dryness, stuffiness, and odors (Bluyssen 1996), further divided by perception type (mold or unpleasant odor) (Tähtinen et al. 2020). IAQ perception is time dependent and can be separated into immediate (e.g., when entering a building) and delayed perception that may build up during the workday. The immediate perception of IAQ is mainly driven by the olfactory sense via stimuli of the olfactory nerve (Wolkoff 2013). Smelly air is not of direct relevance to health risks, because there is no direct association between the odor thresholds of chemical compounds and those of toxicological concern. Taking aldehydes as an example, the odor thresholds for octanal and decanal are two to three orders of magnitude lower than formaldehyde. Occupants' complaints have been very frequent in office buildings constructed in the 1970s and 1980s, when ventilation was reduced for economic reasons in response to the oil crises. All self-reported data are intrinsically subjective and influenced by many possible factors, first and foremost those of psychosocial nature, and probably IAQ perception above all. Complaints by office workers as regards air quality are typically dominated by stuffy and dry air (Wargocki et al. 1999), being the perception of odors less frequent and correlated to specific odor sources. Large-scale studies in offices showed that office employees reported frequent complaints about stuffy and dry air (25–30% of respondents), and personal control of the indoor environment resulted in occupants being more satisfied with the overall air quality (Sakellaris et al. 2019).

For over 40 years, measurements of IAPs and their possible association with self-reported symptoms and health effects related to building-related problems have been made in offices to assess acute health symptoms related to short-term exposures.

Most of the studies are based on a cross-sectional design (data gathered at the same point in time) and the collection of self-reported symptoms and IEQ perception using self-administered questionnaire. In some cases, the focus was specifically on “sick” buildings (Thörn 2000), otherwise in nonproblem buildings (Muzi et al. 1998) or on the comparison of these two situations (Sunesson et al. 2006), sometimes with randomly selection of buildings/occupants to ensure representativeness (Finnegan et al. 1984), with some insights on building sealing (Rios et al. 2009) and building renovation. Surveys done in the late 1980s and 1990s on SBS and building-related illnesses (BRIs) were aimed to provide a standardized approach for the estimation of the prevalence of symptoms and IEQ perception, which should be tested for reliability and reproducibility to provide an unbiased assessment. The reliability of self-reported symptoms can be tested based on the judgment of a medical expert (occupational physicians for office workers) or against objective measurements of health effects. In the same way, the reliability of IEQ factors such as IAPs, noise, and microclimate indexes can be evaluated via expert judgment by IAQ experts or occupational hygienists or against objective measurements by environmental monitoring (see the next paragraph).

Questionnaires were initially based on a short list of basic and simple questions in which the intensity of factors/symptoms was not usually considered, and whose common core topics regarded health-related symptoms and IEQ perception including IAQ, microclimate, noise, and light. Later, it was found that general questions were not sufficient to obtain good validity, but specific questions on perceptions and observations were needed, as well as some contextual information about personal history, medical history, and family history of atopic diseases (Engvall et al. 2004). Psychological factors should be also carefully assessed as potential modifiers of perception and responses (Lu et al. 2018). Other factors like noise, distance from window, and privacy also may influence the overall perception of IAQ and the prevalence of symptoms.

Some examples of standardized questionnaires for the assessment of indoor environment and health can be found in Ooi et al. (1998) and Engvall et al. (2004). Recommendations for the optimal design of questionnaire-based surveys in offices, e.g., to increase the response rate, ensure anonymity, select the best administration mode, can be found elsewhere (Wolkoff 2013; Carrer and Wolkoff 2018). Questionnaire surveys are also recommended as a first step to assess work-related risks and monitor the health status of office workers (Carrer and Wolkoff 2018). Results from the questionnaire survey are useful to assess the occupant’s perceptions of IAQ and indoor climate, other than their psychosocial aspects. This information is fundamental to prioritize the hierarchy of potential interventions. Some important issues should be considered when assessing questionnaires data: (i) to distinguish whether the reported symptoms are specifically associated with the indoor working place and not with other outdoor/external issues (e.g., home, transport, or nearby industry); (ii) to determine if an alternative causality may prevail in occupants’ answers (Brauer et al. 2006).

Productivity of office workers can be also assessed by text-typing speed and errors tests (Wargocki et al. 1999; Bakó-Biró et al. 2004), as well as calculation

(Wargocki et al. 1999), addition (Lan et al. 2011), and proofreading (Bakó-Biró et al. 2004) tasks. Open-ended tests of creative thinking, memory, and recall can also be assessed (Wyon 2004). Another way to assess the health impacts in office-like environments is the analysis of number of days of sickness absence (Steensma 2011), which should be done using a longitudinal study design and have been correlated to the number of occupants in open-plan offices (Pejtersen et al. 2011). Several experimental studies have demonstrated deteriorated workers' performance caused by poor IAQ, but general conditions of the office (e.g., lighting and noise) should also be considered. A complete understanding of the causal link behind the loss of work productivity and performance is complex. Chemical pollutants and bioeffluents, rather than CO₂ itself, have been suggested to cause mental distraction and stress by perceived poor IAQ (Zhang et al. 2017), but other mechanisms are also in play (Zhang et al. 2017). The overall concern about work performance is not only related to absenteeism and associated diseases due to the work environment (IAQ), but it may result in less comfortable working conditions (Wyon 2004).

Among the IAPs postulated to be associated with office workers symptoms, a particular attention was paid to VOCs from the 1990s onwards, despite an association with airborne particles and SBS cannot be discarded (Apter et al. 1994). Some VOCs and semi-VOCs are indeed well known for their sensory irritation and neurotoxic potential at high doses from the accumulated knowledge in the field of toxicology and industrial hygiene, while the relevance of total VOCs as a risk index for health and discomfort effects in buildings was somewhat refuted by the scientific literature (Andersson 1997). The detail on specific airborne chemicals and biological agents in relation to perceived symptoms in office buildings grew over time, so that in more recent studies a variety of VOCs were monitored (Sakellaris et al. 2016) to test the hypothesis that health symptoms could derive by exposure to an air mixture of many chemicals at low concentration rather than only one or a few highly concentrated compounds. As a complete analysis and identification of all the compounds present in the indoor air mixture is almost impossible, and there are reasons to argue that compounds that are difficult to be collected and analyzed can play a role on the onset of health-related symptoms (Wolkoff et al. 1997). Parallelly, a growing attention was paid toward individual microbial species and their products (e.g., endotoxins, mycotoxins) rather than total bioaerosol contamination (Straus 2009).

Large-scale research has analyzed a dataset of more than 20 IAPs collected in 37 office buildings across 8 European countries (Sakellaris et al. 2016). Here, frequently reported symptoms were eye irritation (mostly dry eyes and watering or itchy eyes), respiratory symptoms (mostly blocked or stuffy nose), and general ones (mostly headache). Although IAP concentrations were generally below guideline values, the multivariate analysis showed significant associations between ethylbenzene and eye irritation as well as respiratory symptoms, xylenes with general symptoms (e.g., headache), formaldehyde, acrolein, and alpha-pinene with respiratory symptoms and styrene with skin symptoms. O₃ was associated with almost all symptom groups. Besides, there are some indications that several acids are more concentrated in problem buildings, probably due to their high reactivity, e.g., with O₃ and hydroxyl radicals to form secondary organic pollutants (Sunesson et al. 2006).

On the other hand, some studies aimed at addressing the correlation between IAPs concentrations and SBS symptoms in office workers did not confirm these supposed associations (Rios et al. 2009), and in some cases, psychosocial factors seem to play the biggest role in determining perceived symptoms (Eriksson 1996).

In the case of the California Healthy Building study, the focus was moved to sources as independent variables affecting IAQ-related perceived symptoms rather than to single chemicals. In short, 39 individual VOCs were measured in 12 offices, and data analysis was based on exposure metrics defined by a preliminary principal component analysis to account for the irritant potency of VOC mixtures. Among the principal component vectors obtained, the one represented by cleaning products and water-based paints showed the highest correlations with the vector representative of irritant symptoms prevalence, in particular for eye, skin, and mucous membranes (Brinke et al. 1998), and 2-butoxyethanol was the compound with the highest contribution on this factor.

Still about the relationship between sources and self-reported symptoms in offices, the early studies of the 1980s and 1990s indicated the use of photocopiers and work in crowded areas (Taylor et al. 1984), handling of paper (Skov et al. 1989), visual display terminal work (Hedge et al. 1989; Skov et al. 1989), and mechanical ventilation and/or air-conditioning (Finnegan et al. 1984; Hedge et al. 1989) as SBS risk indicators. More recently, one study concluded that the time/frequency of exposure to carbonless copy paper, paper dust, and emissions from photocopiers and printers increases the risk for respiratory, eye, and skin symptoms, as well as middle ear infections (Jaakkola et al. 2007). Within the context of offices, it is worth noting that intensive video display terminal work can cause ocular symptoms by altering blinking behavior and disturbing the tear film (Wolkoff 2008), but it can be regarded as a cause of psychosocial distress as well (Kubo et al. 2006). It was also argued that the presence of PCs could increase dissatisfaction with the perceived air quality and office workers performance, probably due to indoor air contamination at low levels by the so-called and supposed “stealth chemicals” effect (Bakó-Biró et al. 2004).

It is well known that indoor settled dust has a relevant allergenic and inflammatory potential, and this was confirmed also in relationship with SBS symptoms (Allermann et al. 2007). There is a quite large body of literature demonstrating the causal relationship between indoor dampness and molds and perceived health symptoms, in particular mucosal symptoms (Zhang et al. 2012). These could be, at least partially, attributed to the increased chemical emissions by wet polyvinyl chloride floor materials from the alkaline degradation of acrylate polymers in water-based glue or plasticizers (Campagnolo et al. 2017).

IAQ and Health Outcomes in Office Workers

Exposure to poor IAQ can cause or exacerbate a series of short- and long-term health outcomes (allergic symptoms and asthma, chronic obstructive and pulmonary diseases, airways infections, cardiovascular effects, and lung cancer) (Jantunen et al.

2011). Studies in the 1960s to the 1980s were focused on serious office-related illness such as hypersensitivity pneumonitis, Legionnaires' disease, and cancer due to asbestos exposure. Radon is also risk factor to be assessed for lung cancer prevention especially among people working in underground rooms, which sometimes can happen in some indoor work settings such as banks.

The so-called BRIs (Seltzer 1994) are characterized by the onset of a disease with clear diagnosis (e.g., legionellosis) and well associated to a specific risk factor and the time spent in a specific building.

Health effects potentially related to exposure to IAPs in office environments include acute and semi-acute effects and longer-term based effects. Acute effects are referred to into immediate perceived IAQ that is related to odor perception (olfactory nerve), while semi-acute effects (like sensory irritation in eyes and airways (trigeminus nerve), and symptoms related to the central nervous system (e.g., headache and fatigue)) are characterized by some latency (Jaakkola et al. 2007). Long-term effects (i.e., due to continuous or repeated exposure to IAPs) may be associated with aggravation of asthma exacerbation and allergic responses, oxidative stress and inflammation, chronic obstructive and pulmonary disease, lung cancer, and cardiovascular diseases. However, studies in office buildings have focused primarily on acute health symptoms (unspecific symptoms of irritation of eyes, nose, and mucous membranes, fatigue, and headache) experienced by office worker. Long-term effects are generally not evaluated in office workers due to the complexity and required resources for clinical testing, which seem unrealistic in view of occupants' mobility and the inhomogeneity of exposures (Carrer et al. 2015).

As several diseases can be associated to office working, a medical evaluation (focused on occupants) should guide environmental surveys and monitoring, especially when the indoor environmental and air quality measurements suggest compliance with air quality guidelines (Lukcsó et al. 2016). In the framework of IAQ assessments and management actions, individual health surveillance or individual clinical examination should be proposed only when periodical health surveillance is already being performed for other risks factors or when the occurrence of symptoms such as sensorial disturbances, eyes infections, respiratory and inflammatory effects in upper and lower airways appears to be clearly associated with inadequate IAQ. The examination of individuals must encompass (Carrer and Wolkoff 2018):

- (i) Workplace description (building and offices, ventilation, lighting, cleaning, mold growth, smells, thermal climate (e.g., such as experience of cold feet, cold/warm air, dry or stuffy air, static electricity), and noise).
- (ii) Description of symptoms and signs. Special regard should be reserved for mucous membrane (sensory) irritation, skin and general symptoms, and relationship with work (symptom development). The typical time of symptom onset during the week (morning/afternoon, working days/weekend), and seasonal variations should be also addressed. Routine physical examination generally implies a particular focus on eyes, nose, throat, skin, and lungs.

- (iii) Allergy (atopy) evaluation, when indicated; for example, in case of asthma and/or rhinitis, where allergens are suspected at the workplace, e.g., mold growth, animal fur, and plants.
- (iv) Other risk factors: for instance, transport conditions, use of medication, and use of contact lenses. Furthermore, it should be considered that the worker may be affected by an unrecognized disease that influences the overall perception of the IAQ and symptom reporting.

More in detail, some specific physiological methods have been applied to study health effects of the indoor environment. Ocular methods include measurement of tear film break-up time, blink frequency, detection of corneal damage by vital staining of cells or inflammatory markers in tear fluid. Nasal methods include acoustic rhinometry, rhino stereometry, and nasal peak expiratory flow. In addition, the concentrations of biomarkers of inflammation can be measured in the nasal lavage fluid. Field studies have demonstrated associations between ocular and nasal physiological response and the indoor environment (Bakke et al. 2008).

Oxidative stress has been in focus as an important mechanism behind health effects of outdoor air pollution, but it has been also shown that it can be an important biological factor for SBS symptoms in relation to indoor chemical indoor exposure.

Risk factors in the office environment could be heterogeneous. Eye symptoms were associated with proximity to outdoor pollution like traffic, portable humidifiers, and crowded spaces (Wolkoff 2017), visual display unit work, inadequate ventilation (Sundell et al. 2011), low humidity (Wolkoff 2018), or high temperature (Wolkoff 2017). Mold in moisture-damaged buildings is another risk that may have an impact on the IAQ and susceptible people (e.g., with asthma symptoms) (Zhang et al. 2012). Other office-related factor could have an impact in symptoms and occupants' health: for example, generally, more dissatisfaction and increase of adverse health effects are reported in crowded offices (Bergström et al. 2015; Leder et al. 2016).

Then, potential synergies between indoor air and psychosocial stress on health and comfort of office workers have been explored (Azuma et al. 2015). Odor annoyance and exposure to unpleasant odors influence general comfort (fatigue, impaired power of concentration, headache, nausea, and insomnia, including possible mood disorders) (Hurraß et al. 2017); psychic reactions with nonspecific symptoms are plausible, but they would not induce direct physiological reactions like sensory irritation in eyes and upper airways (Hurraß et al. 2017). Susceptible people, with high distress or being diagnosed with asthma or multiple diagnoses of asthma/allergy, may react more intensely to poor IAQ than people with low distress or without asthma (Claeson et al. 2016).

IAQ Management and Risk Mitigation Measures in Offices

IAQ monitoring and assessment, combined with source identification and control (e.g., using low-emitting materials and products as well as control of some indoor activities such as smoking, use of candles, and of air fresheners, etc.), has been

increasingly recognized as the prioritized strategy for improving IAQ and reducing the combined health risks associated with indoor exposures. Other management measures, such as the adjustment of ventilation rates, should be implemented after source control to account for any residual pollution (Carrer et al. 2018). However, the identification of sources and determinants of IAPs is particularly complex: researches have examined several specific factors (e.g., temperature, various chemical compounds, or mold), sources of pollution (e.g., environmental tobacco smoke, occupational activities such as manufacturing, combustion of fuels, consumer cleaning products), and control technologies (e.g., ventilation systems) in order to define the determinants of major IAPs, as well as the effect of seasonal variations and environmental conditions on indoor air pollution (Campagnolo et al. 2017; Spinazzè et al. 2020).

Evidence from intervention studies is also available: for example, after the replacement of scented cleaning agents in modern office buildings, substantially lower concentrations of IAPs and some oxidation products (secondary pollutants) were also reduced in line with limonene (Nørgaard et al. 2014).

The deployment of networks of heterogeneous devices based on wireless communication infrastructures and equipped with smart devices and IAQ sensors allowing increased spatial resolution of real-time IAPs concentrations offer unprecedented opportunities for planning and controlling a new generation of office buildings. Due also to their miniaturization and affordability, low-cost sensor systems are increasingly used for the monitoring of air contamination and can be applied in intelligent and autonomous control systems for a real-time and long-term optimized management of IAQ, energy consumption, and microclimate. On the one hand, this would provide building managers with integrated and adaptive management systems for a nearly real-time energy and IAQ control (Kumar et al. 2016). On the other hand, some critical issues and challenges for their large-scale deployment remain, such as the manipulation and analysis of the big amount of data obtained and the need of affordable services for sensor-network maintenance.

Conclusions

Since different studies have addressed IAQ and associated exposure-related symptoms in office workers, a careful assessment and management of IAQ in office-like environments is of key importance for the protection of human health and to ensure optimal comfort and well-being for office workers. For this purpose, the development of appropriate monitoring strategies is crucial to properly characterize the chemical and physical complexity of IAQ dynamics and subsequent potential impact on office occupants. To obtain comprehensive and representative conclusions about IAQ problems in office-like environments, and to prioritize the order of management interventions, a multilevel approach should be implemented. This should include a general survey of the building and of the offices, occupants' questionnaire surveys (concerning IAQ, symptoms, and psychosocial working aspects), and environmental measurements. IAQ monitoring and assessment, combined with source identification

and control, and adjustment of ventilation rates as well, has been recognized as the prioritized strategy for improving IAQ in office-like environments and reducing the combined health risks associated with indoor exposures to IAPs.

Whatever the objectives and methods of the evaluation, it is important to combine multiple expertise in the process and properly inform the employer, HSE (health, safety and environment) managers, and last but not least workers and building occupants in active collaboration with other prevention professionals.

In summary, when there is the need to achieve a comprehensive understanding of IAQ and its related determinants or effects, it is recommended to collect integrated information about the building and its occupants by inspection visits to offices, questionnaire surveys (concerning perceived IAQ, symptoms, and psychosocial working aspects) and environmental monitoring, to reach sound conclusions about IAQ or exposure assessment, source identification and/or apportionment, and the most effective risk management options.

Abstract

A growing body of literature indicates that concentrations of indoor particulate matter and gaseous pollutants in elderly care centers (ECCs) often exceed those recorded in nearby outdoor environment. At present, unlike the outdoors, indoor air quality (IAQ) in ECCs is not regulated and is seldom monitored. Elderly citizens commonly spend most of their day indoors where they are exposed to indoor air pollutants, even at low concentrations, for long periods of time. Given that many ECCs residents, especially those of advanced age, are more susceptible to the effects of air pollutants, this prolonged exposure may adversely impact their

health. Despite these facts, there are few data among older adults and their exposure to IAQ pollutants in ECCs. In the current pandemic situation, IAQ has become an even more prominent research topic, encompassing issues such as the need of good ventilation of indoor spaces. Thus, this chapter presents the highlights of the existing knowledge on IAQ in ECCs. It summarizes the most recent findings related to: (i) major indoor air pollutants, its source signatures, levels and health relevance; (ii) current and future perspectives on IAQ health-based guidelines; and, finally, (iii) strategies to assure a healthy indoor environment. This overview underlines that indoor air pollution in ECCs represents a major global public health problem requiring further efforts in research that can inform evidence-based risk management and public health interventions to reduce current and future risks associated with poor IAQ in ECCs in line with the 2030 Agenda for Sustainable Development.

Introduction

The built environment is undergoing constant changes driven by global megatrends such as global warming and urbanization, resulting in increased ambient (outdoor) air pollution that inevitably impacts indoor air quality (IAQ). The relationship between the outdoor environment and IAQ is well known, being evident from several research works that the concentration of indoor air pollutants are two to four times higher than those of outdoor air pollutants (Campagnolo et al. 2017; Madureira et al. 2016). Nevertheless, unlike the outdoors, IAQ is not regulated and is seldom monitored. With higher concentrations of pollutants inside buildings, IAQ is one of the world's highest environmental health risks (WHO 2017) that cannot be neglected.

While prior studies of indoor environments have focused mostly on office buildings (e.g., Campagnolo et al. 2017), homes (e.g., Madureira et al. 2016, 2020a), or school facilities (e.g., Madureira et al. 2016), recent scientific studies on elderly care centers (ECCs) have found that poor IAQ may adversely affect both cardiorespiratory systems and that the elderly are at higher risk of suffering from such health problems than other age groups due to the progressive decline of their body' function leading to increased vulnerability, frailty, or sensitivity (Mendes et al. 2018; Maio et al. 2015).

According to the European Commission, by 2050, the number of people aged 65 and above in the EU is projected to rise more than twice and the number of persons aged over 80 is expected to grow by 170% (UN 2017). This inevitable increase in the share of older persons that results from the decline in fertility and enhancement in survival constitutes a new demographic reality and a major societal challenge common to all European countries to fulfill the pledge of the 2030 Agenda for Sustainable Development that “no one will be left behind.” With these trends, it is

anticipated that many more elderly will live in ECCs, and because most of older citizens in industrialized countries typically spend a significantly larger number of hours (19–20 h/day) indoors compared to the general population (Almeida-Silva et al. 2015; WHO 2010), the need to ensure they are not unnecessarily exposed to indoor pollutants becomes crucially important.

While the volume of aging research output has increased in the last decade, knowledge about the indoor air conditions of older people living in ECCs remains limited. The expansion of such knowledge is critical to enable policy-makers, ECCs staff, and other key stakeholders to anticipate health risks among the most susceptible and proactively implement policies and programs needed to respond to the challenges and opportunities of coming decades. Beginning in 2020, the rapid spread of SARS-CoV-2/COVID-19 (severe acute respiratory syndrome coronavirus-2/coronavirus disease 2019) pandemic and the related containment measures has led to “tragic” consequences in ECCs’ residents and has revealed several weaknesses in monitoring, preparedness, and resources to mitigate the transmission of airborne infectious diseases, such as improved ventilation (Morawska et al. 2020). Therefore, it is both timely and necessary to integrate the environmental and human health aspects to improve indoor environments and provide healthy conditions for elderly people that occupied them.

Thus, the purpose of this chapter is to highlight the existing knowledge on IAQ in ECCs. It summarizes the most recent findings related to the major indoor air pollutants, its source signatures, levels, and health relevance. Following this, an overview of existing and future perspectives on IAQ health-based guidelines is also presented considering the most recent state-of-the-art on this field. Finally, a separate section is devoted to strategies for control and mitigation of indoor pollutant concentrations in line with the 2030 Agenda for Sustainable Development.

A Paradigm Shift to Address Indoor Air Quality

Outdoor air pollution has been recognized as a serious problem in many urban places worldwide, and has being investigated over the years from economic, social, and legislative as well as lifestyle habits perspectives (EEA 2018). The primary outdoor air pollutants are particulate matter (PM), volatile organic compounds (VOCs), nitrogen dioxide (NO_2), ozone (O_3), carbon monoxide, and sulfur dioxide(SO_2) (EEA 2018). In urban areas, the increase in emission of these air pollutants is largely due to fossil fuel burning, automobile emissions (Morawska et al. 2017), which in turn is affected by global warming and urbanization levels. Several long-term policies, programs, and interventions across different sectors (i.e., transport, housing, energy, and industry) have been implemented for public health purposes (EEA 2018). The 2005 World Health Organization (WHO) air quality guidelines (AQGs) offer global guidance on thresholds and limits for key outdoor air pollutants that pose health risks (WHO 2006) including PM, O_3 , NO_2 , and SO_2 . This guidance was revised on September 2021 (WHO 2021) and updated recommendations, produced based on stronger body of evidence that shows how air pollution affects different

health outcomes, resulted in almost all the AQG levels being strengthened in comparison to the AQG established in 2005. In addition, the WHO's new guidelines highlight good practices for the management of certain types of PM, as black carbon/elemental carbon, ultrafine particles (UFP), particles from sand and dust storms, for which there is currently insufficient evidence to establish AQG values. To be noticed that the updated recommendations are applicable to both outdoor and indoor environments globally, and cover all settings, including ECCs (WHO 2021).

In the last decades, IAQ has become a relevant area of concern and has received increasing attention from the scientific community. The US Environmental Protection Agency (USEPA) defines IAQ as "the air quality within and around buildings and structures, especially as it relates to the health and comfort of building occupants." The indoor air monitoring can be challenging due to several factors and its interrelationship, such as pollutants coming from outdoor sources, building features, and, to a large extent, occupants' behavior. Building features include, geographic variations and climate; building age; building design, construction and maintenance; and ventilation rates. With such a wide variety of building types and characteristics, establishing rigorous and repeatable protocols for monitoring indoor air pollutants is a challenging task. In addition, the occupants' behavior has nearly as many varieties and activities as there are occupants, and includes, for example, cooking, cleaning, pet ownership, smoking habits, frequency of opening window, as well as patterns of use (e.g., time spent indoors). The contribution of each of these factors to indoor air pollutants concentrations is difficult to estimate due to not only the specific characteristics of each location and building use, but also due to the variability over time of indoor concentrations and chemical reactivity leading to the formation of secondary pollutants. However, many studies have confirmed that IAQ is highly influenced by outdoor air quality and can be more polluted than outdoor environment (Campagnolo et al. 2017; Madureira et al. 2016). Poor IAQ has been linked to adverse health effects as described in the section of this handbook on IAQ and human health.

Indoor air quality does not affect everyone in the same way: older persons are considered particularly at risk for detrimental health effects from indoor air pollution (Mendes et al. 2018; Maio et al. 2015) due their reduced immunological defenses and multiple chronic diseases. The quality of air inside ECCs is an essential determinant of a healthy life. Improvements of the indoor environment may be the most cost-effective way to reduce the burden of indoor exposure. However, little research has been conducted in regard to older adults and their exposure to IAQ pollutants in ECCs.

Major Chemical Pollutants, Source Signatures, and Health Relevance

Indoor air of ECCs contains numerous pollutants, such as airborne particles of complex composition and widely differing sizes and VOCs. Other pollutants, such as NO_2 and O_3 are classical pollutants of outdoor air that penetrate indoor

environments in different ways in addition to releases from indoor sources (Wichman et al. 2010). According to Annesi-Maesano et al. (2013), high temperatures and relative humidity levels might contribute to the increase of concentrations of some of these pollutants.

The relevance of measuring the concentrations of these pollutants indoors has been recognized (WHO 2010, 2021) since many chemical pollutants that are hazardous to human health are present in concerning concentrations. Within this chapter, information about PM, VOCs, NO₂, and O₃ will be presented taken into account the likelihood of their presence in ECCs and their potential contribution to elderly's health. According to Carrer et al. (2018), it is estimated that indoor air pollution is responsible for a loss of over 700,000 healthy life-years within the EU.

Despite the large number of pollutants present in indoor environments, only a few of them are typically measured. In addition to the four chemical pollutants previously mentioned, information about carbon dioxide (CO₂) will be also considered since this gas is an important parameter to monitor and control given the evidence of their presence in indoor air and their common use as proxy of ventilation rate.

Particulate Matter

Particulate matter is a complex mixture of organic and inorganic chemicals, including sulfates, nitrates, polycyclic aromatic hydrocarbons (PAHs), and metals (cooper, zinc, iron) (Hamanaka and Mutlu 2018).

Airborne PM span a range of diameters from a few nanometers to tens of micrometers, such as PM₁₀, PM_{2.5} (PM with aerodynamic diameter <10 µm and <2.5 µm, respectively), and PM_{0.1} (PM with aerodynamic diameter ≤0.1 µm), called UFP; being their composition and toxicity very complex and variable, with similarities but also differences to outdoor PM (Leikauf et al. 2020). PM_{0.1} are also called nanoparticles because of their size, although many authors use the word "nanoparticles" to the 100 nm or smaller PM manufactured through controlled engineering processes, in contrast to ambient or indoor PM, which are incidentally derived from natural or fossil fuel combustion processes (Li et al. 2016a).

Indoor particles are comprised of ambient PM of different size fractions that infiltrate from outdoors, and particles that are generated indoors. Ambient PM in the urban environment originate mostly from fossil fuel burning, automobile emissions, resuspension, or chemical and thermodynamic processes, but also from long range transport since they can travel large distances (>100 km) (Rivas et al. 2020; Morawska et al. 2017). Outdoor air is a major PM_{2.5} source in roadside buildings (Rivas et al. 2020). Cooking, fireplaces, fossil fuels combustion activities, smoking, secondary formation processes, and dust resuspension (Stabile et al. 2021; Almeida-Silva et al. 2014) are the main possible sources of PM inside ECCs.

In a study developed with elder living in Amsterdam and Helsinki, the authors found indoor PM_{2.5} average concentrations of 16 µg/m³ and 11 µg/m³, respectively (Lanki et al. 2007). In both European cities, the main determinants of PM_{2.5} were environmental tobacco smoke (ETS) and cooking; although outdoor air concentrations

were also strongly associated with indoor levels. Previous studies have demonstrated that ETS is a major source of exposure to PM_{2.5} among nonsmokers' homes (Ferro et al. 2004) and that cooking has often been associated with episodic peaks in PM_{2.5} concentrations (Amouei Torkmahalleh et al. 2017; Li et al. 2016b; Lanki et al. 2002) because high-temperature can lead to water vapor and other solid and liquid particles emissions. However, it is possible to find studies with higher particles concentrations, such as the one developed by Chao and Wong (2002) where PM_{2.5} (mean) levels of 45 µg/m³ were measured due to smoking, cooking, and burning incense practices. Lin et al. (2008) showed that incense burning generates PM>45 mg/g compared to 10 mg/g from cigarette burning. A review study revealed relationships between PM emissions and some important cooking variables as cooking method, cooking oil employed, cooking pan, food being cooked, cooking temperature, energy source, additives, and source surface area (Amouei Torkmahalleh et al. 2017). This review also concluded that: (1) cooking on gas burners produce higher PM compared to electric stoves and changing in cooking manner may reduce the cooking PM emissions; and (2) increased ventilation rates were efficient in reducing indoor PM concentrations during and after cooking. Hopke et al. (2003) reported that in a retirement facility in Baltimore, MA (USA) the average indoor PM_{2.5} level was significantly lower than outdoors (7.9 µg/m³ vs. 21.7 µg/m³) showing the influence of the outdoor air quality. By contrast, Kim et al. (2014) stated that mean indoor PM_{2.5} levels (23.3 µg/m³) was slightly higher than outdoors (21.2 µg/m³) in four ECCs in South Korea. In another Korean study, the mean PM₁₀ concentration was 58 µg/m³ in facilities for susceptible populations (Hwang et al. 2018). The same study indicated that indoor PM₁₀ concentrations were higher than outdoor concentrations at all ECCs studied and exhibited a significant weak positive correlation with CO₂ concentration, which is influenced by human density and movement (Hwang et al. 2018). Similarly, Segalin et al. (2017) investigated PM in 59 elderly residences in metropolitan area of São Paulo, Brazil. The authors obtained mean values of measured PM₁₀ and PM_{2.5} of 35.2 µg/m³ and 27.4 µg/m³, respectively. They further report that about 77% and 40% of the residences had higher PM_{2.5} and PM₁₀ indoors than those in outdoor environments, mainly due to smoking and cooking. PM_{2.5} levels were also studied in four French ECCs by Baudet et al. (2021). The authors reported median PM_{2.5} levels of 9.0 µg/m³ associated with human activity, including the resuspension of deposited particles due to human movements and also affected by PM_{2.5} outside. Mixed results were reported in Portugal by Almeida-Silva et al. (2015) who conducted measurements in four ECCs. The study found that the average living room PM₁₀ concentration was slightly lower than outdoors (19 µg/m³ vs. 21 µg/m³), but the average bedroom concentration was significantly lower than outdoors (11 µg/m³ vs. 24 µg/m³). According to the same authors, the higher levels of PM₁₀ found in the living rooms than the bedrooms were attributed to the density of occupation of the former, as well as the higher ingress of the outdoor pollution through the doors and windows that were frequently opened were occupied (Almeida-Silva et al. 2015). A study developed in Hong-Kong residences (Chau et al. 2002) reported that indoor microenvironments contributed to 38.7%, and 32.1% of the PM₁₀ exposure for adult and elderly, respectively. Likewise, in China and for the same age groups, Wang et al. (2008) estimated

that PM₁₀ in indoor microenvironments contributed to higher percentages of PM₁₀ exposure (54%, and 80%, respectively). In 2016, PM composition and sources influencing elderly exposure was investigated by Almeida-Silva et al. (2016) in an urban ECC. This study suggests that the proximity of highways and the airport (located less than 500 m from the ECC) have a great importance for both indoor and outdoor PM₁₀ levels; whereas organic carbon concentration was significantly higher indoors, being associated with the sub-micrometer fragments of paper, skin debris, clothing fibers, cleaning products, and waxes (Almeida-Silva et al. 2016). Hopke et al. (2003) postulated that personal care products, such as a Zn oxide powder that might include talc (Conner et al. 2001), represent a source of indoor PM exposure among a population with a mean age of 84 in Baltimore.

A rich body of literature has demonstrated significant adverse health implications following the exposure to PM, namely, PM_{2.5} such as the fact that increased concentrations of PM_{2.5} were associated with increased rates of hospitalization and emergency department visits (Hopke et al. 2019). Morawska et al. (2013) concluded that 10–30% of the total burden of disease from PM exposure resulted from indoor-generated particles. Bentayeb et al. (2015) carried out a study on geriatric health effects of air quality in nursing homes in Europe (GERIE study) among 600 individuals 65 years of age and older who resided in 50 nursing homes in different 7 European countries. The indoor mean level of PM₁₀ concentrations was higher than 50 µg/m³ in 12% of the nursing homes (mean value 29.8 µg/m³) (Bentayeb et al. 2015). The authors reported that exposure to elevated concentrations of indoor PM₁₀ in the main common rooms of these facilities was associated with breathlessness and cough. Mendes et al. (2016) conducted a similar study in 22 ECCs, Portugal. The authors obtained a relatively high prevalence of respiratory symptoms among ECCs residents. In the frame of the same study, Mendes et al. (2016) found a higher risk of allergic rhinitis in those elderly that were exposed to high concentrations of PM₁₀, even at concentrations lower than 50 µg/m³. Consistent with these results, higher risks for respiratory symptoms with increasing indoor PM₁₀ concentrations was reported in a study of Chinese older adults (Venners et al. 2001). Chen et al. (2019) also observed that the decline of lung function in the elderly (≥ 65 years) was related to PM exposure. Other epidemiological studies indicate that exposure to PM is associated with low bone mineral density and osteoporosis-related fractures (Prada et al. 2020); whereas Calderon-Garciduenas et al. (2013) described an association with cognitive deficits, oxidative stress, neuroinflammation, and neurodegeneration. Saenz et al. (2021) also suggested that household air pollution from the use of polluting cooking fuel may play an important role in shaping cognitive outcomes of older adults in India, Mexico, and China where reliance on polluting fuels for domestic energy needs still prevails. According to Pohl et al. (2011), several metals present in the PM, including aluminum, arsenic, cadmium, lead, manganese, and mercury, have been shown to affect the nervous system, while the general accumulation of metal ions in the brain can exacerbate oxidative stress and neuronal damage. Bentayeb et al. (2015) reported that wheeze in the past year was associated with PM_{0.1} exposure among elderly living in nursing homes. In addition, chronic obstructive pulmonary disease (COPD), defined on the basis of

the Forced Expiratory Volume in the first second (FEV1)/forced vital capacity (FVC) ratio, was highly related to PM_{0.1}. Because of the absence of data, it is not possible to compare these results with previous epidemiological studies, despite the fact that UFP are more dangerous than larger PM since when inhaled they may reach the peripheral regions of the bronchioles and interfere with gas exchange inside the lungs (Madureira et al. 2020b; Li et al. 2016a; WHO 2013). Moreover, UFP may lead to an increase in oxidative stress, exacerbating asthma and other respiratory symptoms (Li et al. 2016a).

To reduce exposure to indoor PM and its adverse health outcomes, WHO have formulated updated guidelines for PM_{2.5} and PM₁₀ with values of 5 µg/m³ and 15 µg/m³ for annual and 24 h for PM_{2.5}, respectively; and 15 µg/m³ annual averages and 45 µg/m³ for 24 h for PM₁₀ (WHO 2021). These guidelines can guide the development of effective mitigation strategies to mitigate exposure to indoor PM and have a key role in the support government's making decisions on IAQ regulation. Furthermore, substantial reductions in exposure to PM can be achieved by using existing ventilation guidelines that aim to maintain good IAQ irrespective of sources and activities (ASHRAE 2016; EN 15251 2007), which, in addition to increasing the supply of fresh air, include controlling pollution from emission sources, cleaning the air, and improving the efficiency of ventilation. Thus, ventilation practices and interventions can reduce the airborne concentrations and reduce the overall exposure of occupants. This is particularly relevant for elderly homes or geriatric centers, which, although not subject to specific regulatory requirements, are buildings that require appropriate air-conditioning and ventilation systems essential to enable the elderly people who live in these facilities to achieve a good standard of living in terms of their personal well-being, due to their special needs in terms of health and comfort. For instance, in a study of elderly (60–75 years) people, an 8% improvement in microvascular function was detected following 48 h of air filtration in their homes (Bräuner et al. 2008).

Volatile Organic Compounds

The term VOCs includes a large set of chemical substances emitted from liquids or solids, many of those known or expected to be irritating or even carcinogenic (Wolkoff 2017; Weschler 2006). Based on the categorization provided by ISO 16000-6 (2011), VOCs and very volatile organic compounds (VVOCs) are indoor organic compounds with a boiling point range of 50–100 °C and 240–260 °C; and <0 °C to 50–100 °C, respectively. They differ from the family of semi-volatile organic compounds (SVOCs) that present boiling point range of 240–260 °C and 380–400 °C.

Volatile organic compounds are emitted from a very wide range of indoor and outdoor sources (Lee et al. 2018; Madureira et al. 2016, 2020a; Annesi-Maesano et al. 2013), through human activities, including cooking, smoking, and the use of cleaning and cosmetic/personal care products; building materials, new furnishings, and decoration products; indoor chemical reactions; and penetration of outdoor air nearby

traffic and industrial emissions (Bonnet et al. 2018; Annesi-Maesano et al. 2013). Typical VOCs found in the indoor environment include benzene, toluene, ethylbenzene, and xylenes from fuel combustion and building renovations; benzene and styrene from cigarette smoking; alkanes from natural gas; formaldehyde and terpenes such as α -pinene from wood-based building materials, and limonene from fragranced cleaning and laundry products (WHO 2013; Kotzias et al. 2005). Cleaning solutions, detergents and disinfecting are largely used and have particular significance for the emission of broad spectrum of VOC indoors ECCs because of the need for maintaining infection control (Baudet et al. 2021; Pereira et al. 2021; Bonnet et al. 2018; Su et al. 2018; Almeida-Silva et al. 2014; Bessonneau et al. 2013). Furthermore, the recent pandemic (COVID-19) has seen a sweeping and surging use of products intended to clean and disinfect, such as air sprays, hand sanitizers, and surface cleaners, many of which contain fragrance. Additionally, personal care products are generally used for personal hygiene, grooming, and beautification in ECCs. These include hair and skin care products, perfumes, soap, and shampoos that contribute to the indoor levels of VOCs and SVOCs at ECCs (Khalid and Abdollahi 2021). Some studies were identified to have investigated total and specific VOCs in the indoor air of ECCs as described below. Hwang et al. (2018) investigated the total VOCs in 62 ECCs facilities. The mean total VOC ($126.1 \mu\text{g}/\text{m}^3$) concentrations reported by the authors was higher than in other indoor environments used by children, including classrooms ($114.0 \mu\text{g}/\text{m}^3$) in an elementary school in Seoul (Yang et al. 2015) and elderly people in 21 Portuguese ECCs ($110.0 \mu\text{g}/\text{m}^3$) (Mendes et al. 2016). Hwang et al. (2018) also revealed that total VOC concentrations may be attributed less to emissions sources and more to poor ventilation of ECCs indoor spaces; while Mendes et al. (2016) identified that VOCs were emitted from indoor sources in their building materials. In Korea, Lee and colleagues performed a study to characterize the indoor and outdoor levels of VOCs in 30 ECCs (Lee et al. 2018). Findings of this study showed that indoor total VOC levels were significantly higher than those of their outdoor levels ($230.7 \mu\text{g}/\text{m}^3$ vs. $137.8 \mu\text{g}/\text{m}^3$; $p < 0.05$) and that indoor/outdoor (I/O) ratio for formaldehyde was 2.48. These results suggest that both total VOC and formaldehyde are mainly emitted from indoor sources at ECCs, such as such as carpets, paints, and new wooden furniture. Sim et al. (2010) reported that the elderly who live in newly constructed residences could be exposed to high concentrations of VOCs and formaldehyde from construction materials. Under the framework of the GERIE study, the mean concentration of formaldehyde was $7.21 \mu\text{g}/\text{m}^3$ while the maximum indoor level (weekly average) was $21 \mu\text{g}/\text{m}^3$ (Bentayeb et al. 2015). These findings are in agreement with Almeida-Silva et al. (2014) that found low indoor levels of formaldehyde in ten Portuguese ECCs. Nevertheless, the authors also underlined the importance of the time activity patterns of elderly and the IAQ in different microenvironments for the daily exposure and inhaled dose estimation. Walgraeve et al. (2011) measured 25 VOCs in 6 elderly homes in Antwerp, Belgium. Overall the indoor total VOC concentration ranges from $12 \mu\text{g}/\text{m}^3$ to $311 \mu\text{g}/\text{m}^3$. The main contributor to the high total VOC concentration is limonene, but also increased levels of aromatic hydrocarbons were found. Toluene, with a mean concentration of $60.8 \mu\text{g}/\text{m}^3$, accounted for more than half of the aromatic hydrocarbons (69%), representing 25% of the total VOC

indoor concentration. Alcohols (ethanol, isopropanol), ketones (acetone), and aldehydes were the three VOCs with the highest concentrations in French ECCs as reported by Baudet et al. (2021), where cleaning activities were indicated as the main sources of these pollutants. Su et al. (2018) reported that cleaning tasks, using products containing chlorine, resulted in elevated exposures to chloroform, α -pinene, and limonene. Likewise, Singer et al. (2006) reported a concentration of 200 ppb of limonene following cleaning indoors. According to Nematollahi et al. (2019), a chemical analyses and comparisons of fragranced and fragrance-free cleaning products showed that all of the fragranced products emitted terpenes (e.g., α -pinene, β -pinene, limonene), but none of the fragrance-free products emitted terpenes that can act as both primary pollutants as well as react with O_3 to generate a range of secondary pollutants, such as formaldehyde.

The assessment of human exposure to SVOCs in indoor environment and respective risk assessment is an emerging research topic, since limited studies were performed due to analytical challenges (Weschler and Nazaroff 2008). Nonetheless, ECCs may have elevated exposure concentrations to many SVOCs due to the frequent use of several cosmetics, health care and household cleaning products (Bonnet et al. 2018; Annesi-Maesano et al. 2013). Arnold and colleagues were the first to report indoor concentrations of a large range of SVOCs in senior care facilities in the USA and in Portugal (Arnold et al. 2018). The authors found that organophosphate esters (OPEs), PAHs, and brominated flame retardants (BFRs) were the most prevalent, and organochlorine pesticide (OCPs) and polychlorinated biphenyls (PCBs) were the least abundant SVOC groups in these indoor environments. Furthermore, the levels of OPEs, PAHs, and BFRs were significantly higher in USA buildings compared to Portuguese facilities, reflecting the widespread use of some of these chemicals. More recently, Baudet et al. (2021) found that diisobutylphthalate, diethylphthalate, and dibutylphthalate were the three most quantified phthalates in a French investigation including four ECCs, with median concentration levels of 270, 240, and 77 ng/m³, respectively. Thus it is crucial to use low-emitting and non-absorbent consumer products and building materials in order to minimize pollutant exposure-related risk.

Findings by studies in various countries suggest that the exposure to VOCs, primarily emitted from indoor sources, was associated with adverse health outcomes, such as headaches, upper and lower respiratory symptoms (e.g., irritation of the nose and eyes), and may contribute to the worsening of the respiratory diseases, namely, asthma attacks and exacerbations (Hulin et al. 2012; WHO 2010) and additional health problems related to neurological gastrointestinal, dermatological, and immune systems (e.g., WHO 2010). An excess of asthma was observed among French school children exposed to concentrations of formaldehyde higher than the established standards in their classrooms (Annesi-Maesano et al. 2012) or dwellings (Hulin et al. 2012). In a longitudinal study performed in Sweden between 1989 and 1992, the prevalence of self-reported asthma was higher among subjects living in newly painted dwellings compared to others (Wieslander et al. 1997). In an adult population, a significant association was showed between asthma and exposure of VOCs, especially aromatic compounds (Arif and Shah 2007). A recent review of

epidemiological studies highlighted that the use of cleaning and disinfecting products is harmful to respiratory health and increases the risk of asthma (Folletti et al. 2017).

Despite the fact that elderly is likely more exposed to indoor air pollutants, very few studies targeted the respiratory effects of VOCs in this age group. In one study conducted in elder people, the urinary levels of hippuric acid and methyl-hippuric acid (metabolites of toluene and xylene, respectively) were significantly associated with a harmful effect on pulmonary function due to the reduction of FEV1, FEV1/FVC, and forced expiratory flow at 25–75% of FVC (Yoon et al. 2010). Another study, carried out in France, explored the relationship between exposure to VOCs and respiratory health outcomes in the elderly population (Bentayeb et al. 2013). The findings revealed a significant relationship between toluene and o-xylene levels and breathlessness among the elderly participants. These results are in agreement with those from Yoon et al. (2010), under the hypothesis that breathlessness and dyspnea are a proxy of lung function deterioration. A relationship between increased indoor concentrations of VOCs and pulmonary infection was noted by Belo et al. (2019).

Nitrogen Dioxide

Another common indoor pollutant is NO₂. Since NO₂ is a traffic- and industrial emissions-related pollutant (EEA 2018), concentrations of NO₂ are commonly higher in urban than in rural environments, and generally higher in outdoor air compared to indoor air, if no specific indoor sources are available, such as gas appliances like stoves, ovens, or water heaters, fireplaces and tobacco smoke (WHO 2010). Moreover, as indoor concentrations of NO₂ are modulated by ventilation, optimized ventilation is an important factor in the prevention of adverse effects of NO₂ pollution (Bentayeb et al. 2015).

The evidence from epidemiological studies for a threshold for long-term exposure to NO₂ is inconsistent, with some large studies suggesting that the threshold for increased symptoms it is likely to lie below 19 µg/m³ among asthmatic children (Belanger et al. 2013). In addition, a concentration–response relation has been determined between long-term NO₂ concentration and mortality, with most concentrations below 20 µg/m³ among adults (Raaschou-Nielsen et al. 2012).

However, little is known about exposures to NO₂ in indoor environments such as in ECCs. The results from Hwang and Park (2020) study indicated that NO₂ concentrations were significantly higher in the four facilities with susceptible occupants (19.9 µg/m³) than in the general facilities (11.8 µg/m³); however, in all the studies facilities, the respective I/O ratio was less than one, which suggest that the outdoor traffic generated origin of NO₂, rather than indoor sources. Similar mean indoor NO₂ concentrations (20.1 µg/m³) were reported by Bentayeb et al. (2015) who documented that elevated indoor NO₂ concentrations was associated with decreased lung function and COPD. This association was observed for NO₂ levels below 40 µg/m³ and was amplified in ECCs with poor ventilation and in elderly residents over the age of 80 (Bentayeb et al. 2015). In a previous Italian study

(Simoni et al. 2002), highest weekly indoor NO₂ levels were found in a rural area when compared with urban area (54.5 µg/m³ vs. 62.0 µg/m³, $p < 0.05$ in winter and 41.4 µg/m³ vs. 37.6 µg/m³, $p < 0.01$ in the summer for urban and rural areas, respectively). This population-based study also indicated an association between low doses of indoor NO₂ and acute respiratory symptoms and reduced peak expiratory flow in adults, while bronchitis and asthmatic symptoms were significantly more prevalent in the presence of high NO₂ levels. High NO₂ exposure was also associated with greater symptom duration.

Other research works have also indicated NO₂ as a cause of adverse effects on health. A study of British adults showed a significantly reduced FEV1 in study participants who currently used gas for cooking compared to those who used electricity (Moran et al. 1999). The principal indoor source of NO₂ in Australian homes was also the use of gas heaters (Pilotto et al. 1997). The authors showed that the presence of gas heaters at home was significantly associated with increased prevalence of asthma (Pilotto et al. 1997). Gas cooking was associated with increased risk of respiratory problems and impaired lung function in nonsmoking adults in Singapore as reported by Ng and co-authors (Ng et al. 1993).

Ozone

Ozone is a secondary pollutant formed by a complex reaction chain where VOCs, oxides of nitrogen (NOx), mainly comprised of NO₂ and nitric oxide, and solar irradiation are the key actors (Hwang and Park 2020; EEA 2018). This formation mechanism explains why elevated O₃ concentrations are found in several large urban and industrial agglomerations where anthropogenic emissions of its two main precursors (NOx and VOCs) have been increasing (Zhang et al. 2019; EEA 2018). Precursors can be transported by local/regional air mass flows away from the urban areas and toward suburban and rural areas, which are impacted by O₃ episodes. At the same time, O₃ are strongly linked to other factors such as weather conditions (i.e., season, time of day) as well as geographical region; higher temperatures can promote the formation of O₃ and also accelerate the reaction among different precursors and their intermediate products (EEA 2018; Coates et al. 2016).

Indoor O₃ concentrations generally fluctuate from 30% to 70% of the outdoor levels (Zhang et al. 2019) according to the air exchange rate and O₃ removal rate and where specific indoor sources, e.g., air purifiers, laser printers, photocopiers, are not present (Nicolas et al. 2007).

Ozone is a pollutant of concern in any type of indoor environment and elderly is considered a sensitive group of population such as children. By this reason and because studies performed in ECCs are scarce, research developed in schools will also be presented. The average indoor levels of O₃ found in school environments from ten European cities were 8.50 µg/m³ and much lower than the average outdoor levels (HESE 2006). More recently, Dimakopoulou et al. (2017) evaluated O₃ levels in different school buildings in Greece and concluded that: (i) outdoor to indoor transport of O₃ is significant; and (ii) the length of time windows were open was

significantly associated with exposure to O₃. In line with these results, Blondeau et al. (2005) also reported that all I/O ratios <1, suggesting that O₃ indoors derives from the O₃ transport from outdoors rather than internal sources.

In comparison to school buildings, indoor O₃ concentrations were low in European nursing homes (Bentayeb et al. 2015), a finding that corroborates earlier observations in ten Portuguese ECCs (Almeida-Silva et al. 2014), which reported O₃ levels below 0.2 µg/m³ or, in some cases, below the detection limit. Higher indoor O₃ concentrations were reported in 66 ECCs in Korea (Hwang and Park 2020). These authors observed that mean indoor O₃ concentrations were lower in ECCs (26.2 µg/m³) than in museums facilities (32.6 µg/m³); even the highest mean concentrations were observed in summer months compared to the winter months in multiple facilities despite indoor environments not having any identified source of O₃. This suggest that indoor O₃ are influenced by outdoor concentrations and that seasonal variations in O₃ levels might be caused by limited or decreased photochemical reactivity of O₃ during winter (EEA 2018).

Most epidemiological studies published on the health effects have repeatedly reported decrements in lung function associated with O₃ exposure in infants and children; however, estimated individual exposures were obtained from outdoor measurements (Triche et al. 2006). Largely unexplored is the association between indoor ECCs O₃ concentrations and elderly health. According to Brauner et al. (2014) no significant changes in lung function were observed in association with increased levels of residential O₃ among 39 healthy elderly nonsmokers; nevertheless, among the seven study participants with asthma or obstructive airway disease, the authors detected a significant inverse association between residential O₃ and FEV1/FVC.

Carbon Dioxide

Carbon dioxide, a colorless and odorless gas, is a well-known constituent of the Earth's atmosphere contributing to the greenhouse effects and accelerating global warming (EEA 2018; Azuma et al. 2018). Outside levels of CO₂ are relatively constant. Outdoor CO₂ concentration is currently at nearly 412 ppm and rising (NASA 2019), which is primarily the result of the combustion of fossil fuels (EEA 2018). In a usual indoor environment, concentrations of CO₂ range from outdoor levels up to several thousand parts per million (e.g., Madureira et al. 2016). Indoor CO₂ concentrations are commonly used as a good indicator for the concentrations of occupant-generated pollutants, particularly bioeffluents emissions including PM and VOCs, as well as of poor ventilation (Madureira et al. 2016). According to the ASHRAE standard, it is recommended that indoor CO₂ concentrations are maintained below 700 ppm to ensure human health (ASHRAE 2016).

Hwang and Park (2020) evaluated CO₂ levels in multiple ECCs and the mean measured concentration was 598 ppm. In the same study, indoor CO₂ concentrations showed a significant correlation with indoor NO₂ and O₃ levels suggesting that CO₂ can be used as a surrogate for indoor concentrations of other pollutants and housing

factors, since indoor CO₂ concentrations are strongly correlated with indoor ventilation. The GERIE study analyzed CO₂ levels, showing that only 19% of the elderly individuals had an adequate ventilation system in nursing home where they live (Bentayeb et al. 2015). Likewise, Almeida-Silva et al. (2014) reported that in 60% of the studied bedrooms, CO₂ levels exceed 1800 mg/m³ for almost 15 h/day. More recently, Hwang et al. (2018) observed significantly higher mean CO₂ concentrations in facilities for susceptible populations (638 ppm) than those obtained in other general facilities (542 ppm) and subway station platforms (563 ppm) in Seoul. Also in Korea, Park et al. (2010) found that in several ECCs, indoor levels of CO₂ were significantly higher than those in other residences or public facilities. The authors concluded that robust air cleaning and mechanical ventilation systems should be used to reduce indoor pollution levels because indoor levels of CO₂ exceeded 1000 ppm (Park et al. 2010). In Portugal, ventilation in ECCs, based on CO₂ concentrations, which commonly exceed 1000 ppm, appears inadequate (Mendes et al. 2016). Mendes et al. (2016) refers that the main reasons for the high CO₂ levels were elevated density of occupation and poor ventilation of the ECCs' rooms.

In previous epidemiological and intervention studies, CO₂ concentrations have been shown to be related with adverse health outcomes. According to the study performed by Azuma et al. (2018), nonspecific symptoms including headache and dizziness among 107 participants from 11 offices were positively associated with a 100 ppm increase in CO₂ concentration (range from 549 ppm to 1318 ppm), although the correlation was not significant. Prior research has shown that a 100 ppm increase in CO₂ concentration (range from 674 ppm to 1450 ppm) found inside university classrooms was significantly associated with headache among 355 students and this association was independent of temperature, relative humidity, and air exchange rate (Norbäck and Nordström 2008). In Taiwan, Tsai et al. (2012) found a significant increase of eye irritation and upper respiratory symptoms when 111 office workers were exposed to indoor CO₂ concentrations higher than 800 ppm. Nocturnal symptoms related to asthma were associated with higher CO₂ levels in dwellings in Sweden (Norbäck et al. 1995). According to the same authors, the inadequate outdoor air supply, or the indoor concentration of CO₂, leads to increased levels of VOCs and other indoor pollutants. It is postulated that the relationship between indoor CO₂ concentrations and specific adverse health effects exist because the higher indoor CO₂ levels at lower ventilation rates are likely correlated with higher levels of other coexisting indoor generated pollutants that directly cause adverse effects. Thus, further epidemiological studies are advised.

Indoor Air Quality Health-Based Guidelines

The population is evolving, i.e., changing its lifestyle and modifying its consumer product uses due to development of novel household products and building materials. These changes bring a great variety of sources and wide range of indoor air pollutants, even at low concentrations, within the building environment with potential health risks. Therefore, it is essential for the protection of occupant's health the

continuing monitoring and the development of IAQ health-based guidelines. In this context, member states need to adopt and implement measures to ensure adequate air quality in indoor environments in line with the priorities of both national and European prevention plans, such as the programs from the United Nations Sustainability Development Agenda, since, there is no specific European legislation for IAQ so far, except in what regards the ban of tobacco smoke in public buildings and commercial establishments (EC 2007).

Current Guidelines

In recent years, the scientific communities as well as worldwide organizations have attempted to develop and implement IAQ guidelines since there is a common recognized need for a horizontal policy framework, which spans safety, health, energy efficiency, and sustainability aspects across existing legislative instruments and standardization activities related to the indoor built environment. DG SANCO undertook a relevant breakthrough promoting a number of high-grade projects such as Promoting actions for healthy indoor air (IAIAQ), HealthVent (Health-based ventilation guidelines for Europe), EPHECT (Emissions, Exposure Patterns and Health Effects of Consumer Products in the EU), while from the European Commission side, Joint Research Center (JRC) has been for the last 25 years a true leader in what regards IAQ through the European Collaborative Action on Urban Air, Indoor Environment and Human Exposure (http://ihcp.jrc.ec.europa.eu/our_activities/publichealth/indoor_air_quality/eca/eca-publications).

Since 1987, the WHO has developed guidelines, provided technical support and tools to facilitate assessment and quantification of the health impacts of air pollution (WHO 1987). The AQGs are addressed to the whole world in an attempt to produce a set of reference values grounded on the results of scientific studies and from practical experience or consensus based on available knowledge. In September 2021, the WHO updated its 2005 AQGs reflecting the large impact that air pollution has on global public health burden (WHO 2021). They recommend aiming for annual mean concentrations of PM_{2.5} not exceeding 5 µg/m³ and NO₂ not exceeding 10 µg/m³, and the peak season mean 8-h O₃ concentration not exceeding 60 µg/m³ (WHO 2021). For reference, the corresponding 2005 WHO AQGs values for PM_{2.5} and NO₂ were, respectively, 10 µg/m³ and 40 µg/m³ with no recommendation issued for long-term O₃ concentrations. While the guidelines are not legally binding, several countries, such as UK (PHE 2019), Belgium (HGR 8794 2017), France (Décret 2011-1727, 2011; Décret 2011-1728, 2011), and Portugal (DL 60, 2013) have started efforts to design and adopt guideline/reference values for IAQ to protect human health; in some cases, enforced in the legislative acts of these countries while in other the recommended guideline values have no legal value, even though in practice they have reached considerable importance, since these actions will facilitate the detection of problems and the formulation of effective control strategies. Please find all the information related with guidelines/regulations in the dedicated chapter to this topic in this handbook.

Future Perspectives

Indoor air quality is an important determinant of public health and will continue to be a priority topic in the future, namely, within environmental and health programs. Existing IAQ guidelines are based on assessments carried out on individual pollutants and taking into account a single route of exposure. Since in reality humans are continuously exposed to a large set and combination of indoor air pollutants, there is increasing concern about the potential adverse health risks of the interactions between those pollutants. In addition, there are multiple routes of exposure for specific indoor pollutants (Kienzler et al. 2016) and when there are multiple exposures to indoor pollutants, combined health effects (e.g., dose addition, response addition, synergism, and antagonism) are often a cause for concern (Azuma et al. 2016). In light of the above considerations, to reduce the health risks due to chemical pollutants via multi-route exposures, human risk management based on estimates of the total body burden of the pollutants and the relative contributions of these exposures to the total body burden is required. At present at the EU level, there is not a consistent, comprehensive, and integrated recommended approach to conduct risk assessment for chemical mixtures or for combined effects due to co-exposure to different chemicals via different routes (Kienzler et al. 2016).

A novel approach that integrates the contribution of the different routes and pollutants exposure using multi-environmental biomarkers (e.g., oxidative stress markers) to evaluate biological and potential health risks is essential. They can contribute to improve the knowledge on the link between air pollution and human health in a more global and future perspective.

The Challenges of Making Indoors Healthy

According to the last WHO estimates, more than 80% of people living in the urban context are subjected to air quality levels above the concentration limits regarding outdoor air pollution due to the rapid industrialization and urbanization in these areas (EEA 2018). The assessment of outdoor air quality is frequently driven often for regulatory targets compliance purposes. Unlike outdoors, IAQ is not regulated by legislation and seldom monitored. Whereas improving outdoor air quality leads to general improvements of IAQ as well, certain sources of air pollution not covered by ambient air quality regulations/standards can dominate in some indoor environments leading to an indoor environment with poor air quality that can cause potential adverse health effects particularly relevant among the most susceptible groups of the population, such as the elderly. The current pandemic situation placed IAQ under a bright spotlight and emphasized the need to prioritize effective strategies to promote healthy indoor spaces and buildings. However, the success of any IAQ strategy or approach strongly depends on targeted policy changes across the public health, urban planning, and architectural design sectors.

Increased emphasis has been placed in the residential environment for older people as the number of ECCs increases as well as on identifying the relationship between health and the residential environment for older people. The older population risk assessment may require the design of a specific strategy and intervention plan with specific recommendations for controlling, mitigating, and/ or solving risk factors to protect them from exposure to indoor air pollutants. Indoor air quality in ECCs can be improved in three ways: source control, improved ventilation, and using technologies for indoor air treatment. An overview of existing studies performed on ECCs is displayed below; please see chapter on strategies to ensure a healthy IAQ for further details.

The most cost-effective IAQ control strategy is to remove/replace the individual sources of pollution or to reduce their emissions. A reduction in outdoor air pollution will reduce indoor pollution as a flow-on effect. The selection of low emission products and materials with “clean” or “ecological” labels like improved plastics and paints (phenol resins instead of urea resins, polyurethane coatings, etc.) are another example of source control strategy (ECA 27 2012; Kotzias et al. 2005) since some VOCs emissions can be prevented. Mendes et al. (2018) established a set of recommendations and good practices to improve IAQ in ECCs. Among others, the authors have suggested to avoid the use of: sprays, air fresheners, and detergents with intense smell; and carpets, fitted carpeting, plaids on the sofas and draperies, as well as excessive decorative items that make it difficult for cleaning. Moreover, the cleaning processes should be done when there are no occupants in the divisions, being in other microenvironments. Smoking ban measures are also a very effective measure since tobacco smoke is a source of multiple harmful chemicals in elevated concentrations. The suppression of tobacco smoke in indoor places has resulted in consistent IAQ improvements (Kotzias et al. 2005).

In the past few years, the advance on portable and inexpensive sensors and systems has emerged as an additional strategy for the real-time, even remote, monitoring and control IAQ. In this context, it is predicted that the progress on development of materials for IAQ sensors and IAQ-monitoring systems is a promising strategy for control and enhancement of IAQ in the future, namely, in ECCs (Tran et al. 2020).

Another strategy that is used for controlling IAQ in buildings is ventilation. Ventilation is the process of providing fresh and clean outdoor air to a room or building via natural systems or mechanical equipment, such as fans and blowers, to reduce exposure (Carrer et al. 2018). Most recently, researchers have highlighted the role of proper ventilation of indoor spaces as a means to reduce exposure to SARS-CoV-2 (Morawska et al. 2020). Similarly, other entities, such as the Federation of European Heating, Ventilation and Air Conditioning Associations (REHVA), and the American Society of Heating, Ventilating, and Air-Conditioning Engineers (ASHRAE), have recognized the potential airborne hazard indoors and recommended ventilation control measures accordingly (ASHRAE 2020; REHVA 2020), since ventilation plays a crucial role in relation to the indoor pollution levels and minimizing the possibility of health problems as a consequence. The capacity to increase ventilation rates to ensure good IAQ may differ, and may be somewhat limited by their original design specifications and implementation.

Mendes et al. (2018) suggested that combination of controlling the indoor air sources and selecting appropriate ventilation rate was the most effective to reduce health risks in ECCs. In that context, if the indoor emission source cannot be removed or their emissions cannot be reduced to an accepted level, higher ventilation rates, reduced occupant density, and additional mechanical ventilation are recommended to ensure good IAQ. The ventilation rate should differ for different building facilities and rooms according to the occupancy and activities conducted there.

Indoor air pollutants can be removed by place filters in a building's heating, ventilation, and air conditioning (HVAC) system or operate as portable units. There are many HVAC filters that have been developed and used in various buildings, namely, schools and office buildings. It was reported that adsorptive HVAC filters, designed in different shapes, may effectively remove several noxious pollutants, including PM, VOCs, and O₃ (Zhao et al. 2007). According to a review carried out by Kelly and Fussell (2019) there is substantial evidence HVAC filters reduce indoor PM_{2.5} concentrations by at least 50%. Similarly, another study showed that 72-h use of inexpensive, portable air cleaners placed in a low-income senior facility in Detroit, MI (USA) was associated with significant reductions in indoor PM_{2.5} levels (Morishita et al. 2018). Fisk and Chan (2017) suggest that the economic benefits of reduced mortality among elderly during the 2003 California wildfires outweighed costs for HVAC filtration. Despite these facts, this technology has demonstrated several limitations in terms of the adsorption efficiency (Kelly and Fussell 2019), which is remarkably reduced in the presence of humidity, proliferation of molds and germs, limiting their overall role in public health. Therefore, advanced technologies, such as photocatalysis, and other physical-chemical technologies for indoor air treatment, such as electronic filtration or membrane separation, are emerging (González-Martín et al. 2021).

Conclusions

Although few studies have been carried out so far, the current literature confirms that ECCs' indoor environments may play a special role in the elderly health, emphasizing the importance of ensuring good IAQ, as COVID-19 has further demonstrated the need for rapidly developing and deploying IAQ solutions in ECCs. The development of new portable, inexpensive sensors and systems to measure certain air pollutants can be a useful tool to tackle poor IAQ event.

More than ever, more epidemiological research on indoor pollution and elderly health is needed, with a focus on emerging indoor pollutants given that building techniques are constantly evolving and new questions are being raised due to new occupant lifestyle, uses, and products on daily basis. More research is also needed in relation to exposure assessment, various types of short-term and long-term health outcomes. At the same time, further identification of subgroups among the elderly who are susceptible to the adverse effects of air pollutants would also be an important help in the definition of effective preventive and mitigation strategies for

healthy aging. Although various international agencies have continuously developed quantitative IAQ guidelines, it is also of high importance that future studies are conducted on multi-route and combined exposures, including interactions between pollutants, reactions occurring between pollutants and all potential transformation, to close existing knowledge gaps. This requires interdisciplinary studies in which the interactions between IAQ in ECCs toward elderly's health are investigated. Lastly, it is a challenging task for public authorities to embed air quality standards in legislation. They must make social and economic choices to meet air quality standard levels, beyond assessment and information requirements. Nevertheless, there is no doubt that enforceable regulations that require better air quality with the responsibility of governments to monitor, control, and implement regulations are needed in order to mitigate the adverse effects on human health, namely, among the more sensitive to air pollution impacts such as the elderly.

Abstract

Healthcare is one of the largest and fastest growing industries worldwide. It is complex and comprises different occupations directly providing healthcare services, and occupations providing other supporting services. The industry is changing rapidly with advances in medical science and new technologies. It faces new challenges stemming from changing demographics, migration, environmental and geopolitical instability, increased demand and cost of health services, and new disease outbreaks, all contributing to new hazards or exacerbating existing ones. A healthy healthcare workforce is central to sustain healthcare systems and for a prosperous society and economy. However, healthcare workers are exposed to a mixture of hazards that can include chemical (anesthetic gases), biological (pathogens), physical (radiation), ergonomic (musculoskeletal), psychosocial (stress), and safety hazards (violence). Chemical hazards arise from sources, such as cleaning, disinfecting, and sterilizing agents, solvents, glues, metals, hazardous drugs, laboratory chemical reagents, waste

anesthetic gases, surgical smoke, and other indoor air contaminants. Working in healthcare is associated with a spectrum of adverse health outcomes including respiratory, reproductive, dermatologic, neurologic, other systemic outcomes, and cancer. These exposures and health hazards are preventable but continue to occur among healthcare workers in part because industry attention is focused on preventing healthcare-associated infections in patients caused by pathogens. Healthcare workers' exposures to chemicals is consequently not well recognized and disease prevention or exposure mitigation measures are not fully implemented. The focus of this review is to highlight inhalation and dermal exposures to chemicals among various occupations and units in healthcare and identify opportunities for exposure mitigation and disease prevention.

Introduction

Healthcare is one of the largest and fastest growing industries worldwide, especially in many developed countries. An estimated 59 million workers were employed in the healthcare and social sector worldwide in 2006, accounting for over 12% of the working population; over 70% were women (WHO 2006). In the USA in 2020, 20.7 million workers were employed in the healthcare industry, accounting for 14% of the US working population, of which 77.8% were women (BLS 2020). Within this industry, about 6.6 million employees (31.6%) worked in ambulatory care, 7.3 million (35.2%) in hospitals, 3.1 million (15.1%) in social assistance, and 3.7 million (18.0%) in skilled nursing, residential, or home care facilities. The healthcare industry is rapidly changing with advances in medical science, new technologies and products, and enhancement in worker and patient protection leading to improved working conditions and patient safety. At the same time, new challenges are creating new hazards, such as exposure to new chemicals and hazardous drugs, or exacerbating existing ones, such as increased workloads and stress. These challenges stem from aging population and workforce, population growth, gender dynamics, increased demand and cost of health services and products, push toward universal health coverage, globalization and migration, environmental and geopolitical instability, shortages of healthcare professionals and healthcare funding, privatization of hospitals and health services, health inequalities, and new disease outbreaks (ILO 2019). The demand for health services is expected to create 40 million new jobs worldwide by the year 2030. However, this growth is mostly expected to occur in developed countries with projected shortages of 18 million jobs in developing countries (ILO 2019). The healthcare industry is complex and comprises different occupations, some directly providing healthcare services while others indirectly supporting health or other services. Occupations in healthcare settings include physicians, nurses, midwives, therapists, social workers, a variety of technicians in

laboratories and research, pharmacists, and other personnel such as cleaners, administrative staff, dietary staff, laundry workers, medical equipment maintenance workers, and facilities and maintenance workers (NIOSH 2017a). Healthcare workers provide services that occur in a variety of work settings including hospitals, clinics, dental offices, out-patient surgery and care centers, birthing centers, emergency medical care, home healthcare, and nursing homes (OSHA 2021).

A healthy healthcare workforce is central to sustain healthcare systems and for society to prosper and the economy to thrive. It is most critical for the safety and well-being of patients, workers, and the population in general. Although the core mission of the healthcare industry is to care for and promote healing in patients, healthcare workers themselves are exposed to a myriad of health and safety hazards that cause numerous illnesses and injuries. The healthcare industry is among the most hazardous workplaces in the USA; healthcare workers experienced the highest number of nonfatal injuries and illnesses in 2017 (BLS 2018). Healthcare workers are potentially exposed to a mixture of hazards that can include chemical (e.g., anesthetic gases), biological (e.g., pathogens), physical (e.g., radiation), ergonomic (e.g., musculoskeletal), psychosocial (e.g., stress, shift work, and work organization), and safety hazards (e.g., violence). Chemical hazards include well recognized as well as some not-so-well known exposure to gases, vapors, and aerosols resulting in a spectrum of adverse health outcomes including respiratory, reproductive, dermatologic, neurologic, other systemic outcomes, and cancer (Weaver 1997). These exposures and health hazards are preventable, but they nevertheless continue to occur among healthcare workers (NIOSH 2017a). Although a great deal of attention has focused on minimizing biological hazards to prevent healthcare-associated infections (HAI) in patients caused by pathogens, healthcare workers' exposures to chemicals is often not well recognized or controlled. This lack of focus is in part due to hospitals being perceived as clean, hazard-free workplaces, and the selfless nature of the healthcare workforce whose first instinct is to place patient care needs above their own health and safety concerns. Consequently, hazard recognition is lacking, and disease prevention or exposure mitigation measures are not fully implemented. The focus of this review is to highlight the chemical products used by healthcare workers, their ingredients and potential for inhalation and dermal exposures among various hospital occupations in various units, and identify opportunities for exposure mitigation and disease prevention.

Exposure and Health Hazards in Hospital Settings

Hospital workers are exposed to a complex mixture of chemicals simultaneously and sequentially, mostly via inhalation and dermal routes of exposure. These exposures arise from multiple sources, such as sterilizing agents, cleaning and disinfecting products, detergents, solvents, glues, heavy metals, hazardous drugs, laboratory chemical reagents, waste anesthetic gases, surgical smoke, and other indoor air contaminants from products and building and construction materials (Gorman et al. 2013). Some exposures such as cleaning chemicals are pervasive throughout

the hospital potentially affecting patients and workers in all occupations; certain occupations such as housekeepers have among the highest exposures to these cleaning and disinfecting chemicals (Weaver 1997). Many other exposures are unique to specific departments or units affecting selected occupations such as high exposure to solvents (e.g., xylenes) among laboratory technicians (Weaver 1997). Thus, exposure to chemicals in hospital settings can vary considerably by department or unit and occupation, and most workers are exposed to a mixture of chemicals either directly or indirectly as bystanders.

Exposure to Chemicals Used for Cleaning, Disinfection, Sterilization, and Skin Antiseptics

Cleaning, disinfection, and sterilization has special significance in hospital settings, where intensive cleaning and disinfection is performed in an effort to prevent HAIs (Rutala et al. 2008). Hospitals use a rational approach to clean and disinfect surfaces and equipment devised by Spaulding, which places surfaces or items to be cleaned into three categories based on the risk of infection conferred if these surfaces are contaminated.

1. Critical surfaces are those that come into contact with sterile tissue and must be sterile because any contamination could result in infection. These surfaces include items such as surgical instruments that are cleaned using sterilizers such as ethylene oxide gas or high-level disinfectants such as ortho-phthalaldehyde (OPA).
2. Semi-critical surfaces are those that come into contact with mucous membranes or nonintact skin such as respiratory therapy devices and are cleaned using high-level disinfectants.
3. Noncritical surfaces are those that come into contact with intact skin such as blood pressure cuffs and are cleaned using intermediate-level disinfectants such as a strong bleach solution or low-level disinfectants such as quaternary ammonium compounds (QACs).

Table 1 summarizes the chemical ingredients of cleaning, disinfecting, and sterilizing chemicals and antiseptic products as well as their purpose or function, and hospital units and occupations where they are frequently used.

Cleaning and Disinfecting Environmental Surfaces

Environmental surfaces include building surfaces, equipment, and patient care items. Environmental surfaces that only come in contact with intact skin are classified as noncritical surfaces and are cleaned using intermediate-level disinfectants, which are effective against vegetative bacteria, some spores, fungi, and some viruses, or low-level disinfectants which are effective against vegetative bacteria, fungi, enveloped viruses, and some nonenveloped viruses (Rutala et al. 2008). Cleaning and disinfection of environmental surfaces is complex and involves physical action

Table 1 Summary of products and chemical exposure to cleaning, disinfecting, and sterilizing chemicals and antiseptics among healthcare occupations and hospital units

Unit/Occupation	Product or chemical class	Purpose or function	Chemical ingredients
All units and occupations, exposed directly or indirectly as a bystander	Cleaners and disinfectants to disinfect surfaces	Active disinfection ingredients	Alcohols (e.g., ethanol and isopropyl alcohol), sodium hypochlorite (bleach), QACs (e.g., see Table 2), phenolics (e.g., <i>o</i> -phenylphenol and benzoyl-p-chlorophenol), acetic acid, peracetic acid, hydrogen peroxide and their mixture
		Additives to add functional properties, e.g., surfactant or aesthetic or fragrance properties	Terpenes (e.g., pinene, <i>d</i> -limonene), and linalool
		Solvents and propellants	Toluene, alcohols, and glycol ethers (e.g., 2-butoxyethanol)
		Complexing agents to dissolve cations and regulate pH	Ethylenediaminetetraacetic acid (EDTA), nitrilotriacetic acid (NTA), and tripolyphosphates
		Preservatives	Formaldehyde, isothiazolines, and QACs
		Degreasers to remove fatty substances	Alkaline agents (e.g., ammonium hydroxide, sodium hydroxide, silicates, and carbonates)
		Scale removers	Various acids (e.g., acetic, phosphoric, citric, sulphamic, and hydrochloric acids)
Patient care occupations including all nursing occupations, e.g., LPN, RN, NA in different units, and occupations in OR/surgery	Antiseptics and skin disinfectants	Preoperative skin preparation and wound dressings	Ethanolamines
			Alcohols (e.g., ethanol and isopropyl alcohol), chlorhexidine, hexachlorophene, iodophores (povidone-iodine), octenidine, polyhexanide, hexamidine diisethionate, QACs, chlorhexidine gluconate, triclosan, chloroxylenol, and silver-based wound dressing

(continued)

Table 1 (continued)

Unit/Occupation	Product or chemical class	Purpose or function	Chemical ingredients
All occupations	Hand sanitizers	Hand sanitizers	Alcohols (e.g., ethanol and isopropyl alcohol), triclosan
Central supply, surgical suites, endoscopy, procedure rooms, dental clinics, radiology, and pathology	Sterilizers and high-level disinfectants	Sterilizing and disinfecting medical instruments	Ethylene oxide, orthophthalaldehyde, glutaraldehyde, hydrogen peroxide, peracetic acid, formaldehyde, chloramine-T, and chlorhexidine
	Detergents and cleaners	Clean and remove soils	Subtilisin (enzymatic cleaner), fatty acid salts, organic sulphonates, and VOCs (e.g., acetone, formaldehyde, and halogenated alkanes)
Housekeeping	Surface strippers	Floor preparation for waxing and polishing, paint remover	Ethanolamines (e.g., monoethanolamine and triethanolamine), ammonia, phthalates, potassium hydroxide, sodium hydroxide, methylene chloride, 2-butoxyethanol, d-limonene, xylene, and <i>n</i> -methylpyrrolidone
	Surface disinfectants, e.g., furniture and floors	Disinfecting floor and other surfaces	QACs, chloramine T, phenol, chlorine bleach, etc. (see above)
	Polishes and waxes	Polish or wax different surfaces, e.g., wood, metal, etc.	Film formers, polishes (wax, acryl polymers, and polyethylene), and acrylics
	Glass cleaners	Clean windows and mirrors	Ethanolamines and ammonia
	Ceramics cleaners	Clean bathroom surfaces	Acids (e.g., hydrochloric, sulfuric, and acetic acid)

to remove organic material and gross contaminants, followed by disinfection using sprays, wipes soaked in disinfectants, textile, or microfiber cloth, or premoistened wipes (Leas et al. 2015). Cleaning and disinfection can also be done in one step using products that contain ingredients to remove soils and disinfect. Noncritical surfaces that are touched on average > 3 times per interaction are classified as high-touch surfaces and are targeted for cleaning and disinfection (Huslage et al. 2010). Common high-touch surfaces include bed rails, bed surfaces, overbed table supply or medicine carts, intravenous pumps, doorknobs, light switches, and edges of

privacy curtains; the classification of a high-touch surface can vary by unit/location (Suleyman et al. 2018). Low-touch surfaces include walls, ceilings, mirrors, windows, and flooring in patient areas. Patient care items and equipment include oximeters, glucometers, mobility aids, electrocardiogram (EKG/ECG) monitors, respiration machines and spirometers, blood pressure cuffs, stethoscopes and scopes, thermometers, infusion pumps, dialysis machines, ultrasound transducers, and venipuncture tourniquets (Suleyman et al. 2018). A mixture of pathogens may be present on different environmental surfaces, as some pathogens, such as *Pseudomonas* sp., persist in damp places like bathroom surfaces, while others, such as *C. difficile* and vancomycin-resistant enterococci (VRE), are frequently found around toilet surfaces. Methicillin-resistant *Staphylococcus aureus* (MRSA) and *Acinetobacter* sp. are often present in dusty, inaccessible places (Dancer 2011). Thus, a product with a broad spectrum of antimicrobial activity may be needed to disinfect different surfaces. Interventions aimed at reducing surface contamination through enhanced cleaning procedures, change of disinfection products, education of healthcare workers, and evaluation of compliance with cleaning procedures can reduce microbial contamination and lower prevalence of HAI (Rutala et al. 2018). Thus, cleaning and disinfecting environmental surfaces is effective in reducing the levels of pathogens on surfaces and is a critical and integral component of an infection control program.

Cleaning and disinfection of environmental surfaces is performed multiple times daily to reduce the buildup of microbial burden on surfaces, and a more thorough cleaning and disinfection, terminal cleaning is performed when a patient is discharged to ensure the safety of the next patient. Housekeepers are primarily engaged in cleaning and disinfecting noncritical building surfaces and fixed equipment throughout the hospital. Housekeepers have some of the longest durations of cleaning and disinfecting tasks as well as some of the highest exposures to cleaning and disinfecting chemicals and solvents in surface maintenance products (Weaver 1997; Saito et al. 2015; LeBouf et al. 2014). However, almost all healthcare occupations perform some cleaning and disinfecting tasks at least once per shift with endoscopy technicians, dental assistants, nursing staff, and central supply workers spending the highest amounts of time on cleaning tasks after housekeepers (Saito et al. 2015). These occupations mostly clean and disinfect medical instruments and equipment, patient care items, and surfaces touched by patients. Performance of cleaning and disinfection tasks is variable by units with the greatest amount of cleaning done in central supply (sterilization), followed by wards, operating rooms, and emergency rooms.

Cleaning and Disinfecting Products for Environmental Surfaces

There are a multitude of disinfectants that can be used to clean and disinfect environmental surfaces and patient care items with different composition, biocidal capabilities, and application requirements summarized in Table 1. Most products are one-step cleaners and contain multiple functional ingredients: soft water; detergents and soaps as emulsifying agents; alkali to remove protein, fats, and carbohydrates; surfactants to help penetrate soils; water conditioners to prevent formation of scales;

solvents to cut grease; enzymes to remove biofilms; and the active disinfectant ingredient (Stewart and Smith 2017). Numerous factors influence the choice of a disinfectant including the types of microorganisms targeted, surface characteristics, and product toxicity. Antimicrobial characteristics, toxicity, and effectiveness of some common disinfectants are summarized below. Chlorine-releasing products such as bleach or hypochlorite are widely used and are effective against bacteria, fungi, viruses, and some spores. However, they are corrosive to some surfaces, are affected by organic matter, and cause skin and respiratory irritation. Peracetic acid, another commonly used disinfectant, is effective against a wide range of microbes including spores but can corrode metals. Accelerated hydrogen peroxide is effective against bacteria, fungi, viruses, and spores, does not affect surfaces, and is not affected by organic matter. QACs are effective against a wide range of gram-positive bacteria with persistent biocidal effect, but ineffective against spores and non-enveloped viruses, are affected by water hardness, and some QACs are associated with allergic asthma and skin sensitization. Alcohols are broad-spectrum disinfectants but cannot be used as a cleaner and are ineffective against spores. Phenolics are the oldest disinfectants but also have strong adverse health effects, their efficacy is impacted by organic material, and they are ineffective against spores. Finally, aldehydes have a wide range of antimicrobial activity but can cause sensitization (Stewart and Smith 2017; Leas et al. 2015; Rutala et al. 2008). A panel of experts emphasized the importance of proper implementation of cleaning and disinfecting strategy at the local level over the choice of disinfectant used (Leas et al. 2015). Key factors affecting proper implementation include inappropriate preparation (e.g., dilution), or application (e.g., contact time of disinfectants or failure to decontaminate reusable items), interruption of cleaning by patient and other healthcare staff, room turnaround time, inadequate training of housekeepers, lack of cleaning checklists or procedures, hospital safety culture, and low priority given to hiring cleaning staff and purchasing cleaning supplies (Leas et al. 2015).

Ingredients of Cleaning and Disinfecting Products for Environmental Surfaces

Several studies have identified ingredients of cleaning and disinfecting products through headspace analysis of cleaning products or review of safety data sheets (SDSs). Bleach products were found to emit a variety of aliphatic and aromatic halogenated hydrocarbons in the headspace, e.g., chloroform, carbon tetrachloride, and chlorobenzene, of which 13 were quantified (Odabasi 2008). When these products were diluted and applied to various types of surface cleaning tasks such as bathroom, kitchen, or floor, 16 emitted volatile organic compounds (VOCs) were quantified. More varied VOCs may be emitted when bleach products react with organic material in soiled surfaces that are being cleaned. Consumer cleaning products and air fresheners were found to emit a range of terpene hydrocarbons (e.g., α -limonene), terpene alcohols (e.g., 1-terpineol), glycol ethers (e.g., 2-butoxyethanol), and a variety of other VOCs (e.g., eucalyptol, benzyl acetate, and linalool); 2-butoxyethanol was present in most products (Singer et al. 2006). Emissions from the use of these products for various applications to clean and disinfect hard surfaces generated peak concentrations of these VOCs that could

reach mg/m³ level concentrations. Headspace analysis of 37 commonly used consumer spray products identified 156 unique VOCs many of which are classified as hazardous air pollutants (Steinemann 2015). The most common ingredients were terpenes used as fragrances; a vast majority (97%) of the ingredients were not disclosed in the SDS. The study found little difference in hazardous air pollutants emitted from the various labeling of these products such as “green” or “fragrance-free” products, except for the fragrance-free products which did not contain terpenes. Whereas these studies are of consumer products and not professional hospital cleaners, many of the products used in hospitals are formulated similarly and will likely result in similar emission profiles. A survey of 27 hospitals was conducted in Germany to quantify the consumption of 11 classes of biocides for disinfection and human hygiene including alcohols (e.g., benzyl alcohol), aldehyde-releasing agents (e.g., ethylenedioxy dimethanol), aldehydes (e.g., glutaraldehyde), alkyamines (e.g., aminoalkylglycine), glycol derivatives (e.g., propylene glycol), guanidines and pyridines (e.g., chlorhexidine), iodine-releasing compounds (e.g., povidone-iodine), peroxy-compounds (e.g., hydrogen peroxide), phenols (e.g., chlorocresol), QACs (e.g., benzalkonium chloride), and other compounds (e.g., acetic acid) (Tluczkiewicz et al. 2010). Emission estimates were compiled on mass-per-bed-per-day and mass-per-nurse-per-day for hand and skin disinfection, surface disinfection, and instrument disinfection for the 11 chemical classes which can be used to estimate hospital exposures.

A review of the SDSs of 105 common professional cleaning products identified over 132 different chemical ingredients with an average of 3.5 chemicals per product. The most common chemicals found in products were fragrances, glycol ethers, surfactants, solvents, and, to a lesser extent, phosphates, salts, detergents, pH stabilizers, acids, and bases. Over 75% of the ingredients were classified as irritants (Gerster et al. 2014). These products were classified into ten categories of cleaning application: floor, general purpose, carpet, scale removing, bathroom, glass, kitchen, surface, disinfection, and polishing products. Glycol ethers were present in most products for most cleaning applications; ethanolamines, which are surfactants known for their sensitizing properties, were present in kitchen, floor, and general-purpose cleaning products. Another study reviewed 185 SDSs of products used by hospital workers and grouped the product ingredients into 27 chemical classes based on their common physical (e.g., phases) and chemical properties (e.g., functional groups): acid, acrylate, alcohol, aldehyde, alkane, amide, amine, ammonia, aromatic, base, carboxylic acid, enzyme, ester, ether, fragrance, glycol ether, halogenated compound, metal, metal salt, metalloid, oxidizer, phenolic, QACs, salt, surfactant, terpene, and others (Saito et al. 2015). The chemical composition of products used varied by occupations, with housekeepers using products with the most complex and widest number of ingredients, followed by instrument disinfection occupations, laboratory occupations, and patient care occupations. Many of these frequently present ingredients are classified as asthmagens by the Association of Occupational and Environmental Clinics (AOEC), which also includes many sensitizers (Quirce and Barranco 2010; AOEC 2012). A study of chemicals in 101 commonly used spray products found most products contained organic solvents (ethanol, isopropyl alcohol [IPA]), fragrances, disinfectants, nonionic surfactants, acids, bases, and salts

(Clausen et al. 2020). Ingredients of concern included ammonia, hypochlorite, QACs, glycols, and glycol ethers.

A review of 299 SDSs of cleaning products used in age care facilities identified 212 chemical ingredients, of which 41 were classified as carcinogenic, mutagenic, toxic to reproductive or other organs, endocrine disrupters, skin sensitizers, and respiratory sensitizers (Bonnet et al. 2018). The ingredients ranged from volatile to semi-volatile and nonvolatile organic compounds used as solvents, disinfectants, detergent, surfactants, scenting agents, and chelating agents. The semi-volatile and nonvolatile ingredients may pose dermal as well as respiratory hazards when these components are aerosolized through the use of spray products, or by adsorbing onto particles on surfaces that are disturbed and particles are re-entrained into the air stream (LeBouf et al. 2017). Although the list of chemical ingredients generated from review of the SDSs is helpful, SDSs do not constitute a complete list of product ingredients because many chemical components are indicated as proprietary and not listed (e.g., fragrances and surfactants) while many others whose concentrations are below the target value for reporting on SDSs are excluded (Steinemann 2015).

Exposure to Cleaning and Disinfecting Chemicals

Exposure to chemicals in cleaning products in hospitals has not been well studied because of the chemical complexity of cleaning products and the difficulty in conducting personal exposure monitoring for multiple chemicals in this work environment. As such, current knowledge of the types of tasks performed, products used, and exposures among occupations is incomplete. The few quantitative exposure assessment studies done in hospitals that report exposure measurements related to cleaning and disinfecting chemicals are summarized in Table 2. The measured chemicals are summarized by ranges of means, geometric means, or measurements for specific chemicals and various occupations, locations, tasks, or activities in each study. These limited data show complex chemical exposure profiles, which are highly variable within and between occupation/unit. These primary ingredients may also react with one another, such as bleach and acid to release chlorine gas or QACs with ozone in the air to generate secondary oxidation reaction products such as carbonyls, carboxylic acids, nitrates, and possibly amines that may not be monitored and can pose additional health hazards.

Modeling factors affecting exposure to cleaning and disinfecting chemicals are essential to explain sources of exposure variability but are also rare in studies conducted in healthcare settings. One study identified product type, task, room volume and ventilation, and product concentration as significant predictors of 2-butoxyethanol exposures in a quasi-experimental study (Bello et al. 2013). A recent study of several healthcare occupations evaluated the determinants of exposure to TVOCs, ethanol, 2-propanol, acetone, α -limonene, α -pinene, and chloroform, focusing on tasks, product application, amount of product, background activities, product ingredients, and local exhaust ventilation (LEV) as predictors (Su et al. 2018). A study of factors affecting real-time TVOC exposure in hospitals identified use of sprays to be associated with increasing exposures, while presence of LEV, large room volume, and automatic sterilizer use were all associated with

decreasing exposures (Virji et al. 2019). These studies of exposure determinants identify factors associated with increasing exposures to target exposure control strategies and factors associated with decreasing exposures to encourage implementation of control measures.

Exposure to cleaning and disinfecting products occurs during routine product use, as well as during preparation such as mixing or diluting products, inappropriate mixing or dilution, spills, cleanup of spills and contaminants, and as a bystander to cleaning and disinfecting activities. Approaches to reduce exposures include avoiding use of spray products, ordering ready-to-use cleaners, using automated

mixing stations, removing soils with water and detergents and only using disinfectants where needed, adequately ventilating various spaces where or when disinfectants are used, spacing out cleaning and disinfection across multiple shifts where appropriate, and, lastly, appropriate use of personal protective equipment (PPE) (Gorman et al. 2013). Whereas there is a trend toward the use of “green cleaning products,” these products do not necessarily contain less hazardous ingredients, and the criteria for their claims vary widely by manufacturers (Saito et al. 2015). The eco-friendly labels are often based on minimizing environmental impact and not necessarily the prevention of respiratory disease, and not well regulated in the USA or the European Union.

Skin Exposure to Disinfectants and Antiseptics

Healthcare workers may be exposed to cleaning chemicals through direct application of hand sanitizers and disinfectants to their skin, unprotected application of skin antiseptics on patients, or application of surface cleaning products. Transmission of pathogens is related to contaminated hands of healthcare providers as well as contaminated surfaces, equipment, and patient care items. Hand hygiene is an integral component of infection control and compliance with hand hygiene recommendations being essential for HAI prevention. Thus, hospitals are constantly promoting hand hygiene programs to achieve higher compliance with hand hygiene guidelines (Boyce and Pittet 2002). A variety of skin antiseptics are used in hospitals (Table 1). Use of alcohol-based hand sanitizers is common practice among most hospital occupation but may result in deterioration of the skin barrier (dryness, cracking, etc.). Chlorhexidine (chlorhexidine gluconate) solution is another extensively used antiseptic for preoperative skin preparation, hand hygiene, medical instrument disinfection, and mouth rinse (Barnes et al. 2019). Other antiseptics used in hospitals include hexachlorophene (used in handwash and surgical scrub), iodophores (e.g., povidone-iodine, with widespread use throughout the world), octenidine (used on chronic wounds and burns to prevent bacterial infections), polyhexanide (used for pressure wounds), hexamidine diisethionate (used widely in some countries), QACs (used for burns, ointments, and mouth and hand washes), chloroxylenol (used in personal care products), triclosan (used mostly in personal care products), and silver-based wound dressing (Barnes et al. 2019). Workers may also be exposed to cleaning and disinfecting chemicals when cleaning surfaces without appropriate skin protection. One study reported that most workers engaged in cleaning and disinfecting occupations wore gloves during their cleaning tasks, while a lower proportion of workers in noncleaning and disinfecting occupations wore gloves during their cleaning tasks. Glove use itself may lead to occlusion of skin and possibly dermatitis if moisture builds up in the glove or allergic reactions to glove materials such as latex and other natural proteins occur (Jungbauer et al. 2005). Quantitative exposure measurements for use of these antiseptic products are not available.

Exposure to High-Level Disinfectants and Sterilizing Chemicals

High-level disinfectants and sterilizers such as glutaraldehyde, OPA, hydrogen peroxide and peracetic acid mixture, ethylene oxide, and hydrogen peroxide

plasma gas are used throughout hospitals to disinfect and sterilize critical and semi-critical medical and dental devices and instruments. Whereas sterilization is performed in central supply and is time consuming, instrument disinfection is performed throughout the hospital wherever there is a need for quick turnaround of disinfected instruments (Gorman et al. 2013). Several occupations in healthcare can be exposed to high-level disinfectants including central supply workers, surgical technologists and assistants, X-ray technicians, pathology/histology laboratory technicians, dental assistants in clinics, nurses and technologists in endoscopy and other surgical/procedural units, and staff in dialysis and intensive care units (González Jara et al. 2013). Several studies have quantified glutaraldehyde exposure in a variety of units such as radiology, endoscopy, and central supply during various jobs, procedures, and tasks, summarized in Table 2. These exposures vary within the activity monitored as well as across the activities with measurements ranging from very low levels to above exposure limit. OPA was introduced as a safer alternative to glutaraldehyde, however exposure measurements are lacking but cases of asthma and dermatitis have been reported in endoscopy nurses (Henn et al. 2015; Mazurek and Weissman 2016). A mixture of peracetic acid and hydrogen peroxide is widely used as a high-level disinfectant for reprocessing endoscopes and other medical instruments but resulting exposure and health data are lacking. A less concentrated version of this product, also containing acetic acid, is used as an intermediate-level disinfectant for cleaning noncritical surfaces and instruments and is associated with higher prevalence of asthma as well as upper and lower respiratory symptoms (Hawley et al. 2017). Exposures to this product are summarized in Table 2, which shows variable exposures by unit and activity.

Guidelines exist on the use of LEV and enclosures, as well as other safe use and handling of high-level disinfectants especially glutaraldehyde in multiple settings including endoscopy suites (NIOSH 2017a). In a 2011 NIOSH national survey of nurses, technologists, dental professionals, and respiratory therapists who completed a module on high-level disinfection, responders reported using glutaraldehyde most frequently followed by peracetic acid, OPA, hydrogen peroxide, and mixtures of peracetic acid and hydrogen peroxide (Henn et al. 2015). A large proportion of the respondents reported not receiving training or not having standard procedures for safe handling of high-level disinfectants or had received training over a year prior to the survey. Less than 50% of responders reported using automated systems and less than 25% reported having a LEV system while manually disinfecting instruments. Other activities that increase exposure include manually pouring disinfectant into automated systems, using manual immersion trays for disinfection, and manually draining disinfectant from automated processing systems. While PPE such as gloves were frequently worn, other gear such as protective gowns or eye protection were not. Workers also reported spills occurring in the last 7 days that were not always cleaned up. In this large national survey of healthcare professionals engaged in high-level instrument disinfection, safety practices and procedures were lacking despite existing guidelines on safe handling of these chemicals.

Ethylene oxide is widely used for sterilizing medical instrument in hospitals, with exposure mostly occurring in central supply workers and to a lesser extent in end users who may come in contact with improperly aerated or packaged equipment (Weaver 1997). In ethylene oxide gas sterilization, items are packaged before sterilization and the gas diffuses through the packaging material during sterilization (Hori et al. 2002). After sterilization, residual gas in the sterilization unit is removed and the packaged items are aerated in a ventilated area to let the gas diffuse out of the packaging. Lack of appropriate equipment or procedures to allow for adequate aeration time can result in high exposure to ethylene oxide (Hori et al. 2002). Several studies have quantified exposure to ethylene oxide in various hospital locations near the sterilizing unit or during certain tasks summarized in Table 2. The exposures are highly variable within and between locations/activities and range from very low levels to levels above the exposure limit. An important determinant of exposure is allowing adequate time to air out the unit after sterilization and before opening the unit door (Hori et al. 2002).

Health Effects Associated with Cleaning, Disinfecting, and Sterilizing Chemicals

Healthcare workers are at an increased risk of asthma, rhinitis, respiratory symptoms, and dermatitis, related to cleaning and disinfecting products. Work-related asthma (WRA) is common among healthcare workers and places a substantial health and economic burden on society but is preventable. WRA includes occupational asthma (OA) that is caused by work, and work-exacerbated asthma (WEA) that is a worsening of existing asthma due to workplace conditions. Based on the 2004–2011 National Health Interview Survey, the prevalence of current and lifetime asthma in healthcare occupations were 9.5% and 13.7%, respectively, for nursing and residential care facilities, 9.3% and 14.7% for social assistance, 8.1% and 12.1% for hospitals, and 7.7% and 12.7% for ambulatory care (NIOSH 2017b). Among all current occupational categories, the category of nursing, psychiatric, and home health aides had among the highest prevalence of lifetime asthma at 14.6% (NIOSH 2017b). Data from the 2013 adult Behavioral Risk Factor Surveillance System (BRFSS) report the highest prevalence of current asthma for the healthcare and social assistance industry (10.6%) and healthcare support occupation (12.4%) among all industries and occupations in 21 reporting states (Dodd and Mazurek 2016). The 2006–2007 Asthma Call-Back Survey, part of BRFSS, further reports that 47.5% of ever-employed adults with asthma potentially have WRA, which is a preventable disease (Knoeller et al. 2011). Among the putative agents, cleaning products were the third most commonly reported agent (15.3%) associated with WRA in the four states reporting asthma cases to the NIOSH Sentinel Event Notification System for Occupational Risks (SENSOR), behind miscellaneous chemicals and materials (22.4%) and mineral and inorganic dusts (16.3%) (NIOSH 2017b).

Epidemiologic studies continue to report increased risk of asthma, rhinitis, respiratory symptoms, and dermatitis in healthcare occupations that perform cleaning or disinfecting tasks (Folletti et al. 2014; NIOSH 2017b; Arif and Delclos

2012; Garrido et al. 2021; Su et al. 2019). Studies have reported associations of asthma symptoms with most major classes of cleaning and disinfecting products including chlorine-based compounds (Arif and Delclos 2012), ammonia (Arif and Delclos 2012), QACs (Gonzalez et al. 2014), peroxygen compounds (Hawley et al. 2017), enzymatic cleaners (Adisesh et al. 2011), detergents (Arif and Delclos 2012), high-level disinfectants and sterilizers (Arif and Delclos 2012), chemicals used for floor stripping and waxing (Wieslander and Norbäck 2010), groups/classes of chemicals such as VOCs, construction dust, and poor indoor air quality (Arif and Delclos 2012; Wieslander and Norbäck 2010), and their functional or aesthetic additives (DeLeo et al. 2018) such as surfactants, preservatives, and fragrances, e.g., ethanolamines and terpenes. Relevant tasks include cleaning instruments or surfaces, patient care, using spray products, washing instruments manually, using aerosol products, cleaning operating rooms, cleaning sanitary rooms, preparing disinfectants, filling devices with cleaning products, waxing floors, spot-cleaning floors, stripping wax floors, and cleaning tiles (Garrido et al. 2021). While the mechanism of asthma related to cleaning and disinfecting is not clear, it is thought to include both irritant- and sensitizer-induced asthma (Tarlo et al. 2017). Many cleaning products are complex mixtures of chemicals that contain both irritants (e.g., chlorinated compounds) and sensitizers (e.g., QACs) (Quirce and Barranco 2010; AOEC 2012; Nazaroff and Weschler 2004).

The outbreaks of communicable diseases beginning in 2020 have resulted in the widespread use of cleaning and disinfecting products to disinfect homes, public spaces, and workplaces. Whereas the effects of increased use of cleaning and disinfecting products on hospital workers has not been evaluated, a study of the general population demonstrated increased use of such products at home is associated with an increase in the risk of uncontrolled asthma (Eldeirawi et al. 2021). The effect on hospital workers is likely to be similar.

Cleaning and disinfecting activities in hospitals are critical for preventing HAIs and transmissions of other respiratory diseases; thus, the need for and efficacy of preventive measures for asthma need to be clearly demonstrated. Although the risk factors for respiratory symptoms associated with cleaning in healthcare and other settings have been identified (Folletti et al. 2014), quantitative exposure metrics and their direct impact on asthma and respiratory symptoms through exposure-response relationships remain unclear. Knowledge of exposure-response relationships is critical for the design of effective preventive measures. To date, only one epidemiologic study has demonstrated longitudinal declines in lung function associated with the use of cleaning products, but quantitative exposure-response relationships with specific products or chemicals were not assessed (Svanes et al. 2018). Additionally, most of the epidemiologic studies of the health effects of exposure to cleaning and disinfection products have investigated a single product or ingredient at a time, however, workers are exposed to a complex mixture of chemicals which may have synergistic effects. The health effects observed are likely due to certain mixtures of these components and not to all or any single component. A study of hospital workers performed hierarchical cluster analysis of exposures and health and observed various combinations of product applications, like using alcohols, bleach,

high-level disinfectants, and enzymes to clean and disinfect instruments, and clean surfaces were identified as risk factors for different asthma symptom clusters, indicating that prevention efforts may require targeting multiple products or ingredients simultaneously (Su et al. 2019).

Glutaraldehyde has been classified as a skin and respiratory sensitizer and associated with dermatitis and asthma (Mazurek and Weissman 2016; Weaver 1997). OPA and the mixture of peracetic acid and hydrogen peroxide were introduced as alternatives to glutaraldehyde, but are also associated with irritant dermatitis and upper and lower airway symptoms (Rideout et al. 2005). Ethylene oxide is associated with central and peripheral nervous systems effects such as headache, vertigo, sleeplessness, dullness, and numbness (Yahata et al. 2001), a variety of respiratory effects such as irritation, upper and lower airway symptoms (Weaver 1997), and irritant dermatitis as well as reproductive effects (NIOSH 2017a). Ethylene oxide is also classified as a group 1 known human carcinogen by the International Agency for Research on Cancer (Weaver 1997).

Healthcare workers are reported to have the highest prevalence of dermatitis compared to workers in other industries, and healthcare providers had the third highest prevalence of dermatitis compared to other occupations (Luckhaupt et al. 2013); nurses in particular often report work-related rash and dermatitis that could be from direct irritant effects or via sensitization and have a high prevalence of work-related dermatitis (Luckhaupt et al. 2013). Use of antiseptics, such as iodoform, iodine tincture, and chlorhexidine, on skin is known to cause irritant and allergic reactions. In a study of nurses and midwives at one hospital, use of hand hygiene products containing chlorhexidine, a commonly used disinfectant in hand hygiene products, was associated with asthma, contact dermatitis, allergy to chlorhexidine, and self-reported dry skin, eczema, and dermatitis (Barnes et al. 2019). Increased risk of uncontrolled asthma has also been reported among nurses who use antiseptics on hands and arms suggesting a link between skin exposure and respiratory health (Dumas et al. 2018). Use of cleaning products, especially bleach products, among healthcare workers conducting disinfection tasks is associated with an increased risk of skin symptoms (Garrido et al. 2021). Aldehyde-based disinfectants such as glutaraldehyde and formaldehyde as well as QACs are associated with dermatitis and sensitization (Mazurek and Weissman 2016). Hand dermatitis is also a concern among healthcare workers due to “wet work” because they frequently perform wet cleaning tasks (i.e., activities involving wet hands or glove use), which is shown to vary by occupation and unit (Jungbauer et al. 2005).

Exposure to Other Hospital Products and Chemicals

In addition to cleaning and disinfection products, hospital workers are also directly or indirectly (as bystanders) exposed to a variety of other chemical substances used or found in different areas of a hospital such as formaldehyde in laboratory technicians, methyl methacrylates (MMA) and isocyanates in dental and orthopedics, aerosolized medications and other pharmaceuticals in respiratory therapy and

pharmacy, high-level disinfectants and biological enzymes in endoscopy and central supply, animal allergens in animal laboratory workers, allergenic proteins from latex gloves, as well as emissions from building materials and products, and mold contamination of building surfaces which are reviewed and summarized in subsequent sections (Mazurek and Weissman 2016).

Exposures to Chemical Hazards in Operating Rooms (OR)/Surgical Units and Orthopedics

In 2015 an estimated 36 million surgeries were performed in the USA and 266 million worldwide under general anesthesia (Varughese and Ahmed 2021). The main chemical hazards of concern during surgery in OR include waste anesthetic gases, surgical smoke, and cleaning and disinfecting chemicals (Table 3). A study of VOCs measured in the air in OR during surgeries, and in breath samples of workers before and after surgeries, reported elevated levels of certain VOCs in air and in breath samples after surgery (Cheng et al. 2019). Specifically, the study reported elevated

Table 3 Exposures in surgical rooms/OR, endoscopy, and procedure rooms

Product/Class and occupation/unit	Exposures
Anesthetic gases – during various procedures among surgeons, anesthesiologists, technicians, nurses, dental surgery in OR, and postsurgical recovery units	Nitrous oxide, nitric oxide, desflurane, enflurane, halothane, isoflurane, methoxyflurane, sevoflurane, and trichlorethylene
Surgical smoke – during cutting, laser, and electrosurgery	Particulates and bioaerosols, acetone, acetonitrile, acetylene, acrolein, acrylonitrile, alkyl benzene, alpha-methyl styrene, benzaldehyde, benzene, benzonitrile, butadiene, butanone, butene, 3-butenenitrile, carbon monoxide, chlorodifluoromethane, chloromethane, creosol, 1-decene, 1,3-dichlorobenzene, dichlorodifluoromethane, 2,3-dihydro indene, <i>n</i> -dodecane, ethane, ethene, ethylbenzene, ethylene, <i>m</i> -ethyltoluene, ethynyl benzene, formaldehyde, furfural, hexadecenoic acid, hydrogen cyanide, indole, isobutene, isopropylbenzne, methane, methanol, 3-methyl butenal, 6-methyl indole, 4-methyl phenol, 2-methyl propanol, methylene chloride, phenol, propane, propene, 2-propylene nitrile, pyridine, pyrrole, styrene, toluene, trichlorodifluoromethane, 1,2,4-trimethylbenzene, <i>n</i> -undecane, 1-undecene, (<i>m,p</i>)-xylene, and <i>o</i> -xylene
Casts	Isocyanates (methylene diphenyl diisocyanate) and acrylics
Acrylates – bone cement, orthopedic prosthesis implantation, tissue repair, and reconstructive surgery	Methyl methacrylate, polymethylmethacrylate, and cyanoacrylate

levels of sevoflurane, anesthetic gas that was measured across surgeries; methyl methacrylate, a component of bone cement after orthopedic surgery; and hexamethyldisiloxane, a marker of electrosurgery. In another study, upper respiratory symptoms and skin reactions among OR staff were associated with elevated levels of VOC exposure (Rautiainen et al. 2019).

In 2015, over 25 million US healthcare workers were potentially exposed to anesthetic gases that leaked out during procedures (Varughese and Ahmed 2021). Surgical personnel, including surgeons, anesthesiologists, nurses, technicians, dentists, and dental technicians, are potentially exposed to a variety of chemicals and gases during surgical procedures in multiple hospital units where surgeries and procedures are performed, such as operating and recovery rooms, labor and delivery rooms, dental surgery rooms, endoscopy suites, and during dermatological and many other procedures (NIOSH 2017a). Additionally, recovery room or post-anesthesia care unit (PACU) staff can be exposed to high levels of anesthetic gases (Norton et al. 2020), while technicians and cleaning staff can be exposed to these chemicals after the procedure during breakdown and cleanup tasks. Several anesthetic gases may be used, including nitrous oxide, diethyl ether, and halogenated or fluorinated anesthetic gases such as enflurane, desflurane, halothane, isoflurane, and sevoflurane (Boiano and Steege 2016). The halogenated anesthetic gases are used alone or in combination with nitrous oxide. Several studies show that exposure to anesthetic gases is associated with reproductive effects especially among female workers in operating rooms, neurobehavioral changes, hematologic, hepatic, immune, and renal effects, as well as various cancers and acute effects, such as headache, dizziness, lethargy, fatigue, memory problems, and upper airway irritation (Boiano and Steege 2016; Van Den Berg-Dijkmeijer et al. 2011).

Leakage of anesthetic gases from equipment, inappropriate equipment and practices, nonautomatic ventilation and scavenging system, and escape of gases from the patients' mouths in OR or recovery room are the main sources of emission into the room, with the latter contributing most to the anesthetist's and surgeon's breathing zone exposure (NIOSH 2017a). Emissions into the room can be minimized by ensuring joints are well connected and sealed, and an appropriately designed face mask, laryngeal mask airway, or tracheal tube is used to connect the patient to the anesthesia machine to minimize escape of gases (Boiano and Steege 2016); any remaining fugitive emissions can be controlled by ventilation and scavenging systems. Government agencies and professional organizations have developed guidelines to minimize worker exposures to anesthetic gases including training, having SDS, labeling, information on safety plans and exposure hazards, appropriate ventilation and scavenging systems, medical monitoring, and record keeping (NIOSH 2017a). Regular monitoring of waste gases enables early detection of leaks and ensures timely equipment maintenance. Exposure measurements for various anesthetic gases in the OR as well as PACU have shown variable concentration ranging from below detection to much higher exposures (Norton et al. 2020).

Surgical smoke generated by lasers, ultrasonic scalpels, power tools, and electro-surgical devices during electrosurgical procedures contains numerous organic chemicals such as benzene, hydrogen cyanide, polycyclic aromatic hydrocarbons

(PAHs), and formaldehyde and particulate matter in the respirable size range (Table 3) (Lester et al. 2012; Gorman et al. 2013). Electrosurgical tools are used for cutting, cauterizing, and burning tissue in a variety of procedures such as wart ablation, LASIK, and laparoscopic cholesteectomy performed in hospital ORs or other clinical settings (Gorman et al. 2013). The chemical composition of VOCs in the surgical smoke plume is complex and various studies have identified different mixtures of VOCs and PAHs present at highly variable concentrations (Limchantra et al. 2019; Benson et al. 2019). There are numerous factors that could affect the generation and levels of chemicals in the smoke plume such as surgery and tissue type, tools used, and controls present, which have not been evaluated making meaningful synthesis of exposure data quite difficult (Benson et al. 2019). Exposure to surgical smoke is associated with ocular and upper respiratory airway irritation, and some components have mutagenic potential (NIOSH 2017a). Surgical smoke can be effectively controlled by: (1) LEV, such as a portable smoke evacuator, which consists of a nozzle, hose, filter, or scrubber to remove contaminants, and a vacuum pump, and (2) general room ventilation, although this system is not sufficient to capture particles (Lee et al. 2018; NIOSH 2017a). Suctioning smoke at the source is the most efficient way to eliminate the hazard (Lester et al. 2012). A laboratory study demonstrated significant reduction in aerosol concentrations generated from electrosurgical devices through the combined use of filtration, suction, and irrigation (Schramm et al. 2021). In addition, recent advances in air cleaning technology can easily be integrated into existing controls equipment to reduce air contaminants in the OR; evaluation of such technologies suggest that the technology is effective in reducing exposures.

Methacrylates are present in surgical cements and adhesives used in orthopedics (Table 3). Surgeons mix the cement before applying and the use of mixing trays with vacuum, local suction during applying or surgical helmets can result in significant reduction in exposure (Gorman et al. 2013). Exposure to MMA is associated with asthma, dermatitis, irritation, respiratory symptoms, and acute neurological effects. Options to reduce exposure include using existing systems for mixing products connected to exhaust devices, installation of LEV, or working in negative pressure hoods (Darre et al. 1992). In one study, use of local suction and PPE during a cementation procedure reduced MMA concentration to less than detectable, however, exposures can vary depending on the type of procedure, the tool used to apply the cement, and the surface area of the exposed cement (Darre et al. 1992). Orthopedic surgeons and nurses have an increased risk of exposure to not only polymethylmethacrylate but also to methylene diphenyl diisocyanate when working with plaster or fiberglass casts (Lester et al. 2012; Suojalehto et al. 2011). Exposure to diisocyanates is associated with asthma and skin dermatitis and sensitization (Mazurek and Weissman 2016).

Exposure to Chemicals and Dust in Dental Clinics and Laboratories

Dental personnel, including dental assistants, hygienists, technicians, and dentists, perform a variety of tasks and are potentially exposed to a wide range of chemicals from multiple sources including cleaning and disinfecting products, anesthetic gases, adhesives, and various materials used in dental applications, e.g., dentures and

amalgams, gases, vapors, and dusts (Table 4), associated with adverse respiratory effects and allergic contact dermatitis (Gambhir et al. 2011). As in other patient care occupations, exposure to biological agents including bioaerosols is a constant hazard of concern in dental clinics and a great deal of attention is given to sterilizing or high-level disinfection of instruments, and cleaning and disinfecting surfaces after each patient (Leggat et al. 2007). Additionally, disinfection of hands is frequently done with alcohol-based hand sanitizers and/or QACs. In developed countries, dental personnel generally sterilize dental instruments using steam autoclaves instead of high-level disinfectants (Leggat et al. 2007).

Acrylates are commonly used by dental personnel for prostheses and tooth fillings. The handling of acrylate monomers and methyl methacrylate can cause adverse health effects from inhaling vapors and dusts, including irritation, respiratory hypersensitivity, asthma, and numbness in the fingers (Gambhir et al. 2011; Leggat et al. 2007; Hong et al. 2015; Nayeb zadeh and Dufresne 1998). In a Finnish study, methacrylate and natural rubber latex exposures were very low (Henriks-Eckerman et al. 2001) ranging from not detected to 0.01 mg/m^3 for methyl methacrylate and a median of $0.12\text{ arbitrary units/m}^3$ to a maximum of $1.1\text{ arbitrary units/m}^3$ for latex allergen in dust collected from air (Henriks-Eckerman et al. 2001). These same researchers also measured personal exposures to isobutylmethacrylate (infrequently detected to 0.12 mg/m^3), 2-hydroxymethylmethacrylate (maximum 0.033 mg/m^3), and triethyleneglycol dimethacrylate (maximum 0.015 mg/m^3). Several studies have quantified exposures of dental personnel to various acrylates,

Table 4 Exposures in dental occupations and units including dentists, dental assistants, hygienist, and laboratory technicians

Products/Class	Function	Exposures
Metals	Amalgams and composite resin fillings	Mercury, beryllium, zinc oxide, silver, and eugenol
Particles	Dust during grinding	Dust, silica, metals, and acrylates
Acrylic paste, cements and resins, polymers, and monomers	Bonding dental composites, prosthetics resin used to make dentures	Glass ionomers, methyl methacrylates, cyanoacrylate, ethylene glycol dimethacrylate, triethylene glycol dimethacrylate, bisphenol A diglycidyl methacrylate, 2-hydroxyethyl methacrylate, and polymethylmethacrylate
Solvents	Developing solutions, neutralizers, and preservatives in medical imaging	Acetic acid, diethyl glycol, glutaraldehyde, hydroquinone, potassium hydroxide, sulfur dioxide, ammonia, and formaldehyde
Anesthetic gases	Dental surgeries and procedures	Nitrous oxide, halothane, and lidocaine
Other exposures including cleaners and disinfectants, and natural rubber latex	Sterilizing, cleaning, and disinfecting	See previous tables for detailed ingredients and exposures

aldehydes, and VOCs during different procedures (Santarsiero et al. 2009; Hagberg et al. 2005). Others have found in laboratory studies that respirable composite dust emitted during grinding with a dental burr can release unpolymerized methacrylate, which could be available for inhalation exposure (Cokic et al. 2017). Other potential sources of exposure are the use of amalgam containing mercury or beryllium, nitrous oxide gas used for anesthesia, ethylene oxide used for sterilization, glutaraldehyde used for high-level disinfection, cleaning and disinfecting chemicals, and latex gloves (Gambhir et al. 2011; Leggat et al. 2007; OSHA 2002).

Dental laboratory technicians can be exposed to a variety of metals from working with precious and nonprecious alloys. Technicians cast and finish dental alloys creating potential exposures to metallic fumes and dusts, which when not well controlled can pose both inhalation and dermal hazards. Metals include both non-precious (cobalt, chromium, nickel, molybdenum, and beryllium) and precious (palladium, platinum, silver, and gold) metals (Nayeb zadeh and Dufresne 1998). Exposure to silica during finishing and polishing is also of concern. Kim et al. 2002 found a threefold increase in respiratory symptoms among dental technicians (76.5%) compared to controls (28.6%). Respiratory protection was not used and dental technicians performed cutting, grinding, and polishing tasks that generated dust close to their breathing zone (Kim et al. 2002). Neurological effects from methyl methacrylate and solvent exposure, pneumoconiosis and asthma from metal and porcelain dust exposure, allergic contact dermatitis from latex allergies and methyl methacrylate exposure, and IPF are some of the main health effects of concern.

Exposures to Chemicals in Other Hospital Occupations and Departments

Patient care occupations are exposed to chemicals in almost all departments in the hospital. In addition to surface cleaning and disinfecting products, patient care workers apply antiseptics to patients (e.g., chlorhexidine), use glues containing acrylates to apply bandages, and use various solvents to remove glue from the skin (Table 5). Exposure to mercury, mostly from thermometers and blood pressure machines, was previously of concern in nursing stations, but there is a trend away from using mercury-containing patient care items (Gorman et al. 2013). Exposure to mercury occurs during equipment repair and spills from breakage. Chronic exposure to mercury is associated with neurologic and neurobehavioral outcomes, while acute exposure is associated with bronchitis and pneumonitis (Weaver 1997).

Respiratory therapists, nurses, or physicians may administer a variety of aerosolized medications using a nebulizer or other aerosol generating system to treat various respiratory diseases and infections. During treatment, healthcare personnel may be chronically exposed to low levels of these aerosolized medications that escape/leak from the delivery system. These medicines include ribavirin (antiviral), pentamidine (antiprotozoal), amikacin, colistin, and tobramycin (antibiotic), which are associated with adverse reproductive effects, kidney toxicity, respiratory irritation, asthma, and asthma symptoms (Tsai et al. 2015). Because there are no less toxic substitutes for these medications, exposure control should follow the hierarchy of control scheme starting with engineering controls, administrative controls, and PPE.

Table 5 Exposures in other hospital occupations and departments

Unit/Occupation	Product or chemical class	Purpose or function	Chemical ingredients
Patient care occupations including all nursing occupations, e.g., LPN, RN, and NA in different units	Antiseptics and skin disinfectants	Skin disinfection	Alcohol, chlorhexidine, and hexachlorophene
	Glues	Applying bandages, wound dressing, and plasters	Acrylates (e.g., cyanoacrylate)
	Solvents and adhesive removers	Removing bandages and adhesives	Acetone, dipropylene glycol methyl ether, ethanol, isoparaffinic hydrocarbons, and isopropanol
	Metals	Thermometers and blood pressure devices	Mercury
Respiratory therapists and pulmonologist and nurses	Aerosolized medications	Antiprotozoal	Pentamidine
		Antibiotics	Amikacin, colistin, and tobramycin
		Antiviral	Ribavirin
Clinical, histology, and pathology laboratories, and morgue	Laboratory chemicals and reagents	Solvents	Toluene, xylene, acetone
		fixative solutions	Formaldehyde, and glutaraldehyde
Pharmacy and oncology	Medications and drugs	Antineoplastic, antibiotics, and cytotoxic drugs	Alpha-fluoro-beta-alanine, amoxycillin, amoxicillin + clavulanate, ampicillin, budiastase, biperiden, bleomycin, bortezomib, carboplatin, cecisplatin, cefepime, cefoperazone, cefotiam, cefotaxime, cefoxitin, cefazolin, ceftazidime, ceftizoxime, ceftriaxone, chlorhexidine, chlorpromazine, ciprofloxacin, clindamycin, cyclophosphamide, cytarabine, daunorubicin, dicloxacillin, 2',2'-diflurorodeoxyuridine, doxorubicin, docetaxel, Empynase®, epirubicin, etoposide, flomoxef, flucloxacillin, 5-fluorouracil, gemcitabine, gentamycin, idarubicin, ifosfamide, irinotecan, meropenem, methotrexate, nitrogen

(continued)

Table 5 (continued)

Unit/Occupation	Product or chemical class	Purpose or function	Chemical ingredients
			mustard, omeprazole, oxaliplatin, paclitaxel, pantoprazole, pantothenine, propacetamol, pemetrexed, penicillin, penicillin G, perphenazine, phenobarbital, piperacillin, piperacillin + tazobactam, propercizaine, psyllium, sodium benzylpenicillin, sucralfate, sulfamethoxazole + trimethoprim, taxol, tazobactam, thioridazine, topotecan, vinblastine, and vincristine
Radiology	Chemical mixture	Film processing and development chemicals	Hydroquinone, glutaraldehyde, formaldehyde, glycols, acetic acid, sulfur dioxide, ammonium chloride, and silver compounds
ICU and emergency	Nitrates and nitric oxide, treatment for cardiovascular stabilization	Escape from ventilators	Nitric oxide and nitrogen dioxide
Laundry workers	Mixed exposure	Contaminated clothing or linen	Various biohazards and drugs
Maintenance and construction	Mixed exposure	Repair and construction of building, grounds maintenance	Dusts, VOCs, formaldehyde, molds and moisture, material off-gassing, phthalates, and pesticides

Laboratory personnel and technicians may be exposed to formaldehyde, and previously glutaraldehyde, tissue preservatives, and fixative solutions. Additionally, they are exposed to a variety of solvents containing VOCs such as acetone, xylene, and toluene that are used in pathology, histology, other laboratories, and autopsy suites (Table 5). Laboratory technicians and other workers in these areas have some of the highest inhalation and skin exposure to these VOCs (Weaver 1997). A study of VOCs in histology laboratories reported high levels of ethanol, isopropanol, 2-butanone, ethyl acetate, thiophene, toluene, ethylbenzene, limonene, xylene, and ethylbenzene (Cipolla et al. 2017). Formaldehyde is a confirmed human carcinogen and a skin sensitizer and is associated with irritation and upper airway symptoms (Gorman et al. 2013). Exposure to solvents is associated with central nervous system effects (Weaver 1997).

About eight million U.S. healthcare workers are potentially exposed to drugs, in various occupations and departments such as pharmacy, nursing professionals, and physicians (e.g., in oncology), OR personnel, and research laboratory personnel as they prepare, handle, or administer a multitude of drugs daily some of which are hazardous (NIOSH 2020). Maintenance, shipping, laundry, and housekeeping staff are also at risk of exposure to these drugs through contaminated work surfaces, linen and clothing, or shipping packages (NIOSH 2020). These hazardous drugs include some antibiotics, antineoplastic drugs, hormone agents, and bioengineered drugs. NIOSH maintains a list of common hazardous antineoplastic drugs, which was last updated in 2016 (NIOSH 2020). Exposure primarily occurs through inhalation and dermal routes of exposure, but accidental ingestion through hand to mouth contact and accidental injection through needle stick injury can also occur. Numerous studies have conducted surface contamination and skin exposure assessments for hazardous drugs in pharmacy and different hospital locations among staff who handle these drugs at various stages from preparation to delivery (Crul et al. 2020; Poupeau et al. 2018). Exposure to these drugs can cause acute and chronic effects including respiratory and skin irritation, reproductive problems, and cancer (NIOSH 2020). Antibiotics, including penicillin, amoxicillin, and dicloxacillin, are known to cause allergic dermal reactions (exanthema, eczema, and erythema) (Pinheiro et al. 2018). Exposure to frequently used antineoplastic drugs, such as cyclophosphamide, 5-fluorouracil, and paclitaxel, are associated with increased risk of allergic respiratory and dermal reactions, nasal sores, loss of hair, carcinogenicity, and irritant contact dermatitis (Ivanova and Avota 2016). There is mixed evidence for reproductive effects of exposure to antineoplastic drugs among nurses in various departments. Various guidance from government and professional societies exist to minimize opportunities for exposure.

Numerous chemical hazards exist in radiology from using chemicals for film processing and development, such as hydroquinone, glutaraldehyde, formaldehyde, glycols, acetic acid, sulfur dioxide, ammonium chloride, silver compounds, and many others (Teschke et al. 2002; Byrns et al. 2000). However, the current trend is toward digital imaging that eliminates these hazards. Exposure to aldehydes is associated with asthma. Increased risk of asthma has been reported for radiographers and technicians who process films. Approaches to minimize these hazards include recognizing their presence, installing appropriate LEV controls, and moving toward digital imaging.

Maintenance workers may be exposed to vapors and dusts from various repairs to the building or mechanical systems, building materials, and exposures prevalent in any areas where they work. Laundry workers may be exposed to detergents from laundry, biological hazards, and hazardous drugs that contaminate linen and clothing. Maintenance and laundry workers may also be exposed to cleaning and disinfecting chemicals.

Conclusions

Hospital workers are exposed to complex mixtures of chemicals mostly via inhalation and dermal routes of exposure. These exposures arise from multiple sources, such as cleaners and disinfectants, sterilizing agents, detergents, solvents, heavy

metals, hazardous drugs, laboratory chemical reagents, waste anesthetic gases, surgical smoke, and other indoor air contaminants from products, building, and construction materials. Exposures to these gases, vapors, and aerosols result in a spectrum of health outcomes including respiratory, dermatologic, reproductive, neurologic, other systemic outcomes, and cancer. A great deal of attention is focused on preventing HAIs, and consequently exposure to chemicals is often not well recognized or controlled and prevention measures are lagging. This review highlights the chemical products used by healthcare workers in different occupations and units, their ingredients and potential for inhalation and dermal exposures, and opportunities for exposure mitigation and disease prevention. In particular, preventing HAI through cleaning and disinfecting surfaces creates chemical hazards that are associated with asthma, rhinitis, dermatitis, and sensitization, presenting a significant challenge. There is thus a need for a more integrated approach to infection control and asthma prevention, requiring cooperation among professional organizations in infection control, industrial hygiene, and occupational medicine in formulating guidelines. Additionally, the numerous health and safety hazards present in hospital setting need to be recognized, monitored, and mitigated.

Abstract

Although commuters spend a small proportion of their time in vehicles, transport microenvironments (TME) are a significant contributor to their total daily air pollution exposure, thereby affecting the citizens' health and well-being. The vehicle interior is a specific environment of small volume, affected by traffic-related air pollutants, and by the emissions from a variety of building materials, some of them harmful to the human health. The aim of this chapter is to identify the key factors affecting the exposure in TME. It identifies the principal pollutants influencing the air quality inside vehicle cabins, discusses advantages and

disadvantages of the main measuring and modelling approaches used to assess these pollutants, and presents control measures. It is difficult to compare and rank the exposures experienced in buses, cars, motorcycles, trams, trains, subways, cycling, or walking. The exposure varies considerably within and between the different modes of transport, due to disparities in the measurement protocols, vehicle characteristics, ventilation settings, road typology, atmospheric conditions, temporal variations, and user habits. Considering public health, efforts should be made to prioritize active travel, optimize vehicle ventilation and filtration, avoid heavily trafficked roads and rush hours, and maintain indoor cabin hygiene. The information in this chapter can contribute to develop transport and planning policies in urban areas.

Introduction

The study of commuter exposure to air pollutants is not a new field of research. Indeed in 1966, Haagen-Smit (1966) made a series of carbon monoxide measurements on heavily traffic roads in Los Angeles. Since then, the importance of the topic increased as a consequence of population growth, the increased number of motor vehicles, and the higher degree of proximity to vehicular emissions.

Personal exposure to environmental substances is largely determined by time-activity patterns while moving across locations or microenvironments (Duan et al. 2022). Time-activity pattern studies performed in European (Cunha-Lopes et al. 2019), North America (Klepeis et al. 2001), and Asian (Chau et al. 2002) cities have reported that time spent commuting varies between 3.4% and 10% of the day. However, although people only spend a reduced fraction of time in-transit, commuting lead to a substantial contribution to their total daily exposure and inhalation of air pollution, especially in high vehicle-density metropolitan areas.

Transport microenvironments (TME) have higher air pollutant concentrations than other settings most people occupy in their daily routines. Aboveground transports are affected by the exhaust emissions from nearby cars, trucks, and buses, the evaporative emissions from the fuel system, and the abrasion emissions from brakes, clutch, and tires. The underground systems are mainly influenced by the mechanical abrasion between wheels, brakes, and rails. The concentrations of most traffic-related air pollutants are particularly high along busy roads, which often do not meet air quality standards, principally during morning commute hours. During the commuting time, drivers and passengers are also exposed to high pollutant concentrations emitted by the cabin materials. The volatile organic compounds concentrations in a vehicle cabin could be much higher than normal ambient levels. According to Mandalakis et al. (2008), the inhalation intake exposure to polybrominated

diphenyl ethers (PBDEs), which is a flame retardant, during an 80-min drive is approximately equivalent to 16.5-h exposure at home.

Consequently, commuters are exposed to short periods of high pollutant concentrations. Indeed, a study conducted in Barcelona showed that commuting contributed to 11% of the daily exposure to nitrogen dioxide (NO_2) (de Nazelle et al. 2013). In Los Angeles, Fruin et al. (2008) estimated that the influence of measured in-automobile ultrafine particles (UFP) on daily exposure ranged between 33% and 45%. Moreover, the personal exposure to BC during commuting showed to contribute in 21%, 19%, and 12% to the total daily exposure in Belgium (Dons et al. 2012), Lisbon (Cunha-Lopes et al. 2019), and Paris (Paunescu et al. 2017), respectively.

Several reviews have been published in the last years about the factors affecting the exposure in different travel modes and about the associated health impacts (Cepeda et al. 2017; de Nazelle et al. 2017; Hachem et al. 2019; Karanasiou et al. 2014; Knibbs et al. 2011; Kumar et al. 2018; Ma et al. 2020; Xu et al. 2018). These works have flagged the exposure while commuting as a priority topic of further investigations.

The objective of this chapter is to better understand personal exposure during commuting by different modes of transport and under different conditions and to contribute for making informed decisions to manage and reduce the health risks in cities.

Most Important In-Cabin Pollutants

TME have become a significant source of exposure to several air pollutants. The wide range of commuting modes, vehicle cabin designs, and modes of operation result in a large variation in the occurrence of pollutants species, concentrations, and personal exposure levels. The sources of air pollutants in-cabin can be classified, as in other indoor environments, as outdoor air, interior materials and finishes, and human behavior (Fig. 1).

Particles ($\text{PM}_{2.5}$, aerodynamic diameter $<2.5\ \mu\text{m}$; PM_{10} , aerodynamic diameter $<10\ \mu\text{m}$) emissions from road vehicles include emissions from the tailpipe and non-exhaust emissions due to tear and wear of vehicle parts such as clutch, brake, and tire and resuspension of dust (Padoan and Amato 2018). As stringent policies and technological upgrades have led to sizeable reductions in exhaust emissions, the contribution of non-exhaust emissions is becoming more important. Rexeis and Hausberger (2009) estimated that the contribution of non-exhaust PM to the total PM emissions will increase from about 50% up to some 80–90% by the end of the decade. Non-exhaust emissions are usually characterized by trace metals, such as Ba, Cu, Mn, Sb, Zn, although organic markers, such as polycyclic aromatic hydrocarbons (PAHs) and n-alkanes, have also been used as markers (Pant and Harrison 2013). Exposure to PM increases the risk of cardiovascular diseases and stroke (Lee et al. 2018a), central nervous system diseases (Babadjouni et al. 2017),

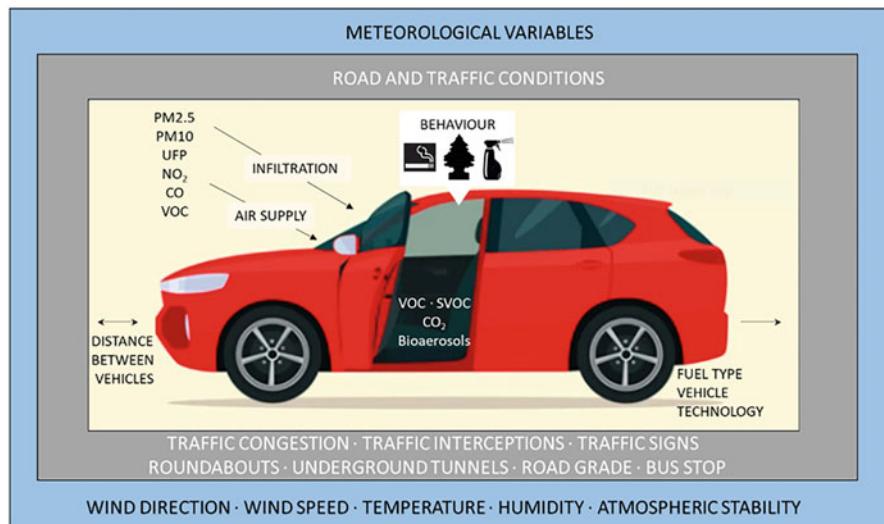

Fig. 1 Principal pollutants influencing the air quality inside vehicle cabins and key factors affecting the exposure in TME

neurodevelopmental and neurodegenerative diseases (Chen et al. 2017), and mortality (Pun et al. 2017).

Ultrafine Particles (UFP, mobility diameter <100 nm) typically constitute more than 90% of particle number concentrations in polluted roadside environments (Morawska et al. 2008). Although there are several natural sources of UFP, the combustion of fossil fuel for heating and transportation is the principal source in congested urban environments with heavy-duty diesel powered vehicles the dominant contribution to UFP concentrations (Morawska et al. 2008). UFP from vehicles can be emitted as primary particles or generated as a secondary aerosol, such as following homogenous nucleation of SO₂, NH₃, and NOx into SO₄²⁻, NH₄⁺, and NO₃⁻ (Morawska et al. 2008). Ambient UFP number concentrations are typically elevated on and near busy roads, and decay to background within 500 m of the edge of the road (Padró-Martínez et al. 2012). Previous studies have demonstrated cardiovascular and respiratory health effects of UFP, which likely have different and partly independent effects from larger particles, due to their small size, large surface area, high number concentration, different chemical composition, greater bioavailability of reactive compounds, content of redox-active compounds, ability to penetrate deep into the alveolar system, and increased lung retention (Araujo and Nel 2009).

Black Carbon (BC), a component of PM_{2.5}, originates from the incomplete combustion of wood and diesel engine exhaust (Dons et al. 2013), and is a suitable indicator of traffic-related air pollution (Janssen et al. 2011). Transportation is a major source of BC in urban areas where road vehicles contribute to ~58% of total BC emissions (Kumar et al. 2018) and lead to high BC concentrations on and near

busy roads (Padró-Martínez et al. 2012). BC is considered a better indicator of harmful particulate substances from combustion sources (principally traffic) than undifferentiated PM mass (Janssen et al. 2011) and has been associated with adverse cardiovascular effects (Gan et al. 2011), respiratory diseases (Patel et al. 2013), decreases in childhood cognition (Suglia et al. 2008), and mortality (Gan et al. 2011).

Nitrogen Dioxide (NO_2) is formed through the rapid reaction of NO, which is primarily emitted by the combustion of fossil fuels by vehicles, with O_3 . NO_2 is a well-established indicator of air pollution stemming from motor vehicle sources. The health impacts associated to exposure to NO_2 have been discussed because NO_2 and PM usually occurs in the same environment, and the relative contribution of individual components of the mixture is difficult to disentangle (Ackermann-Liebrich et al. 2019). However, recent works have dedicated to NO_2 as a possible independent contributor to adverse health impacts, and reported associations of long-term exposure to NO_2 with increased all-causes, cardiovascular, respiratory, cancer, ischemic heart, cerebrovascular, and pneumonia mortality (Do Eum et al. 2019), and associations of short-term exposure to NO_2 with risk of all-cause, cardiovascular and respiratory mortality (Mills et al. 2015).

Carbon Monoxide (CO) results from incomplete combustion of diesel or gasoline in traffic engines. High concentrations of CO generally occur in areas with heavy traffic intensity affecting the health of people who work or live nearby these areas. CO concentrations are spatially heterogeneous within a city, with higher levels on busy roads and especially in street canyons. Multisite studies performed in 19 European cities (Samoli et al. 2007) and in 126 US urban counties (Bell et al. 2009) found significant associations of CO with total and cardiovascular mortality and with risk of cardiovascular disease hospitalizations, respectively.

Volatile Organic Compounds (VOC) are emitted by vehicle exhaust, the most abundant of which include benzene, toluene, ethylbenzene and m-, p-, and o-xylene isomers, ethane, ethylene, acetylene, 1-butene, isobutene, propane, propene, isopentane, n-pentane, i-pentane, 2,2-dimethylbutane, 2-methylpentane, n-hexane, 3-methylhexane, ethylbenzene, m-ethyltoluene, and various trimethylbenzene isomers (Watson et al. 2001). For benzene, toluene, and xylene, a comparison between concentrations measured in the car with those determined immediately outside showed little difference (I/O ratio = 1.17) indicating their outdoor origin (Leung and Harrison 1999). However, organic compounds are also emitted from interior materials inside vehicle cabins. Yoshida et al. (2006) measured the concentrations of organic compounds in the interior air of 101 different types of Japanese domestically produced private-use cars and identified a total of 275 organic compounds, including many aliphatic and aromatic hydrocarbons, demonstrating that the air inside vehicle cabins is contaminated by high concentrations of a large variety of organic compounds emitted by the interior materials. Benzene, emitted by vehicle exhaust, and formaldehyde, the most familiar organic compounds affecting indoor air quality in transports, are classified as carcinogen by the International Agency for Research on Cancer.

Semi-volatile Organic Compounds (SVOC) are ubiquitous components of indoor environment. Some SVOC, such as PAHs originating from combustion, are

well-known pollutants contributing to human exposure, while other SVOC are less studied because they have been produced in large amounts only within the last half-century (Weschler and Nazaroff 2008). Since SVOC account for a large quantity of the material weight and their emission rates are relatively slow, they tend to exist in new and old vehicles for a long time (Xu et al. 2018). SVOC occur as active ingredients in personal care products and cleaning agents, and as main additives in materials such as electronic components, furnishings, and floor coverings (Weschler and Nazaroff 2008). Some SVOC are known to be toxic (e.g., dioxins, benzo[a]pyrene, pentachlorophenol), and for others, there are emerging indicators of concern. Phthalate esters have been associated with the change of the semen quality (Hauser et al. 2007) and with allergic symptoms in children (Bornehag et al. 2004). Certain SVOC are linked to endocrine disrupting activity such as brominated flame retardants (Birnbaum and Staskal 2004) and di-2-ethylhexyl phthalate (Sharpe 2005).

Carbon Dioxide (CO_2) concentrations can build up due to exhaust emissions and human exhalation. According to Gladyszewska-Fiedoruk (2011), a car driver exhales as much CO_2 as during physical exercise, due to the needed focused attention and concentration that affect the human metabolism, while a passenger exhales approximately the same quantity of CO_2 as a person taking a rest. The rate of increase of the CO_2 concentration is dependent on the occupation and several vehicle-specific parameters, such as the vehicle volume, and the air ventilation rate. CO_2 is considered a nonpoisonous gas; however, when concentrations in the air are too high, headaches, sore eyes, breathing difficulties, and declining concentration can occur, which can be unsafe while driving.

Bioaerosols refer to aerosols containing biological particles, such as fungi, bacteria, and viruses, and have allergenicity, infectivity, and pathogenicity (Wen et al. 2020). Microbes are ubiquitous in the TME and can enter inside vehicle cabins through the ventilation system, attached to people and objects, among other pathways (Buitrago et al. 2021). The vehicles' cabins provide the conditions for growth and propagation of wide range of pathogens, due to crowded population, foods and garbage produced by passengers, limited ventilation, and thermal environment (Wen et al. 2020). The infection transmission depends on several parameters, such as the load and proximity of the biological agent, host susceptibility, and exposure time (Nasir et al. 2016). The exposure to high concentrations of microorganisms is frequently associated with inflammatory reactions, asthma, pneumonitis, and hypersensitivity (Jo and Lee 2008). Worldwide field research focuses on concentrations, diversity, sources, and virulence – and survival – associated characteristics. Existing research shows that the most common microbes include aspergillus, alternaria, bacillus, cladosporium, chrysosporium, geotrichum, micrococcus, propionibacterium, penicillium, and staphylococcus (Wen et al. 2020). Most of these microbes are associated with the human body and activity (Buitrago et al. 2021). Nowadays, the possibility of SARS-CoV-2 infection while travelling in public transport is a huge concern for all the commuters and transport companies. The scientific evidence related to COVID-19 transmission on public transportation is very limited. However, the spread of COVID-19 in transports follow the same routes of transmission of respiratory viral diseases: through small airborne microdroplets,

via larger respiratory droplets, which fall close to where they are expired, and through contact with contaminated surfaces. Hadei et al. (2021) investigated the presence of SARS-CoV-2 RNA in the air of transports in Tehran and concluded that 67% of samples collected were positive (100% in subway trains and 50% in buses). Moreno et al. (2021) evaluated the presence of traces of SARS-CoV-2 RNA in the air, surfaces, and air-conditioning systems of subway trains and buses and found that from a total of 82 samples, 30 showed evidence for the presence of one or more of the 3 target RNA gene regions of SARS-CoV-2 virus. This work showed that positive results were more common in surface swab samples from support bars than in ambient air inside the vehicles and that there was a notable decrease in RNA traces detected after the bus cleaning.

Methods to Assess the Exposure During Commuting

Measuring

Fix Monitoring Stations

Measurements from fixed monitoring stations (FMS) have been commonly used to estimate the personal and community exposure levels to air pollutants. The most relevant advantage of FMS is the ability to provide highly accurate air quality measurements. Nevertheless, the high operation costs associated with the FMS maintenance means that only a few stations are available within the whole city, assuming that the air quality is homogenous within several kilometers around. A more accurate assessment of exposure during transportation needs the spatial distribution of air pollutants along the commute route, which is impossible to be fulfilled from FMS measurements. Several studies showed that urban background FMS significantly underestimate the exposure of the commuters. Asmi et al. (2009) assessed the relationship between UFP concentrations in the drivers' cabin of buses to that measured at an urban background site and reported ratios between 1.2 and 6.9, depending on the route, time of the day, and age of the bus. Zuurbier et al. (2010) found ratios between background and vehicle between 1.6 (diesel car, electric bus) and 2.5 (diesel bus), and reported correlations between 0.01 (diesel bus) and 0.87 (bicycle on low-traffic route). The roadside FMS appear to better represent the traveler's exposure although the concentrations recorded are still lower. Kaur et al. (2005) obtained ratios of 1.5 (bus), 1.6 (car), and 1.8 (taxi) when the personal measurements of PM_{2.5} were compared with roadside FMS, while ratios of 3.4 (bus), 3.8 (car), and 4.2 (taxi) were found for the comparison with the background FMS. These studies highlight the need for direct personal measurements to assess the personal exposure experienced during commuting.

Portable Devices and Low-Cost Sensors

Personal monitoring is the most direct approach to assess the individuals' exposure during commuting, and it can provide detailed information about short-term exposure in a specified area (Steinle et al. 2015). With the development of novel

Table 1 Instruments used for measurement of PM_{2.5}, PM₁₀, UFP, BC and CO

	Measuring principle	Equipment
PM	Light scattering	Grimm (model 1.101, 1.108, 1.109); Thermo (pDR 1200, pDR 1500); Turnkey (OSIRIS, DUSTMATE), TSI DustTrak (models 8520, 8530, 8533, 8534); TSI OPS (model 3330)
	Laser particle counter	TSI AeroTrak (model 9306); Lighthouse Handheld (model 3016)

CO	Electrochemical monitor	Langan DataBear (models T15, T15v), Draeger Industry PAC II CO, TSI IAQ-track (model 7545), Graywolf (610 IAQ probe), Draeger PAC II CO

observation technologies, portable instruments enable the measurement of air quality data at a higher spatial resolution and have been widely used in the assessment of the individual exposure inside vehicles along the commute route. The main air pollutants measured with personal equipment include PM_{2.5}, PM₁₀, UFP, BC, and CO, and the most frequently used equipment are listed in Table 1.

Portable instruments can be installed in travelers' backpacks, carried in hand, worn over the waist, or mounted inside the vehicles. The devices used to characterize the exposure inside the different transport modes have differences in terms of concentration range, measurement frequency, particle size resolution (for UFP monitors), battery life, clock drift, and portability. Therefore, the selection of the monitoring device can affect the quality of the assessment and the comparability between studies. For example, the P-Trak only detects UFP greater than 20 nm diameter, while TSI CPC 3007 or 3785, Philips NanoTracer and testo DiSCmini count particles as small as 10 nm, which is relevant considering that fresh emissions from vehicular traffic can have a large fraction of particle number below 20 nm. One disadvantage of using portable PM monitors, based on light scattering, is that the optical properties of PM are known to be affected by factors such as particle size, composition, and age. Moreover, optical PM monitors are commonly sensitive to ambient temperature and humidity, and therefore monitors must be checked against

reference instruments (Wang et al. 2009). The instrument microAeth AE51 measures the rate of change of light absorption (880 nm) due to the accumulation of BC on a filter. Nevertheless, the accumulation of BC on the filter reduces the effective optical path resulting in a loading-dependent relationship between the measured absorption and BC mass. Therefore, correction factors must be applied during post-processing of the data to compensate this measurement artifact (Park et al. 2010; Virkkula et al. 2007). Furthermore, in metro, the main sources of PM – the mechanical abrasion between wheel, brakes, and rails – produce high concentrations of particulate iron that result in a BC overestimation by the microAeth AE51 since iron absorbs light at 880 nm.

One of the disadvantages of using these portable devices is that they can only be applied to small-scale studies due to the cost and time required to undertake the fieldwork (Ma et al. 2020). However, the air pollution monitoring paradigm is quickly changing thanks to the fast evolution of the available small sensors technologies, increased computational and visualization capabilities, and wireless communication infrastructure (Morawska et al. 2018). These sensors have two main advantages over classical devices. First, some of these sensors are relatively low cost, which allows the simultaneous monitoring of a large number vehicles with different operating conditions. Secondly, sensor units are small, battery powered, and therefore are easy to worn by people or install inside the cabins. The most promising tool for future exposure assessment during commuting is the development low-cost microsensors that could be integrated in a mobile phone circuit board, allowing seamless tracking of the individuals. Currently, smartphones have been used in Barcelona to track person-level time, geographic location, and physical activity patterns, and showed to be more accurate and efficient than the conventional method using GPS tracker (Donaire-Gonzalez et al. 2016). On the other hand, these sensors present disadvantages such as the selectivity in the case of PM measurements. PM sensors are based on light scattering so they cannot measure properly PM smaller than 0.3 μm .

Exposure Modelling Techniques

The ability to accurately model in-transit exposure has numerous applications in urban planning, transport, and policy development. Modelling techniques avoid the limitations of personal monitoring by extending the studies to wider areas and by scaling sampling sizes to the population level. The exposure models estimate the time-averaged concentration for the exposed individual based on the variation in air pollutant levels over time and space, and the time-activity pattern of the individual. Several exposure models have emerged in the last years aiming at predicting interindividual variability in exposure levels taking into account: (1) the time that each individual spends in each microenvironment over the day, (2) ambient air quality, (3) infiltration of ambient air to indoor microenvironment, (4) characteristics of the indoor microenvironment such as air exchange rates, and (5) population demographics at high spatial resolution such as from census data (Kumar et al. 2018).

The increased availability of population-based information regarding time-location patterns allowed the development of a new generation of exposure models that simulate interindividual variability in exposure, thanks to the increasing use of mobile electronic devices such as smartphones, which often have imbedded GPS receivers, and dedicated GPS dataloggers to collect personal time-location information (Duan et al. 2022; Breen et al. 2014).

The exposure models include temporally and spatially resolved ambient monitoring data and/or predictions of air quality models. Two frequently used air quality modelling techniques are air dispersion models and land use regression (LUR) models. Air dispersion models simulate air pollutant concentrations by using pollutant source information, meteorology, and the underlying surface. The LUR is an application of geographic information system (GIS) that is gaining momentum as a tool to predict exposure to a multiplicity of pollutants. The LUR models estimate the ambient pollutant concentrations at un-sampled points of interest by considering the influence of the land use and the environmental features of the surrounding area. This is based on the construction of a multiple linear regression with explanatory variables, such as distance from the road, altitude, and population density (Gressent et al. 2020). More recently, other methods are used for mapping such as machine learning techniques (Support Vector Regression, Decision Tree Regression, Random Forest Regression, or Extreme Gradient Boosting) (Gressent et al. 2020).

Concurrently, exposure models are also based on the relationship between ambient air quality and pollutant concentrations in indoor microenvironments, which is usually based on mass balance or statistical models. The mass balance approach quantifies infiltration considering air exchange rate, penetration factor, and deposition rates. Several recent studies adopted a more mechanistic, mass-balance modelling approach for automobiles. These works have been based on measurements of the effects of cabin ventilation, filtration, particle penetration, or deposition on in-cabin concentrations (Knibbs et al. 2011). The statistical methods typically estimate the ratio of indoor-to-outdoor concentrations as a single parameter or as part of a linear regression model in which the intercept term accounts for non-ambient pollution of indoor origin. For instance, Correia et al. (2020) measured ambient and in-vehicle concentrations in multiple transport microenvironments in Lisbon to quantify the ratio of in-vehicle to ambient concentrations.

As an example, the Stochastic Human Exposure and Dose Simulation (SHEDS) model has been used by Liu and Frey (2011) to model in-vehicle human exposure to ambient fine particulate matter.

Factors Affecting the Personal Exposure During Commuting

Various studies have focused on personal pollutant exposure in diverse transport modes, such as bus, car, motorcycle, tram, train, subway, cycling, and walking (Buitrago et al. 2021; Correia et al. 2020; de Nazelle et al. 2012; Kaur and Nieuwenhuijsen 2009; Kumar et al. 2021; Martins et al. 2016, 2021). The exposure has been found to vary considerably within and between the different modes of

transport, which can be associated with disparities in the measurement protocols, vehicle characteristics, road typology, and temporal variations. In this review chapter, the several factors that affect the personal exposure were broadly classified into four categories, including (i) transport characteristics; (ii) road and traffic conditions; (iii) meteorology variables; and (iv) individual behaviors.

Transport Characteristics

Several studies have reported that the traffic-related pollutant concentrations inside the vehicles are lower than those in the respective ambient air, evidencing that the vehicle cabin may offer a protective effect (Alameddine et al. 2016; Correia et al. 2020; Leavey et al. 2017; Matthaios et al. 2020; Vijayan and Kumar 2010; Zuurbier et al. 2010). However, vehicles are not built to be airtight and pollutants enter the cabin through leaks in door and window seals and other openings (Martins et al. 2021). Alameddine et al. (2016) attributed the differences in-cabin PM_{2.5} concentrations among car **brands** and **models** to possible distinct penetration factors of the car shells.

Type of Fuel, Vehicle Category, and Emission Standards

The vehicle exhaust emissions are not only affected by **fuel type** but also by **vehicle category** (transport mode) and **vehicle emission standards**. The emission standards are in different stages of development around the world. For example, the European Union is imposing increasingly stringent requirements on exhaust emissions since 1992. The vehicle manufacturers have continually improved engine technologies and have introduced various emission-control systems to comply with the European legislation. Clean fuels, such as lower sulfur content gasoline and diesel fuel, compressed natural gas (CNG), liquefied natural gas (LNG), and hydrogen, are associated to much less pollutant emissions than the traditional ones (gasoline and diesel) due to their physical or chemical properties.

Most of the studies reported that the exposure to traffic-related pollutants during commuting is mainly affected by the emissions from the surrounding vehicles, rather than from the vehicle the individual is commuting in (Karanasiou et al. 2014 and references therein). In a short experiment conducted in Barcelona, particle number concentration (PNC) and BC concentration inside an electric vehicle were higher than in a gasoline vehicle both under traffic and stable conditions (cars parked side by side with the engines off and no passengers inside) (Karanasiou et al. 2014). The indoor concentrations were highly dependent on the outdoor levels, evidencing that the electric car had higher infiltration rate than the gasoline car, which should be related to the vehicle structure and the building materials (Karanasiou et al. 2014).

Other studies have related fuel type of the vehicle with self-pollution. Zuurbier et al. (2010) found that PNC and soot levels in diesel-fueled buses were higher than in electric buses. In diesel buses, a percentage of the existing exhaust pollutants was associated with vehicle self-pollution (Zuurbier et al. 2010). The PM₁₀ concentrations in-cabin of diesel and electric buses were not significantly different, probably

due to the resuspension of particles, created by the passengers' movement and the air flowing when doors open (Martins et al. 2021; Zuurbier et al. 2010). Targino et al. (2020) reported in-cabin of a diesel-fueled buses higher BC concentrations but less particles with smaller diameters than in a biodiesel bus, which was related to the different emission factors of diesel and biodiesel engines. Recently, Zheng et al. (2021) also found that the type of fuel used can influence the PM concentrations inside cars and buses. They observed that PM_{2.5} concentrations inside gasoline-fueled cars were higher than those powered by CNG and even higher compared to those powered by methanol. PM₁₀ concentrations were comparable inside electric and CNG buses (Zheng et al. 2021).

Ventilation Settings

Vehicle cabin ventilation can occur by four different modes, namely natural ventilation, mechanical ventilation, hybrid ventilation, and infiltration (Tong et al. 2019). In natural ventilation, the air enters intentionally into the vehicle' cabin through apertures due to outdoor air movement and pressure differences (e.g., windows open). Mechanical ventilation uses fans to move air into vehicle' cabin; this air can be recirculated inside the cabin or be introduced from outside into vehicle. In these two mechanical modes, the air passes through the cabin filter before (re-) entering the in-vehicle environment. The hybrid ventilation occurs when natural and mechanical forces are used simultaneously, providing a comfortable internal environment. During the vehicle' motion, outside air can also infiltrate into the cabin through leaks due to pressure differences because vehicles are not built to be airtight.

The ventilation control and cabin air filters are capable of improving thermal comfort and indoor air quality (Buitrago et al. 2021; Kumar et al. 2021; Martins et al. 2016; Matthaios et al. 2020). Different air pollutants are affected differently by the ventilation and the filter used. The **filtration** efficiency is dependent on the filter type used in the ventilation system. For instance, cabin air filtration system equipped with a particle filter is efficient to remove pollen, spores, dust, and soot, while the activated carbon filter, besides the function of the particulate filter, also absorbs odors, harmful gases, ozone, benzene, and nitrogen dioxide.

Several authors have assessed the air pollution exposure of vehicle occupants under different ventilation modes, and their results are consistent, demonstrating that the lowest particle exposure occurs when the **air recirculation** is on with the **windows closed** (e.g., Correia et al. 2020; Kumar et al. 2021; Matthaios et al. 2020). The air recirculation reduces the particle concentrations by moving the air inside the vehicle through the cabin filter multiple times. Moreover, other authors have observed that complementing the recirculation with **air-conditioning** mode, the concentrations of particles can be further reduced (Alameddine et al. 2016; Matthaios et al. 2020). In-cabin pollutant concentrations tend to track those existing outdoor when windows are open (Leavey et al. 2017). Particles are dominantly coarse with windows open, while under recirculation or fan on (outdoor air intake), the particles are mainly fine, evidencing the effectiveness of filters removing coarser particles (Kumar et al. 2021). Alameddine et al. (2016) found no statistical difference in PM_{2.5} concentrations between windows half open and air-conditioning with fresh

air intake. Buitrago et al. (2021) verified that the concentrations of VOC, CH₂O, fungi, and bacteria were lower when the ventilation was on. These pollutants were mostly associated with indoor sources and the ventilation promotes dilution.

The **position of the ventilation air intake** also have shown to influence the exposure to air pollutants in-vehicles due to the vertical pollution gradient. For example, Limasset et al. (1993) reported that when the air intake is from the roof of bus, the in-vehicle pollutant concentrations are significantly lower than under the typical front air admission.

Matthaios et al. (2020) evaluated the effect of protection of vehicle structure to outdoor air pollutants, conducting measurements with mechanical ventilation switched off and windows closed. They observed that the personal exposure to UFP, NO₂, and PM2.5 in-vehicle was approximately 63%, 30%, and 20% lower than outdoor, respectively. However, under this lack of ventilation or using recirculation mode, the CO₂ exhaled by vehicle occupants tends to accumulate inside the cabin, which may impair cognitive function, and cause drowsiness and anxiety (Matthaios et al. 2020).

In subway system, the mechanical ventilation also improves air quality, removing more efficiently coarse particles (Lee et al. 2018b; Martins et al. 2015). Martins et al. (2015) tested several ventilation protocols to evaluate PM concentrations differences and observed that the ventilation intensity is very important in the control of air quality. Weak ventilation enhanced the accumulation of PM in the Barcelona subway stations (Martins et al. 2015). Inside the subway trains, the ventilation system provides a clear abatement of PM concentrations due to the particle deposition and filtration (Martins et al. 2015; Van Ryswyk et al. 2017). In trains where the windows are usually open, such as in Athens (carriage windows can be open by the passengers), the concentrations can increase when passing through tunnels (Martins et al. 2016), due to the entrance of polluted air from tunnels and platforms into the trains.

Interior Materials

Different manufacturers design vehicles with different characteristics such as interior volume, ventilation settings, and building materials, which highly influence the commuters' exposure (Xu et al. 2018). VOC constitute the biggest proportion of pollutants in vehicle cabin (Geiss et al. 2009). Yoshida et al. (2006) measured air pollution in 101 cars due to organic compounds diffusing from the interior materials and found 275 VOC and SVOC being the sum of the aliphatic and aromatic hydrocarbons 45% of all compounds identified.

The **main sources** of VOC in cabins are the plastics (such as polystyrene, polyethylene, polypropylene, polyamide, polyester, polyacetal, acrylonitrile-butadiene-styrene), fibers, textiles, natural or artificial leather, rubber, polyurethane foams, coatings, and adhesives, which are used to produce components in the cabin interior: steering wheel, wrapping of the steering wheel, dashboard, insulations, seats and couch, upholstery, soundproofing, roof ceiling, floor mats, and seat covers (Faber and Brodzik 2017). Chien (2007) analyzed interior parts of domestic cars and verified that 2,6-di-tert-butyl-4-methylphenol, a common antioxidant in plastics, rubbers, and petroleum products, was the most frequent chemical in the interior

parts, followed by aliphatic hydrocarbons, such as heptadecane, hexadecane, and tetradecane. Long-chain aliphatic hydrocarbons, namely tetradecane, pentadecane, hexadecane, and heptadecane, respectively, were found in most grease samples. Other long-chain aliphatics, such as eicosane (C₂₀) and docosane (C₂₂), which are commonly applied as synthesis materials or plasticizers, were found in rear panel and carpet samples. The adhesives, which are used to attach the various components of interior parts, are probably the major sources of toluene and xylene (Chien 2007). Among all the materials, it was verified that leather is an important source of VOC. According to Yoshida et al. (2006), the content of VOC increased in luxury cars where the concentrations of aromatic hydrocarbons, alcohols, ethers, furans, and nitrogen-containing compounds increased with price of the cars. Results of this work showed that the contents of alcohols and 1-methyl-2-pyrrolidone were higher in cars with leader seats than in those with fabric seats, and the concentrations of ketones, furans, styrene, and 1-methyl-2-pyrrolidone were higher in cars with leader steering wheels instead of polyurethane steering wheels.

VOC emissions can be divided into **primary and secondary emissions**. Primary emissions are emissions of non-bound or free VOC within building materials, which takes place during the first year after material production date, and are mostly low-molecular organic compounds. The secondary emissions refer to VOC that were originally chemically or physically bound, takes place over 1 year after material manufacture and is mostly connected with organic compounds which are products of degradation, hydrolysis, or oxidation reaction, and others (Kataoka et al. 2012). The concentration of the compounds resulting from the secondary emission is usually several orders lower than from the primary emission (Faber and Brodzik 2017). Therefore, the interior air inside the cabins of new cars immediately after the delivery can be always considered contaminated with very high concentrations of contaminants diffusing from interior materials that tend to decay in the following months. Yoshida et al. (2006) observed that 1 month after the delivery, the TVOC concentrations decreased to about one-fourth. Along with the time of vehicle usage, emission of organic compounds from materials is gradually replaced by emission from external sources, such as the fuel leakages and combustion of fuel. According to Bakhtiari et al. (2018), the vehicle's age increases fugitive emissions of exhaust fumes as gaskets age or joints in the exhaust train become loose. These emissions can penetrate into the cabin through gaps and lead to increased air pollutant concentrations.

Some attempts are being made to establish **indoor air quality guidelines** for passenger cars. The Japan Automobile Manufacturers Association (JAMA) launched the "Voluntary Approach to Vehicle Cabin VOC Reduction" to satisfy government demands for 13 VOC. In July 2007, the Chinese government introduced a vehicle cabin VOC regulation including buses and trucks. In Europe, several German Original Equipment Manufacturers (OEM) have set VOC targets based on VDA (Verband der Automobilindustrie) test methods. The big step to harmonization of test procedures were the ISO 12219, which outlines a method of measuring the types and concentrations of VOC in vehicle cabin air under controlled conditions, and the Mutual Resolution No. 3 (Nations 2018) that outlined the provisions and

harmonized test procedure for the measurement of interior emissions, taking into account existing standards, aiming at encouraging the reduction of the use of materials and chemicals, which can be unsafe to humans, and the increased use of emission-friendly materials, improving the air quality inside the vehicles.

Road and Traffic Conditions

Several studies have identified **horizontal pollution gradients** along traffic roads (Amato et al. 2019 and references therein). Generally, pollutant concentrations decrease with increasing distance from the road edge, being typically elevated on and near heavily trafficked roads. Recently, Amato et al. (2019) found that traffic pollutants decay to urban background concentrations on average within 67 m of the road edge, with higher distances for more busy roads. High commuters' exposure to traffic-related air pollutants are mainly associated to their close proximity to the mobile sources. Short **distance between vehicles** allows the infiltration of pollutants emitted by the neighboring vehicles, resulting in high exposures. McNabola et al. (2009) concluded that keeping a 2 m distance from the preceding vehicle can reduce the exposure to PM and VOC of 30–40% in comparison with vehicles that only keep 1 m distance.

Road traffic conditions – **light or heavy traffic congestion** – can affect the personal exposure during commuting. Commuters can reduce their exposure by travelling in low-traffic roads (Kaur and Nieuwenhuijsen 2009; Zuurbier et al. 2010). Traffic density does not affect significantly the PM10 and PM2.5 concentrations, but it has a greater influence on PNC, BC, and CO levels (Kaur and Nieuwenhuijsen 2009; Zuurbier et al. 2010). Dons et al. (2013) verified that the in-vehicle BC exposure is positively correlated with the traffic intensity.

At **traffic intersections**, there are restrictions laid by **traffic signals**, which affect the traffic flow due to the changes of driving conditions (i.e., idle, acceleration, deceleration, and cruise). At signalized traffic intersections, vehicles frequently stop with idling engines during the red-light period and accelerate rapidly when the traffic signal change to green, which produces higher emission rates. For instance, spending only 2% of commuting time at signalized traffic intersections may account for up to ~25% of the PNC total commuting exposure doses in certain situations (Goel and Kumar 2015). During typical delay conditions at traffic intersections, Goel and Kumar (2015) measured PNC during acceleration up to ~6 times higher than those during idling conditions. Moreover, they also observed that average PNC at traffic intersections during congested conditions can be up to 29 times higher in comparison with **free-flowing conditions**. Similarly, Matthaios et al. (2020) also measured high concentrations of air pollutants close to junctions and **roundabouts**.

The highest concentrations were observed in an **underground tunnel** due to the limited air dispersion (Matthaios et al. 2020). De Vlieger et al. (2000) showed that generally city journeys resulted in higher CO, total hydrocarbons (HC) and NOx emissions than in rural and ring road journeys. **Road grade** also affects vehicle pollutant emissions due to the change in the engine power demand (Zhou et al.

2016). The pollutant emissions during uphill driving increase due to the high demand of engine power (Goel and Kumar 2014 and references therein).

Traffic density varies over time. This variation influences traffic-related emissions and consequent pollutant exposures (Batterman et al. 2015). Brand et al. (2019) measured higher BC concentrations in the morning peak hours in São Paulo and Rotterdam, while in London, higher BC concentrations were recorded during the evening peak hours. In Brussels, the average CO and HC emissions during the rush hours were 80% higher than in smooth-flowing traffic, and 50% for NOx (De Vlieger et al. 2000). During rush hours (at around 13.5 km/h), CO₂ emissions doubled compared to driving at 50 km/h (De Vlieger et al. 2000).

On subway systems, PM concentrations depend largely on the operation and frequency of trains (Martins et al. 2016; Van Ryswyk et al. 2017; Woo et al. 2018).

Meteorological Variables

Meteorological conditions affect the personal exposure to pollutants during commuting. The most important variables to consider are wind speed and direction, temperature, and relative humidity.

Several commute studies have reported negative linear correlations between **wind speed** and in-vehicle air pollutants (e.g., Alameddine et al. 2016; Gómez-Perales et al. 2004; Kaur and Nieuwenhuijsen 2009; Onat et al. 2019; Rivas et al. 2017), since wind speed affects the dispersion and dilution of pollutants and thus atmospheric mixing. For example, Onat et al. (2019) found that wind speed was a significant factor influencing UFP, BC, and PM2.5 in-vehicle concentrations on four travel modes (bus, metrobus, car, and light rail) and explained up to 29%, 20%, and 11% of their variability, respectively. Gómez-Perales et al. (2004) observed reductions in PM2.5 concentrations of 22% and 24% for every 1 m/s increase in wind speed for minibuses and buses, respectively. For CO, the reductions were slightly lower, 18% and 12% for every 1 m/s increase in wind speed for minibuses and buses, respectively (Gómez-Perales et al. 2004). **Wind direction** also proved to have a considerable impact mainly when it comes to street canyons (Kumar et al. 2018).

Diverse studies found negative correlation between **temperature** and outdoor air pollutants concentrations (de Nazelle et al. 2012; Du et al. 2020; Kaur and Nieuwenhuijsen 2009; Leavey et al. 2017). Kaur and Nieuwenhuijsen (2009) verified that temperature is a significant determinant of UFP and CO exposure levels, which explained approximately 12% and 11% of the variability in the respective pollutants. When the vehicle hot exhaust gases mixes with cold ambient air results in optimal conditions to occur particle nucleation (Morawska et al. 2008). At higher temperatures, the nucleation is limited due to temperature dependence of saturation vapor pressure, resulting in lower PNC (Morawska et al. 2008). Vehicle engine operate less efficiently when cold resulting in higher emissions of products of incomplete combustion, such as CO and HC (Du et al. 2020). The cold ambient

temperatures can enhance the cold-start emissions due to the longer warm-up time (Du et al. 2020).

A strong temperature-dependent increase in the concentrations of indoor origin VOC has been reported in several studies (Chien 2007; Yoshida and Matsunaga 2006). Parking in sunlight in summer can increase the interior temperature up to 89 °C, with dashboard temperature reaching 120 °C (Mandalakis et al. 2008). A high temperature promotes the emission of VOC and may also induce photochemical reactions and the production of degradation by-products, which can be more harmful than their precursors. For example, labile decabrominated diphenyl ether, which is the main component of the widely produced flame retardant deca-BDE, can be photodegraded to more toxic tetra- and penta-brominated diphenyl ethers and brominated dibenzofurans (PBDFs) (Söderström et al. 2004). Moreover, through the hydrolysis and thermal degradation, the phthalates, which have been identified in door-panel and adhesive samples from cars (Chien 2007), can result in 2-ethyl-1-hexanol (Wolkoff 1999), a compound whose in-cabin concentrations increase with days lapsed after delivery and with temperature (Yoshida and Matsunaga 2006).

Therefore, the compounds which increase in winter are typically produced during combustion processes and are not predominantly released from equipment parts used inside the vehicle (Geiss et al. 2009). This can occur because the lowest ventilation rate inside the car during the cold period can concentrate pollutants inside the vehicle. Chien (2007) showed that the use of air-conditioning generally reduced the in-cabin VOC concentrations by reducing the interior temperature or dilution but the reduction was not statistically significant probably due to the interference from outdoor VOC.

The analysis of the UFP concentrations in London showed that **humidity** also has a positive correlation with the personal exposure levels (Kaur and Nieuwenhuijsen 2009). The relative humidity affects largely the nucleation mode particles, existing high concentrations during high humidity periods (Morawska et al. 2008). High atmospheric water content favors the formation of new particles (nuclei mode) and also the growth of particles (nuclei mode and primary particles) (Jamriska et al. 2008).

de Nazelle et al. (2012) evaluated the effect of weather variables (wind speed and direction, relative humidity, temperature) on commuters' exposure, and indicated that the only significant variables were wind speed for BC, CO₂, and CO (explaining 6.2%, 1.5%, and 1.2% of the variability, respectively), and humidity for UFP (3.6%). They did not find any significant influence of weather conditions on PM2.5 exposure levels. However, the authors mentioned that the low variance in commuters' exposure explained by weather conditions may be related with low meteorological variations during measurements. Rivas et al. (2017) indicated that among the meteorological predictor variables explored in the study (temperature, relative humidity, and wind speed), the wind speed had the strongest significant linear associations with pollutant concentrations. Comparing transport modes, the wind speed had a higher influence on bus concentrations than on car and walking (Rivas et al. 2017).

Moreover, **atmospheric stability** can also influence the personal exposure to traffic-related air pollutants over the day. Typically, mornings are characterized by stable atmospheric conditions, which favor the accumulation of air pollutants, and in afternoons occurs unstable conditions with greater dispersion (Batterman et al. 2015). Such patterns emphasize the importance of the morning traffic peak.

The impact of meteorological variables on air pollutants varied across studies, because it is dependent on location and transport mode. Although the meteorological factors can influence the ambient pollutant concentrations, the commuters can do little to reduce their personal exposure, especially those travelling by active transport or motorcycle. In subway systems, the weather conditions do not have direct effect in the indoor air quality, and it depends on the existing ventilation in these confined spaces.

Individual Behavior

Driving modes such as speed, acceleration, deceleration, cruise, and idling have an important impact on fuel consumption and vehicle pollutant emissions (Birrell et al. 2014; Sanguinetti et al. 2020). Adopting an **aggressive driving** style (i.e., sudden and frequent acceleration and braking events, late gear changes, and high driving speeds) can be responsible for reducing the fuel economy by 20–40% (Birrell et al. 2014; De Vlieger et al. 2000). De Vlieger et al. (2000) found that aggressive driving resulted in increases of CO up to a factor of 8 compared to **normal driving**. The HC and NOx emissions increased by 15–400% and 20–150%, respectively. Air resistance increases with the vehicle velocity, reducing the fuel efficiency and generating more pollution (Gonder et al. 2011). An experimental test conducted by Lee et al. (2015) indicated that UFP infiltration into passenger vehicles is location-specific and driving-speed dependent. The higher speeds favor the infiltration of UFP due to increased surface pressure. The in-vehicle BC concentrations are elevated at lower speeds (up to 30 km/h) and at speeds above 80 km/h (Dons et al. 2013). At lower speeds, the influence of the emissions from neighboring vehicles is higher. Gonder et al. (2011) verified that reducing accelerations and decelerations together (i.e., stop/start cycles) saves a larger amount of fuel in city trips, while reducing high speeds seems to be the dominant factor for improving highway driving efficiency.

The in-vehicle pollutant concentrations showed to be highly dependent on **window condition** (open vs. closed) and **ventilation setting** (in-cabin recirculation vs. outside air intake), being considerably lower with windows closed and air recirculation on (Correia et al. 2020; Kumar et al. 2021; Matthaios et al. 2020). Drivers should travel with windows closed when commuting in heavy traffic conditions to avoid the entrance of outdoor pollutants into the vehicle (Leavey et al. 2017).

Buitrago et al. (2021) evaluated the influence of **cleaning** on the air quality inside the cars. They observed that cleaning process decreased the concentrations of VOC, CH₂O, fungi, and bacteria inside the cabin.

The use of specific products in cars or by the users had been found to affect the air quality inside the cabins. Yoshida et al. (2006) analyzed the volatile components from 25 **fresheners** and found that the major components were terpenes (β -pinene, limonene, 1,8-cineole, β -linalool, dihydromyrcenol) and esters (ethylacetate, ethylbutyrate, isopentylacetate, and 4-tert-butylcyclohexyl-acetate). Limonene was the compound with maximum concentration in 11 air fresheners.

Smoking cigarettes in car generated high concentrations of several hazardous pollutants, putting occupants at increased health risk (Savdie et al. 2020 and references therein). Even under realistic ventilation conditions in cars, the tobacco smoke pollution can reach unhealthy levels (Sendzik et al. 2009). Airborne nicotine was detected in cars in which drivers or passengers smoked (Yoshida et al. 2006) and significant higher values of formaldehyde were measured in the same cars (Yoshida et al. 2006). The fabric ceiling, seats, and floor mats of the cars are likely to be major sources of nicotine and formaldehyde from tobacco, and esters and terpenes from air fresheners because textiles serve as storage media and as a reversible interim store for chemical substances due to their strong sorption ability (Yoshida et al. 2006).

Other key personal factors that have shown to affect exposure in-buses are: doors opening frequently, bus stop locations, vehicle occupancy (number of passengers), and seating location. In-bus pollutant concentrations are affected by the frequent **door openings**, because the outdoor polluted air can enter the cabin when doors open for passengers to get on and off (Zuurbier et al. 2010). Inside the subway trains, Martins et al. (2016) also observed the occurrence of short-term peaks in PM concentrations after the train doors closed, related to the turbulence and resuspension created by the passengers' movement.

Bus stops are typically located near intersections, which are characterized by high concentrations of air pollution due to the changes of driving conditions (i.e., deceleration, idle and acceleration) (Goel and Kumar 2015; Matthaios et al. 2020). For instance, Choi et al. (2018) estimated that the exposure to UFP can be reduced in 38% if the bus stop is moved from 20 to 40 m after the intersection.

Several studies have shown the **seating location** (i.e., front, middle, or back) can potentially influence the exposure of bus travelers (Vijayan and Kumar 2010; Zuurbier et al. 2010). Vijayan and Kumar (2010) measured at the back area of bus PM concentrations up to 2–7 times higher than in the front. When the driver area has a protective barrier, the driver is exposed to lower PM, BC, and PNC concentrations than the passengers (Zuurbier et al. 2010).

Some air pollutants are highly affected by the **vehicle occupancy**. A number of studies conducted inside vehicles have illustrated that the CO₂ concentrations can increase rather rapidly principally in crowded public transports and during rush hours (Martins et al. 2016; Ramos et al. 2016). Airborne microbiota is also highly influenced by the occupancy of the vehicles and consequently, the bacterial and fungi loads were found to be higher in buses and trains than in cars (Buitrago et al. 2021).

Impacts on Health

Findings from previous studies indicate that commuters inside transport cabins from private or public car, metro, train, or bus are exposed to high concentrations of air pollutants, impacting on healthy individuals but principally on health of vulnerable cohorts of the population such as children, elders, asthmatic, diabetics, and specific professional groups.

Healthy individuals commuting in roadway experienced a decrease in lymphocytes and increase in levels of red blood cell indices, neutrophils, exhaled nitric oxide, C-reactive-protein, and exhaled malondialdehyde, which indicated pulmonary and systemic inflammation and increased oxidative stress (Riediker et al. 2004; Sarnat et al. 2014). A large case-crossover study, with a total of 1459 cases, suggested that exposure during commuting increase the risk of acute myocardial infarction (Peters et al. 2013). In vitro studies indicate that underground particulate matter, as a result of its metal-rich nature, may be more toxic than urban particulate matter, principally in terms of endpoints related to oxidative stress and reactive oxygen species generation (Loxham and Nieuwenhuijsen 2019). Nevertheless, although there are quantifiable impacts on a variety of endpoints following exposure *in vivo*, there is a lack of evidence for these impacts being clinically significant (Loxham and Nieuwenhuijsen 2019).

Children are more vulnerable to the adverse effects of air pollution because they are continually growing, and their defense mechanisms are still immature. The exposure of children during commutes is linked with adverse cognitive outcomes and severe wheeze in asthmatic children (Ma et al. 2020). Among a cohort of 4741 children, McConnell et al. (2010) found that severe wheeze is linked with commuting periods for asthmatic children.

Elderly volunteers that rode for 2 h in a van modified with high-efficiency filtration system, which delivered filtered or unfiltered air to the cabin, experienced a 30% decrease in cardiopulmonary stress biomarkers and 20% decrease in the incidence of atrial ectopic heartbeats when the air was filtered (Hinds 2010). This work indicates a cardiac and vascular response of elders associated with freeway travel. Adar et al. (2007) also showed that fine particle exposures during trips aboard a diesel bus resulted in increased levels of exhaled nitric oxide in elderly adults, suggesting increased airway inflammation.

Type 2 diabetics exposed to pollutants in automobile highway trips during 1.5–1.8 h experienced a decrease in high-frequency heart rate variability the day after exposure, which was more associated with the interquartile range of UFP concentration compared to those of PM2.5, NO₂, and CO (Laumbach et al. 2010).

Professional drivers could be at risk regarding their respiratory health due to the constant exposure to traffic-related air pollutants inside vehicles (Hadei et al. 2019). Several works have showed that professional groups whose workday is constituted by long periods in TME had a higher prevalence/incidence of respiratory symptoms, such as cough, phlegm, wheezing, short breath, throat unwell, chest pain, nose discomfort, and rhino sinusitis (Hachem et al. 2019).

Measures to Reduce Exposure During Commuting

Policy makers and urban planners should make concerted efforts to reduce traffic pollutant emissions by effective implementation and enforcement of stringent policies. Glazener and Khreis (2019) conducted a systematic review of the best policies and practices to improve air quality and support active transportation in cities. They highlighted that implementing a variety of policies simultaneously, such as vehicle use restrictions, vehicle technologies improvements, emission standards, integrated public transportation, urban design interventions, and green space provision, the results are more effective. A study by Wen et al. (2020) formulated mitigation strategies to reduce pollutant concentrations in subway stations based on existing literature findings. The identified strategies are focused on preventing external filtration, limiting internal sources, and eliminating or diluting pollutants, and should be considered by subway system managers. While public policies and practices have a crucial role in improving air quality, individual actions can also be effective in reducing exposure and health risks. For instance, commuters can reduce their exposure by:

- Avoiding heavily trafficked roads and major intersections
- Keeping a distance from the preceding vehicle
- Optimizing vehicle filtration/ventilation
- Maintaining indoor cabin hygiene
- Enhancing the driving-related behavior
- Shifting from motorized to active transport
- Walking and cycling in designated paths
- Using health-optimal routing service

A deliberate effort of the population to practice mitigation measures is crucial to reduce the emission of air pollutants and therefore decrease the health effects and economic costs associated to the air pollution exposure.

Optimizing Driving Behavior

Techniques aimed at changing driving behavior such as eco-driver training, eco-routing, and on-board eco-driving feedback technologies have been demonstrating to be an effective way to reduce fuel consumption and pollutant emissions (Chen et al. 2018; Sanguinetti et al. 2020; Zhou et al. 2016). In the study by Sanguinetti et al. (2020), the use of **on-board eco-driving feedback** showed to improve the fuel economy by 6.6% on average. Chen et al. (2018) established an eco-driving behavior based on vehicle operating and fuel consumption data and provided several driving advice. The **eco-driving behavior** can be achieved by: (i) starting smoothly; (ii) accelerating moderately and evenly until desired speed; (iii) keeping steady speed (cruise mode); (iv) minimizing the brake events by keeping a proper following distance; (v) reducing the number of instances of sharp acceleration and

deceleration, (vi) using engine braking, and (vii) minimizing idling (Birrell et al. 2014; Sanguinetti et al. 2020).

Transition to Active Transportation

World Health Organization (WHO) recommends that adults get at least 150 min of **physical activity** weekly to reduce the risk of early death, cardiovascular diseases, hypertension, type 2 diabetes, and several cancers (WHO 2020). Replacing daily trips from motorized to active transport could enable commuters to achieve the daily-recommended levels of physical activity. The most common modes of active transport are walking and cycling. Proximity to motorized traffic has been associated with high cyclist and pedestrian exposure to traffic-related air pollutants (Dons et al. 2013). Nevertheless, studies have shown that active commuters' exposure can be reduced by increasing the **distance** of walk and cycle paths from traffic (Correia et al. 2020; MacNaughton et al. 2014). MacNaughton et al. (2014) observed that in cycle paths adjacent to road traffic the BC and NO₂ concentrations were around 33% higher than in cycle paths away from the vehicle traffic. They also found that the existence of a **vegetation barrier** affects the pollution concentrations; increasing vegetation density, the levels of air pollution in cycle path decrease. Urban planners should prioritize the selection of off-road walking and cycle paths and/or the inclusion of vegetation barriers whenever possible. Separated paths not only increase safety but also enhance the public perception of safety from the point of view of traffic injury, which may promote active travels (Hull and O'Holleran 2014). Thus, the creation of comprehensive and dedicated **active transport infrastructures** can therefore be an effective policy to promote population behavioral changes, leading to environmental, health, social, and equity benefits (de Nazelle et al. 2011; Mueller et al. 2015). Hull and O'Holleran (2014) makes several recommendations for improving cycling infrastructure provision.

In the past decade, health impact assessment (HIA) has been frequently used as a practical approach to evaluate potential health effects of policies, programs, and projects in the non-health sector. These potential health risks and benefits are considered during the decision-making process. Programs to change travel behaviors are crucial to incentive people to use sustainable modes of commuting. Encouraging active transportation is an effective means of promoting a more active and healthier lifestyle (Mueller et al. 2015). A shift from motorized to active transport contributes to a reduction in traffic volume and consequent reduction of air pollution emissions.

Active commuters may inhale more air pollutants than motorized commuters when travelling the same distance/route due to both longer journey times and higher inhalation rates (de Nazelle et al. 2012, 2017; Martins et al. 2021; Zheng et al. 2021; Zuurbier et al. 2010). Authors of a systematic review (Cepeda et al. 2017) calculated the motorized-to-active travel dose ratios of pollutants based on 12 studies; they obtained the following median ratios: 0.22 for car, 0.38 for motorcycle, 0.49 for rail transport, and 0.72 for bus. Nevertheless, HIA studies have stated that the **health benefits** from physical activity during active transportation largely **outweigh the**

risks associated with the high inhaled dose of traffic-related pollutants (Mueller et al. 2015 and references therein). Andersen et al. (2015) indicated beneficial effects of physical activity on mortality even in high air pollution areas.

Several studies have been estimating the overall impact of switching commutes from motorized to active transport. Cepeda et al. (2017) calculated differences in terms of years of life expectancy (YLE) according to differences in fine particulate inhaled dose and physical activity when commuting, and they concluded that motorized commuters lost up to 1 year more in YLE than cyclists. A Swedish study estimated the potential effects on mortality by shifting commuting from car to bicycle of 111,000 people in Stockholm County area. In annual terms, the reduction of population exposure to NOx related to this modal shift can avoid 63 premature deaths and save 449 years of life (Johansson et al. 2017). The extensive study conducted by Rojas-Rueda et al. (2016) assessed the potential health impacts of reaching two active transportation targets (35% cycling and 50% walking) in six European cities (Barcelona, Basel, Copenhagen, Paris, Prague, and Warsaw), considering the changes in physical activity, exposure to PM2.5, and traffic fatalities. These targets are based on the real levels of cycling in Copenhagen and walking in Paris. The highest benefits can be achieved with the increment of cycling trips to 35%, which can avoid annually around 113 deaths in Warsaw, 61 in Prague, 38 in Barcelona, 37 in Paris, and 6 in Basel. Increasing the walking trips to 50% can avoid approximately 20 deaths per year in Warsaw, 11 in Prague, 6 in Basel, 4 in Copenhagen, and 3 in Barcelona (Rojas-Rueda et al. 2016). Moreover, recent findings reported by Dinu et al. (2019) support the evidence that active commuters can reduce in 8% the risk of all-cause mortality, 9% the cardiovascular disease incidence, and 30% the risk of diabetes. Commuting by cycling was associated with a significant lower risk of all-cause mortality (-24%) and a reduction of 25% of total cancer incidence. The associated environmental benefits from active transportation include the reduction of energy consumption and greenhouse gas emissions (Rabl and de Nazelle 2012).

Healthier Routes Planning

Commuters' exposure may vary substantially depending on the selected route (Hertel et al. 2008). Typically, the commuters tend to choose the route based on the shortest time duration or the shortest distance. **Route planner** incorporating air pollution information may encourage the population to choose the lowest exposure route (Hertel et al. 2008).

Several studies have shown that the mobile air pollution monitoring systems can effectively be used to derive **accurate pollution maps** with high spatiotemporal resolution (Devarakonda et al. 2017; Santana et al. 2021). Using large quantities of sensors in wireless networks can increase the coverage area and spatial distribution of the monitoring systems, especially if mounted on mobile platforms. The deployment of sensor nodes on vehicles, enables the automated collection of large, spatially resolved data sets. Recently, the ExpoLIS project developed a novel and affordable vehicle-mounted sensor system to obtain accurate and fine-grained air pollution road

maps (Santana et al. 2021). A **health-optimal routing service** was developed to help users to reduce their exposure to air pollution by not taking the shortest path between origin and destination but a healthier and slightly longer alternative route, based on multi-criteria optimization techniques.

The online route plan tool “Route2School” provides schoolchildren with indication of less polluted routes to-and-from school (Ahmed et al. 2020). In a study area context (in Antwerp, Belgium), **cleaner alternative routes** have been found for nearly 34% of the commuting trips, with a difference of NO₂ concentration of around 10 µg/m³ between the alternative and the current choice of route. In similar study conducted in Montreal (Canada), the alternative routes were estimated based on the shortest distance and less polluted route; approximately 57% of the cycling trips can be changed by cleaner alternative routes (Hatzopoulou et al. 2013).

Zou et al. (2020) proposed an innovative healthier route planning method that estimates the potential adverse health effects associated to the PM2.5 exposure in routes located in Beijing-Tianjin-Hebei (China). While the other studies consider the distance length, time duration, and pollution exposure, this study also introduces the exposure-response relationship, enabling the identification of routes with lower potential health effects.

In contrast to the previous studies, Vamshi and Prasad (2018) proposed a dynamic route planning algorithm to divert the traffic from busy junctions to low traffic junctions in real time. Thus, the algorithm provides the shortest route with smallest number of busy junctions and therefore reducing the existence of air pollution hotspots at traffic junctions. This algorithm tries to avoid amount and time of air pollution exposure to the commuters travelling from a source to destination.

All these studies suggest that commuters can reduce significantly their exposure to air pollutants and consequent health risks by adopting the suggested less polluted routes.

Conclusions

Transport is a ubiquitous component of life, and the scientific community findings suggest that exposures incurred during commuting can contribute substantially to daily exposure and be associated with adverse health effects in healthy people and susceptible population. Although commuters typically spend less than 10% of their time in vehicles, the emissions from various interior materials of vehicles and the exhaust emissions carried by ventilation supply air are significant sources of air pollutants, which can lead to unhealthy human exposure due to their high concentrations inside vehicles’ cabins. The measures to lower the in-cabin exposure levels of air pollutants include optimizing vehicle ventilation and filtration, avoiding trafficked roads and rush hours, maintaining indoor cabin hygiene, and pre-bake-out of interior materials prior to installation to vehicles.

There are no specific regulations to control air quality within TME, even in public transports systems. Various regulatory bodies have defined limit values for several ambient air pollutant, but these are meant to control ambient pollutant concentrations

and do not represent the human exposure during commuting that varies considerably between different TME and different conditions in each transport mode. Besides that, regulatory levels for important transport related pollutants, such as BC and UFP, are still nonexistent. Therefore, the results reported by the scientific community about the concentrations of pollutants in different TME, factors influencing the exposure while commuting and health impacts are very useful for exposure analyses and may inform planners and decision makers on urban policies. Policy makers need to recognize that commuting contributes substantially to overall pollutant intake and can lead to detrimental health impact and help address air pollution while promoting active travel to yield substantial health benefits in the population.

Abstract

This chapter deals with the air quality in means of air transportation. Since air travel in large passenger aircraft represents the vast majority of travel, the air quality in commercial aircraft cabins is vitally important to the public.

At typical cruising altitudes between 31,000 and 41,000 ft (about 9,500 and 12,500 m), ambient conditions of very low temperature and pressure, elevated ozone concentrations, and dry air constitute a hostile environment to human beings. To create a life-supporting atmosphere inside the aircraft, environmental control systems provide appropriate regulation of pressure, temperature, and ventilation in the cabin. As aircraft cabins increasingly become part of the normal habitat for humans, passenger and crew expectations for the cabin environment are rising, leading to additional requirements for environmental control systems.

Air pollution sources in aircraft cabins can be attributed to passengers and their personal hygiene, activities in the cabin, carry-on luggage, cabin equipment and materials, outside air contaminants, and very rarely, to abnormal conditions or pollution of system components like compressors, ducting, or fans in the air supply path.

Many volatile organic compounds (VOCs) found in aircraft cabins do not differ from compounds found in residential buildings and offices, and concentrations are in the same range or even lower. Some semivolatile organic compounds (SVOCs) from, e.g., flame-retardants or operational fluids are more specific for the aircraft environment but only occur in trace concentrations. Environmental ozone can be reliably reduced in high-temperature sections of the air supply system and by employing converters. Average carbon dioxide concentrations are higher than in other environments but are kept well below regulatory limits for aircraft cabins.

Introduction

Commercial air traffic has significantly increased over the past seven decades with cabin air quality becoming a topic of interest during the same period of time (Crump 2016). In 2019, more than 4.5 billion passengers traveled on board commercial airplanes (Mazareanu 2021). The continuous growth of air travel during the last decades was abruptly interrupted by the SARS-CoV-2 pandemic in early 2020. However, a recovery to prepandemic passenger numbers is expected by 2023–2024 (Airports Council International 2021).

Aircraft cabins represent a special indoor environment for both mainly sedentary passengers and more active cabin crew, and also sedentary pilots in the cockpit. They all encounter high daytime solar loads, reduced pressure (depending on the flight altitude down to 755 hPa), high air change rates, low relative humidity (5–15% r. h.), high occupant density, continuous noise, and three-dimensional motion (Space et al. 2000). Moreover, limited mobility while flying across multiple time zones affects one's circadian rhythm. Cabin conditions may influence the perception of the cabin environment, comfort, and well-being.

Air quality investigations in the past focused on passenger cabins in commercial aircraft with passengers and flight attendants as their occupants. Some studies also addressed cockpits with regard to pilots' working environment. Consequently, several studies investigated cabin air quality and its effect on passengers (Nagda and Rector 2003; Spicer et al. 2004; Lindgren and Norbäck 2005; Spengler et al. 2012; Ahmadpour et al. 2014; Harshada and Mirabelle 2017; Rosenberger 2018) and crew (Griffiths and Powell 2012; McNeely et al. 2014; Wolkoff et al. 2016).

The air quality in the aircraft cabin is mainly controlled by ventilation. The ventilation of aircraft cabins is controlled by an Environmental Control System (ECS). The main tasks of the ECS on board of an aircraft are to ensure proper pressurization of the cabin, to maintain a comfortable thermal environment and air quality for the health and well-being of passengers as well as the working conditions for crew members. The ECS also provides air for other features such as cargo ventilation and air conditioning, potable water, hydraulic reservoir pressurization, and anti-icing for wings and engines.

The ECS provides the necessary amount of air and mixes the cabin-recirculated air with fresh (outside) air. During flight, the air outside of the aircraft is very cold (-56°C), dry (<1% relative humidity at cabin conditions), and low in pressure and hence in oxygen partial pressure (comparable to <5% oxygen on ground), i.e., hostile to human life (ASHRAE 161 2018). The outside air is normally taken from the jet engine compressors before the combustion chamber. Since the withdrawal of already pressurized air from the compressors negatively affects the energy balance of the engine, this air is called bleed air (Hunt et al. 2000). Only one type of aircraft (Boeing 787) currently does not use bleed air but uses separate electric compressors to provide outside air to the cabin (bleed less air). Besides removing contaminants generated in the cabin, ventilation is used to remove the heat generated by the occupants and electrical systems such as inflight entertainment.

The air change rate in the aircraft cabin is about 15 to 20 times per hour with outside air. This air change rate is much higher than in residential or office buildings and even higher than in a surgical or critical care facility (AIA 2001). During ground operations, the air from outside may bring in contaminants such as exhaust from ground support equipment and other aircraft. At cruise altitudes, ozone from the troposphere can be brought into the aircraft cabin (ASHRAE 161 2018; SAE 4766/2A 2021). Particles are removed in the recirculated air path by high efficiency particulate air (HEPA) filters, but bio-effluents from occupants and other pollutants generated in the cabin will be recirculated back to the cabin. These pollutants are diluted with outside air.

Volatile organic compounds (VOCs) can partially be removed on aircraft equipped with carbon-based air purification systems, which are available as standard or optional features on selected aircraft (Donaldson 2018; Simpson et al. 2019). Aircraft are equipped or can be equipped upon airline request with optional personal air outlets (PAOs) above each aircraft cabin seat allowing an adjusted direct air flow to the head/body of the passengers for enhanced personal control of thermal comfort.

Rarely, abnormal events inside or outside the cabin may compromise cabin air quality.

Air Supply in Means of Air Transportation: The Environmental Control System (ECS)

Commercial Aircraft

Introduced in 1918 (and retired in 1931), the British USD.9A was the first attempt at pressurizing an aircraft crew compartment to enable higher altitude flights while providing a life-sustaining environment for the pilots. Most commercial airliners were pressurized by the 1950s enabling high-altitude flights, which were subject to less air turbulence, with improved comfort, range, and fuel efficiency.

Early jet airplanes did not have cabin air recirculation systems and provided 100% outside air for pressurization and ventilation. Bleed air-driven cabin air compressors were used in the first commercial pressurized cabins, such as the Boeing Stratoliner (1938–1945), 707 family (produced 1956–1978), and McDonnell Douglas DC-8 Family (produced 1955–1972). Early jets were powered by highly inefficient turbojet engines in which all the air entering the engine went through the core to provide thrust. Fuel consumption was very high. A small percentage of the total core flow was used to provide outside air to the cabin. Engine technology progress resulted in turbofan engines with a core bypass ratio of about 2 to 1. Fuel consumption for outside air supply was still small enough to make 100% bleed air provision to the cabin cost effective. At that time, average flight lengths were shorter and a lower percentage of direct operating costs was attributable to fuel. Modern turbofan engines have a high 5 to 1 bypass ratio and are much more fuel-efficient. With that, the percentage of fuel needed for outside/bleed air supply significantly increased, almost proportional to higher bypass ratios (Hunt et al. 2000).

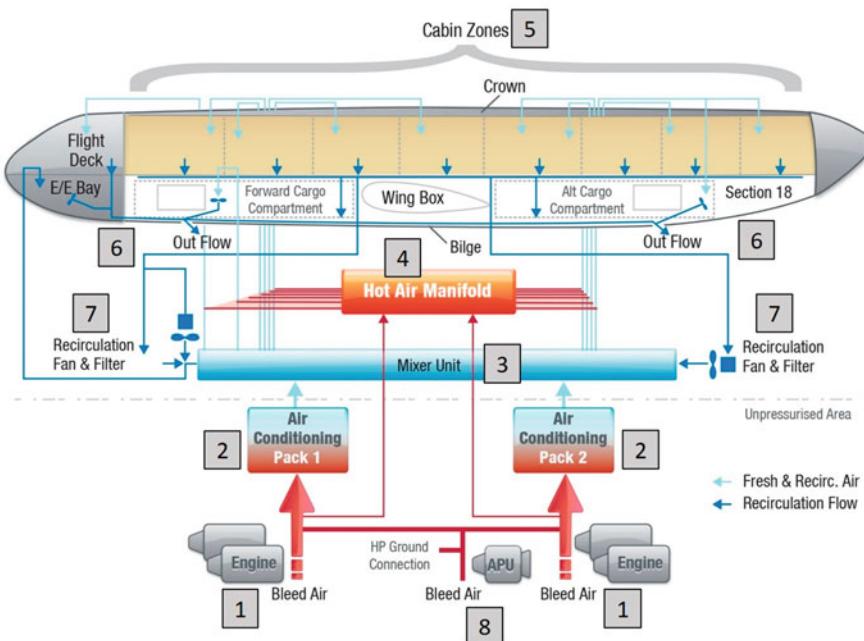

Fig. 1 Simplified Environmental Control System (ECS) on board of commercial aircraft (with exception of B787) – air path for cabin ventilation (© Airbus SAS 2021. All rights reserved)

In the 1960s, increasing needs for more air supply with increasing aircraft size, and the continuous increase in engine bypass ratios with newer engines, resulted in a change in the utilization of the engine compressors and cooled bleed air (through air conditioning packs) to improve efficiency and to eliminate the added weight of external cabin air compressors.

The working principle of a commercial aircraft ECS is shown in Fig. 1. For air supply to the cabin during flight, compressed air is taken from the jet engines compressors before the combustion chamber (#1). An exception is the B787, which does not use engine bleed air per se but an electric compressor to provide outside air. Bleed air has a pressure of up to 40 bar and due to adiabatic compression temperatures may exceed 649 °C (1200 °F) (SAE ARP1796B 2020) depending on the compression ratio during takeoff on limited occasions. Typical takeoff bleed air temperatures are about 350 °C (662 °F) and cruise bleed air temperatures are about 250 °C (482 °F) (NRC 2002). The fraction of air for the ECS cannot be used for thrust, consumes about 2–5% (Rosero et al. 2007) to 3–5% (Zavaglio et al. 2019) of fuel, and contributes to the CO₂ footprint of an aircraft.

On some aircraft, the bleed air is led through an ozone converter to deplete atmospheric ozone especially on polar routes. Bleed supply air is guided from the engine compressors to the air conditioning packs (#2) by which it is cooled down in several steps to typically less than room temperature using outside air as cooling

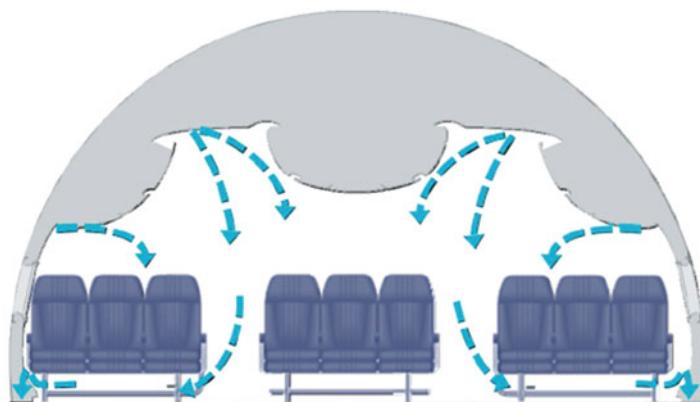

Fig. 2 Cabin cross section with typical airflow from ceiling/lateral outlets to floor dado panels exhaust (© Airbus SAS 2020. All rights reserved)

medium and air cycle machines for compression and expansion cooling. The conditioned outside air then enters the Mixer Unit (#3) where it is mixed with the recirculated air from the cabin. The resulting supply air is typically composed of 40–60% outside air and 60–40% recirculated air depending upon the aircraft model and derivative, the cabin layout, and the actual number of occupants under normal operating conditions (Bezold 2009).

The outside and recirculation airflow split to the flight deck can vary depending upon airplane model and requirements for solar and electronic heat loads (NRC 1986). Some aircraft models supply outside air only to the flight deck under normal operating conditions. A portion of the hot bleed air – the so-called trim air – bypasses the air-conditioning packs to the hot air manifold (#4) for temperature control. The air leaving the Mixer Unit is ducted to each individual temperature control zone in the aircraft (#5, typically 3 to 9, up to 16 zones (A380) in the occupied cabin, including flight deck); if necessary, hot trim air (small amount of bleed air) is used to adjust the air mix to each temperature control zone to provide the desired temperature and then supplied to the cabin from ceiling outlets typically located above and/or below the overhead bins (see Fig. 2).

The airflow in the cabin is generally from top to bottom, either from the ceiling supply outlets above and/or below the overhead bins (lateral) or the personal air outlets above each seat (if equipped) to the cabin return air outlets at floor level at the lower part of the sidewall lining (dado panel). The return air grilles at floor level run the length of the cabin on both sides. The airflow along the cabin from zone to zone is limited.

Approximately 50% of the cabin return air leaves the aircraft by the outflow valves (#6) that are also used to regulate the cabin pressure. The other portion of the cabin return air is guided through HEPA filters (#7), back to the Mixer Unit, and is used again. Recirculation filters may contain additional carbon-based adsorption layers. They are standard on B787 and available as an option for several other aircraft platforms.

Highly efficient recirculation systems were enabled from studies conducted with the National Aeronautics and Space Administration (NASA), the McDonnell Douglas Aircraft Company, and American Airlines in the 1970s. Results indicated that the use of recirculating air allowed a corresponding decrease of bleed air and subsequent fuel savings when applying HEPA filters without compromising cabin air quality (Hunt et al. 2000). The Boeing 757 and 767, brought into service in 1982, and Airbus A300 in 1988 provided cabin air by mixing outside air with filtered recirculated air.

HEPA filters can remove at least 99.95% (ISO 29463-1 2017) or 99.97% (NASA 2016) of particles from air, including spores, bacteria, and viruses. The filters can provide essentially particle-free air through the recirculation system (Strøm-Tejsen et al. 2008; NASA 2016). Additional activated carbon-based filters, offered as optional feature, can effectively reduce the concentration of VOCs in the recirculated air (Schuchardt et al. 2017, 2019; Rosenberger 2018; Destaillats et al. 2018). Air purification was found to be a more important factor than increased humidity for addressing many aspects of passenger and crew complaints including eye, nose, and throat irritation and general dryness (ASHRAE 1999; Strøm-Tejsen et al. 2008; Spengler et al. 2012; Weisel et al. 2017).

The volume of outside air corresponding to the cabin volume is added to an aircraft cabin about every 3 min, so the air change rate with outside air is about 20 h^{-1} . Aircraft are typically overventilated to ensure that minimum regulated airflow requirements are met (see requirements section). In 1986, the NRC found that if the lowest rate of ventilation permitted by current equipment design had been used under nearly full or full occupant loads, the air quality would have been acceptable for nonsmoking flights (NRC 1986).

On ground, supply air may be generated by the auxiliary power unit (APU, #8) drawn in at the back of the aircraft and supplied to the air-conditioning packs or is provided by fixed or mobile air-conditioning units at the airports. An industry standard is currently being drafted that will require ground cart air to be purified (filtered) prior to provision to the air-conditioning packs (high-pressure ground connection) or the mixing manifold (low-pressure ground connection). Ozone converters with VOC reduction capabilities for use during ground operation are also available. The APU may also provide air supply during flight up to a certain flight level.

The ECS must deliver a minimum of 0.28 m^3 (0.55 pounds, 0.25 kg) per minute per person outside air during normal operation to maintain pressurization, thermal control, and avionics cooling (EASA 2020; FAA 2021, see requirements section). For a probable failure condition, the amount of air supplied should not be less than 0.18 kg (0.4 pounds, 0.2 m^3) per minute per person for any period exceeding 5 min (EASA 2020; FAA 2021).

Air-conditioning pack hybrid systems that utilize a combination of air cycle and vapor cycle systems to improve system efficiency are currently under research. Additionally, variable airflow systems that utilize outside and purified airflow to enable improved air quality, airplane economics, and lessen engine emissions are installed on selected aircraft today and currently investigated as well.

New optimized ECS units have the potential for reducing fuel consumption and engine emissions by reducing the outside ventilation rate while increasing filtered/purified airflow to improve overall air quality and comfort. It is estimated that an optimized ECS aircraft could potentially save nearly 0.8%–2% of the fuel in comparison with traditional ECS if the outside air supply rate could be reduced with commensurate increase in filtered/purified airflow (Newman and Viele 1980; Zavaglio et al. 2019).

Business Jets and Helicopters

Business jets and helicopters have similar regulatory requirements for cabin air environment as larger commercial airliners. However, due to weight, cost constraints, and mission profiles, they often do not utilize recirculated cabin air but utilize 100% outside / bleed air to provide air to the cabin and cockpit. In addition, some of these systems may be equipped with vapor cycle, rather than air cycle air-conditioning systems. Vapor cycle systems utilize compressed refrigerant for cooling (SAE ARP 292D 2020). They have traditionally been used because of their high heat capacity and small size. More recently, air cycle machines have been developed that meet the requirements for conditioning business jets and helicopters and are being employed for cooling. Some more complex business jet ECS systems utilize a jet pump to extract cabin air and mix it with incoming air from the ECS pump. Filtration and humidification are also provided as an option on some business jet air supply systems.

Helicopters fly at much lower elevations than jets and do not have a pressurized cabin. Because of the low number of people (crew and passengers) and the low heat load on board, outside air supplied to the cabin of helicopters and business jets is not cooled as much as in commercial aircraft.

Requirements

Regulations

Large airplanes (20 or more passengers) have to fulfill certification requirements of authorities such as Federal Aviation Administration (FAA) in the US or European Aviation Safety Agency (EASA) in Europe. These requirements contain limited regulations on cabin air quality for minimum ventilation rates, sufficient outside air supply to enable the crew members to perform their duties without undue discomfort or fatigue, and limit maximum concentrations for carbon dioxide (CO_2), carbon monoxide (CO), and ozone (O_3) (FAR, CS 25.831 and 25.832, Table 1). The Chinese CCAR has adopted FAA and EASA requirements. In addition, the Russian AP-25 regulation lists maximum values for nitrogen oxides (NOx), selected volatile organic compounds (VOCs), and semi volatile organic compounds (SVOCs) that shall not be exceeded.

(continued)

Table 1 (continued)

Country	Mandatory				Voluntary
	USA	EU	China	Russia	USA
SVOCs	–	–	–	Tricresyl phosphate 0.5 mg/m ³ Diocetyl sebacate 5 mg/m ³	–

The major source of CO₂ within the aircraft are occupants; during the SARS-CoV-2 pandemic, another temporary source was introduced by additional carriage of dry ice to keep COVID 19 vaccines cold. Since the ban of on board smoking, the major source for CO is incomplete combustion from aircraft and ground support vehicles exhaust that may be ingested into the bleed air supply. For O₃, the main source is air outside the aircraft during ground operations and during high altitude, high latitude flights that may be ingested by the engine systems.

The oxygen (O₂) partial pressure on commercial aircraft is set by regulation FAR 25.841 that limits the cabin altitude to a maximum of 8,000 feet (2438 m, 753 hPa), only reached at the highest certification flight altitude of the airplane. Airplanes typically fly with a cabin altitude between 5500 feet (1676 m, 827 hPa) and 7000 feet (2134 m, 782 hPa).

Mandatory Standards

Current airworthiness standards (FAA) or certification specifications (EASA) require that each passenger and crew compartment be ventilated with a sufficient amount of uncontaminated (fresh) outside air (at least 0.55 lb./min per occupant) to enable crew members to perform their duties without undue discomfort or fatigue and to provide reasonable passenger comfort (EASA 2020; FAA 2021).

Regulators may permit alternative variable flow systems in future designs if the system designers can ensure that air quality is equivalent or better than that provided by current system designs. An equivalency approach to control air quality in buildings is being addressed by ASHRAE Commercial Building Standard 62.1 (ASHRAE 2019a) through its Indoor Air Quality Procedure, which is further detailed in a future Guideline 42P that is currently under development and will likely be published in 2022. No such solution has been applied in aircraft so far.

Voluntary Guidelines

Besides the mandatory air quality requirements from certification authorities, some voluntary documents suggest additional limits for environmental parameters related to the aircraft cabin. Among these, ASHRAE Standard 161 Air Quality within Commercial Aircraft (2018) provides guidance for factors affecting air quality

such as temperature, humidity, pressure, and ventilation, including contaminants, (counter-) measures, and measurement procedures. The standard is accompanied by Guideline 28: Air Quality within Commercial Aircraft (ASHRAE 2016), which gives supporting information.

Additional documents addressing air quality in aircraft and possible contamination sources have been and are being elaborated by SAE Aerospace Council:

- SAE ARP 4418B 2018 describes a Procedure for Sampling and Measurement of Aircraft Propulsion Engine and APU Generated Contaminants in Bleed Air. It outlines recommended practices to quantify the concentrations of a subset of bleed air-contaminant marker compounds on an aircraft propulsion engine or APU prior to delivery and installation on civil and military aircraft.
- SAE AIR 7521 2018 provides Measurement Data and Reference Values for Compounds Potentially Found in Aircraft Engine Bleed and summarizes published measurement data and reference values for marker chemical compounds listed in ARP 4418 potentially found in aircraft engine bleed air.
- SAE AIR 4766 2018 provides information on Air Quality for Commercial Aircraft Cabins and some of the factors affecting the perception of cabin air quality in commercial aircraft cabin air.
- SAE AIR 4766/2A 2021 provides information on Airborne Chemicals in Aircraft Cabins, including origins of chemical airborne contaminants during routine operating and failure conditions as well as exposure control measures.
- SAE AIR 1539C 2020 provides information on liquid and particulate contaminants as well as gaseous contaminants such as ozone or fuel vapors, etc. which may enter the aircraft through the Environmental Control System (ECS) from outside.
- SAE AIR 6418, under development since 2016 and to be published in 2022, will detail Sampling and Measurement of Bleed Air Supplies from Engines or APUs and will consider a broader range of contaminants than ARP 4418.

Whereas US standardization groups within ASHRAE and SAE have made progress in elaborating voluntary standards and informative guidelines on cabin air quality, the European Union has been struggling to develop a European cabin air quality standard with concrete requirements since the withdrawal of EN 4618:2009 (Aerospace series – aircraft internal air quality standards, criteria, and determination methods) in 2013. prEN 17436:2021 (Cabin air quality on civil aircraft – chemical compounds) was rejected by national standardization bodies in the 2nd enquiry in 2021 and may now be downgraded from a standard to a Technical Specification (TS) or Technical Report (TR) or the work will be stopped completely because the responsible Technical Committee within CEN (Comité Européen de Normalisation, European Committee for Standardization) did not come to an agreeable wording that is acceptable for sufficient positive votes from national standardization bodies. EN 4618:2009 was a performance-based standard providing health, safety, and comfort limit values for selected possible contaminants of cabin air. The current draft prEN 17436:2021 in contrast is written as a descriptive standard giving – similar to abovementioned US Standards – no clear pass/fail criteria for cabin air quality parameters.

Outside Air Supply Rate

Outside air supply rates for aircraft cabins reported in the literature ranged from 1.7 to 39.5 L/s per person with an average of 6.0 ± 0.8 L/s/p and a median of 5.8 L/s/p, respectively (Wieslander et al. 2000; Lindgren and Norbäck 2002; Spicer et al. 2004; Spengler et al. 2012; Giaconia et al. 2013; Li et al. 2014; Guan et al. 2015; Cao et al. 2019; Liu et al. 2020). All of the reported average values exceeded the minimum required outside air supply rate of 0.55 lb./min/p (3.5–4.7 L/s/p, 0–8000 ft. pressure) (ASHRAE 2018; FAA 2021; CCAC 2016); most even reached the recommended value of 4.7 L/s/p (EASA 2020) or 5 L/s/p stated by the ASHRAE Handbook (2019b).

Relative Humidity

The main sources of humidity in an aircraft cabin during flight are exhaled air and perspiration from the occupants and beverage service. For some aircraft models, humidification systems are available as an option for dedicated cabin areas or crew rest compartments.

Relative humidity measured in aircraft cabins ranges between 0.9% and 77% (Nagda et al. 1992; ASHRAE 1999; Lee et al. 1999; Haghigat et al. 1999; Dumyahn et al. 2000; Ree et al. 2000; Wieslander et al. 2000; Nagda et al. 2000; Lindgren and Norbäck 2002; Waters et al. 2002; Spicer et al. 2004; MacGregor et al. 2008; Spengler et al. 2012; Gladyszewska-Fiedoruk 2012; Giaconia et al. 2013; Schuchardt et al. 2017). The lowest levels most likely occur in cabins during cruise with very few passengers on board and the maximum levels likely on ground at airports in humid climates shortly after closing the doors. The average reported relative humidity was $16\% \pm 5.0\%$; the median was 17%. Reported measurements are from all flight phases, and it is difficult to separate the measurements reported in different studies according to the flight phase.

Standards do not give guideline values for the relative humidity in aircraft cabins; however, for buildings, levels around $40\% \pm 20\%$ (CEN EN 16798-1:2019 recommends a range from 20 to 70%) are considered comfortable. Such humidity levels cannot be reached on aircraft because of the dry outside supply air (< 1% during cruise) used for air conditioning and would require substantial additional weight for humidification with increased risk of water condensation or icing on the cold fuselage during cruise and subsequent moisture damage to aircraft structures or electric systems.

Selected Pollutants in the Aircraft Cabin

Carbon Dioxide (CO₂)

CO₂ created by metabolism is exhaled by the crew and passengers on board, and the level depends on the number of people present and the dilution by ventilation rate, and it is therefore an indicator of outside ventilation per occupant. Dry ice carriage can also influence the CO₂ level in the cabin.

Several studies measured CO₂ concentrations in aircraft cabins (Chen et al. 2021). Some studies mentioned that values were automatically or manually corrected for pressure changes (ASHRAE 1999; Dumyahn et al. 2000; Nagda et al. 2000; Lindgren and Norbäck 2002; Waters et al. 2002; Spicer et al. 2004; Li et al. 2014; Guan et al. 2015; Cao et al. 2019; Liu et al. 2020), whereas some did not report whether a pressure correction was applied (Nagda et al. 1992; Lee et al. 1999; Haghigheh et al. 1999; Wieslander et al. 2000; Spengler et al. 2012; Gladyszewska-Fiedoruk 2012; Giaconia et al. 2013; Schuchardt et al. 2017; Rosenberger 2018). For the first group, the minimum measured CO₂ concentrations were in the range of 410 to 874 ppm, and the maximum in the range of 1485 to 3374 ppm with an average concentration of 1315 ± 232 ppm and a median of 1387 ppm. For the second group, the minimum measured CO₂ concentrations were in the range of 293 to 1100 ppm, and the maximum in the range between 1190 and 5177 ppm, the average CO₂ concentration was 1320 ± 302 ppm, and the median was 1404 ppm. The differences of mean and median between the two study groups are only marginal. However, in the second study group the lowest values reported were lower than the CO₂ concentration in outdoor air, ranging then between 365 and 390 ppm (Sawa et al. 2004; Foucher et al. 2011; Tuzson et al. 2011; ASHRAE 2019b).

All measured CO₂ concentrations were below the regulatory, standard maximum level, occupational health and workplace exposure limit of 5000 ppm (EASA 2020; FAA 2021; CCAC 2016; IAC 2005) with one exception. All average and minimum CO₂ concentrations measured were lower than 2000 ppm, and the reported average CO₂ concentrations were mostly above 1000 ppm, which is generally considered the target for achieving acceptable air quality in low-density occupied buildings for control of building-generated contaminants and odor perception of visitors (Fisk et al. 2019). CO₂ concentrations were usually highest during boarding and deplaning (deboarding) and lowest during cruise. CO₂ concentrations showed a slightly decreasing trend over the last 30 years (He et al. 2021).

Carbon Monoxide (CO)

The source of CO is mostly outside the aircraft, incomplete combustion from vehicles on ground, and enters by ingestion.

CO concentrations measured on board of aircraft (Nagda et al. 1992; ASHRAE 1999; Lee et al. 1999; Nagda et al. 2000; Waters et al. 2002; Spicer et al. 2004; Spengler et al. 2012; Schuchardt et al. 2017; Rosenberger 2018) were in the range of below the limit of detection (LOD) to 9.4 ppm with a median of 1 ppm and a mean of 0.8 ± 0.3 ppm and below standard limits, the maximum value however came close to the 9 ppm 10 min TWA limit (Table 1) during ground operation.

Ozone (O₃)

O₃ may enter the aircraft cabin from outside during cruise, especially on high-altitude polar routes and at some airports during ground operations. Aircraft fly in

the troposphere at elevations generally up to 41,000 feet (Spengler et al. 2004; Yates et al. 2017); some aircraft are even certified for levels up to 43 or 45,000 ft. (B777, B767, B747). At these altitudes, the ambient concentrations of O₃ range between 25 and 900 ppb (WHO 2005; Weisel et al. 2013; Bhangar and Nazaroff 2013) and up to 1800 ppb at 45,000 ft. in winter on polar routes (AC 120-38, FAA 1980). Tropospheric ozone levels have been steadily increasing since AC 120-38 issued guidance on meeting ozone destruction efficiency requirements in 1980 (Cooper et al. 2014).

When entering the cabin, O₃ will decompose on surfaces and may also react with other pollutants in air and on surfaces and may generate new compounds (Weisel et al. 2013). Ozone can be removed from outside air. Ozone removal efficiency in aircraft systems considers the ozone destruction potential of the entire system, including the high temperature areas in engine and bleed air systems, the ozone converter itself, and the other surfaces within the air supply and distribution system.

The levels of O₃ measured in aircraft cabins were between 0 and 275 ppb. The average concentration of O₃ reported was 38 ± 30 ppb, and the median was 33 ppb. Most levels were below 250 ppb, which is the peak regulatory limit for O₃ in aircraft cabins, but some peak measurements exceeded 100 ppb. Regulations limit ozone to 250 ppb peak and 100 ppb three-hour time-weighted average (EASA 2020; FAA 2021; CCAC 2016; IAC 2005). All mean levels reported were below 100 ppb. However, on selected flights average concentration exceeded the recommended airborne exposure levels averaged over 8 h for heavy workloads by the American Conference of Governmental Industrial Hygienists (ACGIH) of 50 ppb. Since ozone is an irritant, on routes where high outside O₃ concentrations are expected, NRC (2002) and ASHRAE 161 (2018) recommended that O₃ converters should be employed and O₃ should be monitored continuously. However, the current certification regarding O₃ rather aims at a robust design of O₃-converter efficiency to reduce O₃ sufficiently until the end of its useful life since an O₃-monitoring concept can be complex and error-prone.

O₃ levels reported in many studies (ASHRAE 1999; Dumyahn et al. 2000; Spicer et al. 2004; Spengler et al. 2004, 2012; Bhangar et al. 2008; Weisel et al. 2013; Ji and Zhao 2014; Gao et al. 2015; Schuchardt et al. 2017; Rosenberger 2018) have been decreasing over time, as more attention has been paid to ozone in aircraft cabins and the utilization of catalytic ozone converters on flights where elevated ozone levels may occur (Chen et al. 2021).

Volatile Organic Compounds (VOCs)

Previous investigations of cabin air quality measured VOC contamination by different sampling methods: active sampling on adsorbent tubes, or passive sampling by diffusion samplers, or (vacuum) canister sampling. Most studies (Dechow et al. 1997; ASHRAE 1999; Waters et al. 2002; Crump et al. 2011a, b; Spengler et al. 2012; Weisel et al. 2013; Ji and Zhao 2014; Guan et al. 2014; Wang et al. 2014a, b; Gao et al. 2015; Rosenberger et al. 2016; Schuchardt et al. 2017) used active

sampling. By that method, a total of 140 VOCs were detected and measured. Passive sampling was only used in a few studies (Wieslander et al. 2000; Lindgren and Norbäck 2002; Spicer et al. 2004; MacGregor et al. 2008) and resulted in 48 detected VOCs. Five studies used canister sampling (Nagda et al. 2000; Spicer et al. 2004; Spengler et al. 2012) to measure 96 VOCs.

The concentrations of VOCs detected by active sampling ranged from 0 to 3 mg/m³ with the highest levels often obtained during meal service (ASHRAE, 1999, Schuchardt et al. 2017) and with average concentrations between 0.1 and 100 µg/m³. Table 2 shows the main chemical compound groups measured on nonsmoking flights in 12 studies (Chen et al. 2021). The most frequently detected compounds were alcohols (57.8%) followed by aldehydes (6.4%), alkanes (4.8%), terpenes (4.5%), aromatics (3.5%), and ketones (3.4%); all other VOC groups accounted for less than 3% of compounds.

Table 3 shows compounds that were most frequently detected in cabin air quality studies.

As shown in Table 3, the compounds most frequently measured in cabin air were the aromatic compounds toluene, xylenes, benzene, ethylbenzene, and styrene, the terpene limonene, aldehydes such as benzaldehyde, nonanal, formaldehyde, acrolein, hexanal, decanal, acetaldehyde, and octanal, the ketones acetone and 6-methyl-5-hepten-2-one, the alkanes undecane, dodecane, hexane, nonane, decane, and heptane, the organochloro compounds tetrachloroethene, trichloroethene, and 1,4-dichlorobenzene, the alkene isoprene, the ester ethyl acetate, and acetic acid (Chen et al. 2021).

Toluene, xylenes, benzene, ethylbenzene, and styrene are fuel-related and engine combustion-related compounds (Knighton et al. 2009), which likely penetrated into the cabin from ground-level emissions. The average benzene concentration of

Table 2 Compound groups and their percentage found in 12 cabin air quality-monitoring studies on nonsmoking flights (Chen et al. 2021, modified, based on data from ASHRAE 1999; Crump et al. 2011a, b; Spengler et al. 2012; Weisel et al. 2013; Ji and Zhao 2014; Guan et al. 2014; Wang et al. 2014a, b; Gao et al. 2015; Rosenberger et al. 2016; Schuchardt et al. 2017)

Compound group	Percentage

$5.9 \pm 5.5 \mu\text{g}/\text{m}^3$ measured exceeded the 8-h recommended exposure levels (RELS) and the Chronic RELs (WHO 2010). Benzene is a genotoxic carcinogen in humans, and no safe level of exposure can be recommended.

Limonene can be emitted by many sources, e.g., fragrances, deodorants, cleaning agents, wet napkins, fruits, or soft drinks (Singer et al. 2006; Sun 2007; Orth et al. 2013; Simpson et al. 2019). Limonene may react with ozone to form secondary organic aerosols (SOAs) (Langer et al. 2008; Rai et al. 2014) as well as oxygenated VOCs and SVOCs including aldehydes like formaldehyde or acetaldehyde (Singer et al. 2006; Sun 2007).

Formaldehyde and acetaldehyde are products of O_3 chemistry occurring in aircraft (Wisthaler et al. 2005; Singer et al. 2006; Weschler et al. 2007; Norgaard et al. 2014), combustion products (Knighton et al. 2009), and associated with lubricant and hydraulic oils as well as fuel (ASHRAE 161 2018).

Benzaldehyde is contained in almonds (Franklin and Mitchell 2019) and used as flavoring in cosmetics (<https://www.whatsinproducts.com/chemicals/view/1/1461/000100-52-7>). It may also be a degradation product of the commonly used adsorbent Tenax TA for VOC sampling for chemical analysis (Kleno et al. 2002).

Nonanal, hexanal, decanal, and octanal were also detected frequently in aircraft cabins. These aldehydes can be associated with the presence of humans as a result of reactions of ozone with human skin oil (squalene) on the skin, on clothing, and on all surfaces that were in contact with human skin such as seats, armrests, and headrests (Wisthaler et al. 2005; Weisel et al. 2013; Gao et al. 2015; Tsushima et al. 2018). Decanal, nonanal, and octanal have very low odor thresholds (Abraham et al. 2012) which are often exceeded in aircraft cabins, so they may contribute to an odor nuisance if the concentrations get too high. Their odor qualities are soapy, citrus-like while hexanal smells rather grassy, green. Also, 6-methyl-5-hepten-2-one is a product of skin reactions.

Acrolein is a combustion product not only from fuels or oils but also of tobacco. Acrolein can also be formed by reactions of hydrocarbons with ozone (Nazaroff and

Weschler 2010). Acrolein is not only toxic but also very reactive; because of the conjugated double bond to the aldehyde group, it can polymerize or react with many compounds to form secondary products (Stevens and Maier 2008).

Acetone is not only a common solvent but also a major bioeffluent. Together with ethanol and isoprene, they are products of human metabolism (Perry 1995), and exhaled in significant amounts. Ethanol is the compound measured at highest concentrations on some flights also because of alcohol consumption by passengers before and during flights.

Alkanes including undecane, dodecane, hexane, nonane, decane, and heptane are common fuel constituents and likely ingested during ground operation. The alkane range in jet fuel is from heptane (C7) to pentadecane (C15); of those, the largest fraction are decane, undecane, and dodecane. Usually hexane is only present in small amounts. Hexane is an organic solvent and may have other origins such as adhesives, cleaners, and lacquers (<https://www.whatsinproducts.com/chemicals/view/1/284/000110-54-3>).

Tetrachloroethene was and still is widely used for dry cleaning (<https://www.whatsinproducts.com/chemicals/view/1/177/000127-18-4>); however, it is considered harmful, even toxic and possibly carcinogenic, and should not be used anymore (Ceballos et al. 2021).

Trichloroethene is also a chloro-organic solvent, which is used as degreaser or stain remover (<https://www.whatsinproducts.com/chemicals/view/1/316/000079-01-6>).

1,4-Dichlorobenzene is hardly degradable in the environment and was/is used as toilet deodorant and insecticide (<https://www.whatsinproducts.com/chemicals/view/1/1464/000106-46-7>).

Ethyl acetate is a common solvent and is contained in nail polish remover, glues (<https://www.whatsinproducts.com/chemicals/view/1/196/000141-78-6>), and also a fruit ester formed by yeast in alcoholic beverages (Saerens et al. 2010).

Acetic acid can be a reaction product of O₃ and squalene (Wisthaler et al. 2005; Gao et al. 2015). It can also be exhaled or be emitted from vinegar-containing foods such as salads or pickles.

A number of compounds have been found less frequently in aircraft cabins, but sometimes at higher concentrations (Chen et al. 2021):

- 1-Propanol (0.6–81 µg/m³) is used as solvent and disinfectant (<https://www.whatsinproducts.com/chemicals/view/1/480/000071-23-8>).
- Isoalkanes C14-C20 (25–62 µg/m³) may originate from lubricants or anti-corrosive agents.
- 1,2-Propanediol (11–45 µg/m³) residues may originate from deicing liquid (Ritter 2001) or from cleaners, hand soap, detergents, dish washer soap, shower gel, hair care products, shaving creams, toothpaste, makeup, deodorants, air fresheners, insect repellent, and paint (<https://www.whatsinproducts.com/chemicals/view/1/47/000057-55-6>).
- Acetonitrile (19–27 µg/m³) from smokers – it can be found in breath up to 1 week after smoking the last cigarette (Jordan et al. 1995).

- Cyclopentasiloxane (9.8–18 µg/m³) from deodorants or hair care products (<https://www.whatsinproducts.com/chemicals/view/1/3705/000000-79-7>).
- Diocylether (0.4–6.4 µg/m³) from sunscreen or hair care products (<https://www.whatsinproducts.com/chemicals/view/1/3774/000629-82-3>).
- Benzoic acid (3.3–5.3 µg/m³) widely used as a preservative (<https://www.whatsinproducts.com/chemicals/view/1/1031/000065-85-0>), but also a degradation product of Tenax TA, often used for VOC sampling (Kleno et al. 2002).

All compounds listed above can be found in other indoor environments with human occupancy as well.

Typical levels of VOCs found in aircraft are similar to or lower than those commonly found in other environments such as office buildings and schools (Spicer et al. 2004; Spengler et al. 2012; Schuchardt et al. 2017; AGÖF 2013). They are also well below indoor air guideline values (MHLW 2002, Chinese standard 2002; WHO 2010; OEHHA 2019; ACGIH 2021; baua 2021; Health Canada 2021, NIOSH 2021; UBA 2021). Measured VOC levels were lower in flight on aircraft equipped with carbon-based air purification (Schuchardt et al. 2017; Rosenberger 2018).

Several compounds are regulated by airworthiness standards such as IAC 2005. Maximum concentrations of compounds measured are below these limits. There are currently no guideline limits set for other VOCs in cabin air.

Total Volatile Organic Compounds (TVOC)

Some cabin air quality studies monitored the TVOC content by online monitors such as flame ionization detector (FID, Lee et al. 1999) or photoionization detector (PID, Crump et al. 2011a, b; Guan et al. 2015; Schuchardt et al. 2017). Average TVOC concentration measured by FID was about 8 mg/m³, and average TVOC concentration measured by PID was 277 µg/m³ with a range from 0 to 38 mg/m³. The average PID TVOC level fits well to TVOC levels measured in other indoor environments such as residential and office buildings, often even lower. AGÖF 2013, e.g., states as TVOC mean value of more than 2500 measurements in residential and office buildings between 2006 and 2012 a concentration of 360 µg/m³ – determined as sum of concentrations of compounds eluting between hexane and hexadecane from the nonpolar column used for VOC analyses according to ISO 16000-6:2011 (ISO 2011).

Semivolatile Organic Compounds (SVOCs)

SVOCs in aircraft cabins and cockpits have been measured and reported in several studies (CAA 2004; Maddalena and Mckone 2008; Denola et al. 2011; Marsillach et al. 2011; Solbu et al. 2011; Spengler et al. 2012; Ree et al. 2014; Rosenberger et al. 2016; Howard et al. 2018; Schuchardt et al. 2019). Of those measured, especially

organophosphates have been in discussion to be potentially neurotoxic and therefore potentially responsible for negative effects on health of passengers and crew (UK Parliament, House of Lords 2000; Civil Aviation Authority CAA 2004; UK Committee on Toxicology 2007; UK Committee on Toxicology 2013; EASA 2009–10 A-NPA Ree et al. 2014; Wolkoff et al. 2016). Measurement of SVOCs at low concentrations is a challenge, and only in recent years, analytical technologies improved and limits of detection decreased. In 2003, Nagda and Rector reported SVOC concentrations below their LODs (under normal operating conditions), except for tricresyl phosphates (TCPs) from engine oils, and tributyl phosphate (TBP) from hydraulic oil.

Table 4 provides a summary of the SVOCs and concentration ranges in cabin air previously detected and reported.

On flights on which a smell was perceived or a leak in an aircraft system suspected that allowed operating fluids to enter the bleed air system, a special focus had been put on the determination of SVOCs, especially organophosphorus compounds. Smell events were documented in nine studies (Nagda et al. 2000; Spicer et al. 2004; Muir et al. 2008; Solbu et al. 2011; Crump et al. 2011a, b; Spengler et al. 2012; Ree et al. 2014; Schuchardt et al. 2017), but a correlation to SVOCs is difficult since event concentrations were not higher than ranges reported from other studies, with two exceptions.

Tris (butoxy-ethyl) phosphate (TBEP) was found by Rosenberger 2018 at a maximum level of up to 2370 ng/m³ on 1 of 17 flights including event flights. Trixyl phosphate (TXP) was only detected by Schuchardt et al. (2019) at levels between 30 and 39 ng/m³ on 2 of 196 samples drawn on A380 and on 2 of 207 samples drawn on A321 flights.

SVOCs in cabin air were frequently measured and reported; their concentrations ranged from below the limit of detection (LOD) to 49 µg/m³. The SVOCs with highest concentrations and high frequency of detection were naphthalene, tris (chloro-isopropyl) phosphate (TCPP), tributyl phosphate (TBP), tri-n-butyl phosphate (TnBP), and triisobutyl phosphate (TiBP).

Naphthalene was used in mothballs; it is also contained in pesticides, varnish, stain remover, or fuel additives (<https://www.whatsinproducts.com/chemicals/view/1/289/000091-20-3>). TCPP is a common flame retardant in many polymer products, e.g., polyurethane foams. TBP, TnBP (likely the same compound with a different name in different studies), and TiBP are major constituents of hydraulic oil.

Tri-o-cresyl phosphate (ToCP) concentrations were reported from 0 to 22,800 ng/m³ with an average of 50 ± 14 ng/m³; in other studies, ToCP was below the LOD (Schuchardt et al. 2019). Wolkoff et al. (2016) observed that the level of 22,800 ng/m³ was a single reading out of 1000 readings, and the level of ToCP that had been reported in that study (Crump et al. 2011b) could have been overestimated because of its chromatographic overlap of other more prevalent ortho isomers. In fact, the methodology used in the study with this extraordinary finding was not specifically designed for TCP and can be considered inferior to the methods used in later studies related to TCP. Based on the isomeric composition of TCP formulations used in engine oils, ToCP is the isomer that can be least expected (Denola et al. 2008). Among SVOCs for which regulations exist, maximum levels of

Table 4 SVOCs ranges measured in aircraft cabins (Chen et al. 2021, modified)

Compound	CAS No.	Concentration [ng/m ³]			
		Min	Max	Mean	SD

cresyl phosphate mixture and dioctyl sebacate (which is an older oil base stock formulation) are stipulated in IAC AP-25 (2005) but have not been measured as such in the studies included in the present review.

Generally, the concentration of SVOCs measured in aircraft cabins was lower than the statutory limits for the compounds, if available, in buildings (MHLW 2002; Chinese standard 2002; WHO 2010, OEHHA 2019; ACGIH 2021; baua 2021; Health Canada 2021; NIOSH 2021; UBA 2021).

A joint study conducted by Kansas State University for ASHRAE and the FAA currently (2021) underway will gain further information on SVOC, VOC, and particulate matter released from contamination of a bleed air heat exchanger; when bleed air inlet temperatures are elevated, results will be published within the next few years.

Particles

Particulate matter has been measured and reported in several cabin air quality studies (Lindgren and Norbäck 2002; Nagda et al. 1992; Lee et al. 1999; Wieslander et al. 2000; Nagda et al. 2000; Waters et al. 2002; Spicer et al. 2004; Cao et al. 2017), some of which referred to them as Respirable Suspended Particulates (RSP). Respirable particles (RSP or PM₄) have a 50% cut point at 4 µm (US EPA 2004; ACGIH 2021). PM₁₀ have a 50% cut point at 10 µm (US EPA 2004). What particulate fraction the authors measured is indicated as subscript number giving the upper particle diameter recorded. Nagda et al. 2000; Spicer et al. 2004, and Cao et al. 2017 reported PM₁₀ and PM_{2.5} in the cabin at concentrations below 10 µg/m³. Lee et al. 1999 reported RSP concentrations from 1 up to 3159 µg/m³ with an average of 57 µg/m³. Waters et al. 2002 reported PM₅ at 38–300 µg/m³ with an average of 120 µg/m³, and Nagda et al. 1992 reported PM_{3.5} at 31–176 µg/m³ with an average of 62 µg/m³. Lindgren and Norbäck 2002 and Wieslander et al. 2000 reported PM_{0.3} at 1 to 253 µg/m³ with an average of 16 and 24 µg/m³, respectively.

Average concentrations are below residential indoor air quality guideline level concentrations (WHO 2005; EU 2008). In September 2021 the WHO published new air quality guideline levels for PM₁₀ and PM_{2.5} that are 10 to 25% and 40 to 50%, respectively, stricter. Particulates are removed from cabin air by dilution with outside air and the HEPA filters installed in the recirculating air path. These filters also are highly effective at removal of spores, bacteria, and viruses from recirculated cabin air. However, particles and microorganisms may be present initially when the source is in the cabin or when they are ingested from outside, e.g., from exhaust plumes on the airport tarmac.

Hydraulic fluids undergo pyrolysis at around 177 °C (e.g., Eastman Technical Data Sheets of Skydrol LD-4 or Skydrol PE-5), which is lower than bleed air temperatures found during main engine idle and APU operation (about 200 °C, NRC 1986, 2002).

Heated oil, on the other hand, pyrolyzes at around 300 °C at the pressure levels found within the bleed air system. At temperatures around 200 °C, if oil is present, it will be primarily in the form of ultrafine particle droplets. Hydraulic fluids at the same temperature would be present as particulate matter and VOCs. Particle size of bleed air contaminants is predominantly in the ultrafine particle size range, with the greatest presence in the 60 to 300 nanometer size range. The particle size range extends up to around 1 micron (Jones et al. 2017).

ASHRAE and the FAA are currently (2021) performing a study on particle size range of ultrafine particles and PM that are generated when oil, hydraulic fluid, or deicing fluid are ingested into an engine. Results will be available by 2022.

Selected Sources of Some Typical Cabin Air Contaminants

Low-level contaminants typical for an aircraft environment include organophosphorus compounds. They are widely used as flame-retardants, hydraulic fluids, or antiwear additives. Trace concentrations of organophosphates are frequently found

in aircraft cabin air. They may enter cabin air via the bleed air system through possible leaks. However, they can also be released from cabin materials, polluted surfaces, or equipment in the cabin or can be ingested into the cabin from outside air on ground on the airport tarmac. Sources for organophosphates may include the following:

Engine Oils

Engine oil is one of the contaminants that is often addressed as a major concern. Engine oil may enter the bleed air system by a leaking seal in the engine. It may also infiltrate into the cabin from outside. However, whether a base constituent of engine oil or a degradation product may enter cabin air, it has not been shown that leaking engine oil may cause any long-term negative health effects that were hypothesized in connection with odor events (UK Parliament, House of Lords 2000; Civil Aviation Authority CAA 2004; UK Committee on Toxicology 2007; UK Committee on Toxicology 2013; EASA A-NPA 2009–10 A-NPA; Ree et al. 2014; Wolkoff et al. 2016). Engine oils are classified based on MIL-PRF-23699G (2014) into four classes, Standard (STD), Corrosion Inhibiting (C/I), Enhanced Ester (EE), and High Thermal Stability (HTS). In commercial aircraft engines, mostly EE and recently HTS engine oils are used. Widely used EE oils are based on esters such as pentaerythritol (PE) esters or trimethylolpropane (TMP) esters. The acidic compounds used are linear or branched saturated organic acids with 5 to 10 carbon atoms, predominantly pentanoic and heptanoic acid, followed by octanoic acid, nonanoic acid, decanoic acid, 2–3-methyl butanoic acid, 3,3-dimethylheptanoic acid, or 3,5,5-trimethylhexanoic acid (Mair et al. 2015; Johnson 2016; Johnson 2018). The type and distribution of acids used vary between brands. In addition, the amounts of additives used to increase the load carrying or oxidative and thermal stability vary from one manufacturer to the next (Sniderman 2020).

Tri-m-and tri-p-cresyl phosphate is most widely used. Triphenyl phosphate (TPP) and isopropylated triphenyl phosphate (TIPP) have also come into use in one brand of oil to reduce potential exposure to tricresyl phosphates. Over the years, there has been much discussion on the types of isomers of tricresyl phosphates used. Tri-orthocresyl phosphate and all other ortho-isomers of TCP, which were originally thought to cause health issues in people who came into contact with aircraft turbine oils, have been almost virtually removed from all additive packages used in the entire industry after the specific toxicity of these particular isomers was recognized in the last century (Henschler 1958). Trimethyl propane phosphate was also proposed by some to be a potential decomposition product from oils based on TMP-Esters but had not been found during any engine or aircraft cabin air tests.

Hydraulic Fluids

On some aircraft, bleed air is used to pressurize the hydraulic fluid reservoir and freshwater tank. The hydraulic pressurization systems that use bleed air to pressurize

the reservoir use dual check valves to prevent backflow of hydraulic fluid into the bleed air. In the rare case of a dual check valve failure, hydraulic fluid could enter the bleed air system.

Hydraulic fluids generally consist of base stocks of tributyl phosphate (TBP) or triisobutyl phosphate (TiBP). TBP is frequently detected in cabin air. Triisobutyl phosphate has a lower density than tributyl phosphate and may offer weight reduction that in turn translates into fuel savings. Generally, the breathing of hydraulic fluid mist should be avoided, and protective breathing apparatus and eye protection worn when working around these fluids. Traces of hydraulic fluids may enter cabin air by outside air ingestion on the airport tarmac on ground. Contaminated surfaces or equipment stored in the pressurized cabin may also be a source for trace contamination.

Exhaust

During ground operation, at the gate, during push back, during taxiing, and during line-up for takeoff, aircraft may ingest exhausts from other vehicles and aircraft. This is common occurrence. By that also, carbon monoxide and nitrogen oxides may infiltrate into cabin air supply. Other major constituents of exhaust that may get into the cabin that way include formaldehyde, acetaldehyde, acrolein, and benzene (Knighton et al. 2009).

Oil aerosol, which may contain organophosphates like tricresyl phosphate (TCP), may be present in aircraft engine exhaust (Cheng 2013; Schuchardt et al. 2019) and may enter cabin air. Also, exhaust particles, in a size range around 10 nm in diameter, can travel to the aircraft cabin, as they behave more like gas than particles.

Deicing Liquids

In winter, airport runways as well as aircraft surfaces, especially the wings and engine cowlings, have to be clear of snow and ice before takeoff. Deicing fluids used for runway applications typically consist of a potassium chloride salt that is distributed on the runway after snow removal. Aircraft deicing utilizes one or more of four types of deicing, depending on the aircraft ground hold-time that is necessary following deicing, and which conform to SAE AMS 1424R/2020 for Aircraft Deicing/Anti-icing Fluid. Primary fluid base stocks include ethylene glycol, diethylene glycol, and propylene glycol mixed with water, corrosion inhibitors, wetting agents, and a dye. Ethylene glycol is used by some operators but is more infrequently used because of environmental toxicity. Propylene glycol is the most prevalent base stock for aircraft deicing and is typically mixed 50/50 with water. Liquid-deicing fluid that is sprayed onto aircraft surfaces must be done with proper procedures such as nozzle orientation to minimizing spraying the liquid into the engines/APU inlet and closing bleed air supply valves during deicing. If deicing liquid is ingested into the ECS, it is vaporized.

Rosenberger et al. (2014) detected high amounts of propylene glycol (up to 2.5 mg/m³) in cabin air on flights after aircraft deicing – with running APU. They also reported up to 1.5 mg/m³ of 1-hydroxyacetone, a degradation product of propylene glycol. Other contaminants such as organophosphates were not detected in this study at elevated levels after deicing.

A joint study being conducted by Kansas State University for ASHRAE and the FAA is underway. It will publish further information on VOC and particulate matter generated during the ingestion of deicing fluid after the study has been completed by the end of 2021.

Possible Unlikely Failure Cases That May Compromise Cabin Air Quality

Contaminants mentioned before may enter cabin air during normal operation by ingestion from outside while on the ground, often without being particularly noticed or concerned. In addition, each year hundreds of reports on fume and smell events causing discomfort to either crew or passengers on board an aircraft are filed with authorities. For one-third of them, the source is unknown, and one-quarter of them has its source in the air-conditioning system, mostly fan failures that generate odor when failed bearing allows the impeller to contact the inside of the fan housing, which is a focus of current investigations. Almost another fifth of reports is sourced to the APU and ingestion of contaminants from outside. With much lower frequency, events are sourced to the hydraulic power or other cabin systems. If events happen to be prominent in the news, they are often said to be caused by engine oil in the bleed air system; however, only 0.3–0.4% of all reported events can be related to engine oil or engine air. Number of events reported to FAA by Airlines for America (A4A) between 2012 and 2017 are shown in Table 5 by source and the respective aircraft part or system (ATA Chapter number, ATA Spec. 100, 1999).

Pathogens

The SARS-CoV-2 pandemic has documented the profound economic impact of infectious pathogens on the aviation industry. Many airlines suspended operations or canceled a significant proportion of flights. Airports have closed or shut one or more terminals. Airlines stopped and/or altered routes and frequency, with the number of seats offered by airlines in 2020 50% less and the overall number of passengers 60% less compared to 2019 levels (ICAO, 2021). Still, given the volume of daily commercial flights, carrying millions of passengers worldwide, the number of documented incidents of infectious disease transmission occurring on board remains infrequent (HSPH 2020). There have been few reports of SARS-CoV-1 and SARS-CoV-2 transmissions on board of aircraft during flights (Olsen et al. 2003; Khanh et al. 2020). Based on previous investigations of tuberculosis transmissions on (long-haul) flights, the distance from an infected passenger with high likelihood

to catch the infection is two rows forward and backward (CDC, 1995). However, SARS transmissions were also reported to passengers sitting as far as 7 rows to the front or 5 rows to the back (Olsen et al. 2003) or even two zones apart; however, transmission may have also occurred at the gate, during boarding, via a crew member as transmitter or during deplaning (deboarding), baggage claim, or immigration (Khanh et al. 2020). Transmission becomes possible across the whole cabin when the ECS is not operational as, e.g., happened on a grounded aircraft in Alaska with an influenza outbreak with ECS off for 3 h (Moser et al. 1979). Consequently, for transmission avoidance the ECS should always be operational when people (passengers, crew, or ground personnel) are on board.

The aircraft ventilation offers enhanced protection for diluting and removing airborne contagions in comparison to other indoor spaces with conventional mechanical ventilation being substantially better than residential situations. This level of ventilation effectively counters the proximity travelers are subject to during flights. Based on the available scientific evidence, it is the view of Harvard APHI that a very low number of infections only could be attributed to exposure on aircraft during travel (HSPH 2020).

The significant advantages of aircraft cabin environment in controlling pathogens and limiting the spread of disease compared to other indoor spaces are related to air change rates, filtration, passenger position, and airflow direction. Air change rates in the cabin are high compared to other indoor spaces, with about 15 to 20 air changes per hour with outside air and commensurate air changes with hospital grade HEPA-filtered recirculation air resulting in an equivalent total air change rate of up to 35 to 40 per hour. Air supply is predominantly downward, enters the cabin at the top through the air supply nozzles, and exists through return air grilles at floor level (Fig. 2). The ventilation system is designed to minimize airflow between the different temperature control zones along the cabin. Additionally, airplane seat configurations (forward facing, high-back seating) help to isolate occupants from each other and contribute to a reduction in passenger exposure to particles compared to other indoor environments (Freeman 2020).

The United States Transportation Command (USTRANSCOM) conducted tracer particle releases to simulate an infected passenger in multiple rows and seats on wide body and standard body commercial aircraft, to determine the exposure risk via penetration into breathing zones in that row and numerous rows ahead and behind the index case (40+ seats measured). The cough scenarios were conducted on ground and inflight with over 65 releases of 180,000,000 florescent particles and utilized real-time optical sensors, coupled with DNA-tagged tracers for aerosol deposition. Measured inhaled mass in the breathing zones of occupants adjacent to the simulated infected passenger showed the maximum inhaled mass was 0.46% of the exhaled mass, with medium inhaled mass of 0.009% (Kinahan et al. 2021).

The results from detailed CFD analysis and ground/inflight measurements (USTRANSCOM) are complimentary and further demonstrate that the airplane cabin is a mixed flow system and shows more characteristics of a plug flow system than a uniformly mixed system for particulates. The flow regime results in higher concentrations of particles near the infected individual and lower concentrations in the seats at a greater distance. As a result of the ventilation system design, inhaled masses in the cabin are low especially compared to other indoor spaces (HSPH 2020; Davis et al. 2021a, b; Kinahan et al. 2021).

Besides transmission by air, transmission by contact is also a possible way of spreading. Contact transmission may occur by touching of commonly used surfaces such as seat backs, armrests, tables, or door handles. Disinfection of such surfaces by disinfecting liquids containing, e.g., quaternary ammonium salts, hydrogen peroxide, phenols, sodium chlorite, sodium hypochlorite, isopropyl alcohol, ethanol, peroxyacetic acid, citric acid, and lactic acid, or by UVC radiation is appropriate means of transmission risk reduction (Pradhan et al. 2020; EPA List N 2021).

In addition to the existing solutions to control risk of infection, other solutions have been implemented (during SARS-CoV-2 pandemic) in a multilayered approach to keep passengers and flight crews healthy. They include physical distancing during boarding, deplaning (deboarding), and jet bridge, masking, providing appropriate ventilation gate-to-gate, vaccinations, washing hands, avoiding travel for individuals feeling unwell, and thorough cleaning/disinfecting the airplane cabin and flight deck between flights (HSPH 2020).

Physiological Response

Although it is not the main objective of the present chapter, it is worth mentioning studies that investigated the effects of exposures to pollutants in the aircraft cabins on human responses.

Human subject testing was performed with different CO₂ and VOC loads / different outside and recirculation air rates with and without air purification to evaluate comfort, health, and physiological responses. Air purification was found to be a more important factor than increased humidity for addressing the most prevalent and highest intensity passenger and crew health-related symptoms including eye, nose, and throat irritation and general dryness (ASHRAE, CSS 1999; Rankin et al. 2000; Strøm-Tejsen et al. 2008; Spengler et al. 2012; Weisel et al. 2017).

Most recent human subject testing has taken place shortly before the SARS-CoV-2 pandemic (January 2020): “CO₂ and VOC requirements for aircraft cabins / occupied spaces based on cognitive performance, comfort responses and physiological changes depending on pressure level” (CognitAir, 2018–2021) and “Investigation of cabin ventilation strategies impact on aircraft cabin air quality and passengers’ comfort and wellbeing through subject study in realistic aircraft environment” (ComAir 2018–2021, <https://cordis.europa.eu/project/id/820872>). Results of increased recirculation air rates on cabin environment parameters have been published (Norrefeldt et al. 2021), so have preliminary results on subjects’ wellbeing and health under the traditional air ventilation regime (Herbig et al. 2020). Results on subject responses and performance under non-traditional ventilation regimes with increased recirculation air rates have not been available before the completion of this chapter but will be published within the next two years.

Conclusion

The air in commercial aircraft cabins is generally of very good quality, usually better than in other means of mass transport operating on ground. The range of VOCs detected in cabin air is similar to other indoor environments such as offices or residential buildings (e.g., AGÖF 2013), and their levels are often at lower concentrations. Permissible levels, if existing, or levels recommended for other indoor environments are usually not exceeded. One exception – according to some

publications – is benzene. There are no particular limits or guideline values that are exclusive for aircraft cabins, and it is debatable if this was useful.

Many of the compounds found in occupied aircraft cabins originate from passengers (bioeffluents), their belongings, or their activities. Ethanol and sometimes also acetone concentrations are often elevated in aircraft cabins compared to offices or residential buildings, or other means of mass transport on ground (Dumyahn et al. 2000; Nagda and Rector 2003). Both compounds are typical human bioeffluents. Ethanol is also released by alcoholic beverages served on board, and contained in consumer products (cosmetics, cleaners).

CO₂ levels increase during boarding and deplaning (deboarding) – typically because the ECS is not always fully operated during these phases – and quickly decrease during flight. Average levels are comparable to other means of mass transport on ground (train, subway, and bus) and are within the recommended levels.

During ground operations, contaminations from outside the aircraft such as diesel exhaust from ground vehicles or engine exhaust from other aircraft or uncombusted fuel vapor can enter the cabin air. These trace contaminants may contribute to odors during boarding, push back, and taxiing. Traces of aircraft operational fluids in the bleed air and ECS systems may contribute particularly odorous pollutants. Though the initial air entering the cabin is not filtered, the high air change rate, the operation in very clean environment, and filtration of recirculated air contribute to the general good air quality on board of commercial aircraft. Most odors perceived in the cabin are not bleed air related (Table 5). Also, SVOC levels, including aviation typical organophosphates, are only found in trace concentrations and below the limits prescribed for indoor environments.

The likelihood of catching an infection on board of an aircraft is low provided the ECS is operational and additional required hygiene measures are obeyed. The risk increases if the ECS is turned off or an infected person is sitting in the immediate proximity and hygiene measures are neglected.

Maintaining adequate air quality through proper ventilation, filtration, and purification of the aircraft cabin air is important not only from the passenger and crew member point of view but also for the airline because economically significant fuel savings can be achieved if the systems for maintaining cabin environmental quality are operated and controlled according to the actual pollution loads while not exceeding the permissible levels of the parameters defining the quality of air in the aircraft cabin. Recently published and ongoing studies provide additional data that will aid design of systems that can optimize passenger and crew comfort and health while maximizing fuel efficiency leading to less emissions and hence reducing the environmental impact of air travel.

Abstract

This chapter discusses the indoor air quality of industrial buildings with high pollution sources. Firstly, the basic characteristics of indoor air quality in industrial buildings and the differences between industrial buildings and civil buildings in indoor source and control demand are briefly introduced. Then it discusses the emission and diffusion characteristics of three kinds of typical pollutants in industrial buildings with high pollution sources: high-temperature particles, droplets, and harmful gases, and introduces the analysis methods and research conclusions of these pollutants in the indoor environmental control of industrial buildings. On this basis, the refined ventilation control methods for indoor air pollution in industrial buildings in recent years are presented, including zoning environmental control strategy for overall indoor air quality and novel local ventilation technology for centralized pollution sources. Finally, the assessment indexes of high pollution industrial buildings in different industrial sectors in China and three prediction methods for indoor air quality schemes are introduced.

Keywords

Industrial building · High pollution sources · Industrial ventilation · Assessment indexes · Prediction method

Introduction

The primary purpose of industrial buildings is to meet the needs of production, leading to significant differences in indoor air quality compared with human-oriented commercial and residential buildings. In addition to the environmental issues common to all buildings discussed previously, the indoor air quality of industrial buildings needs additional attention to meet the increasingly stringent occupational health, environmental protection, and carbon emission reduction requirements. Distinct differences exist between industrial and civil buildings indoor air quality in terms of indoor sources and control demand (Wang and Cao 2017).

Indoor Sources. In industrial buildings, source terms often exist, producing large amounts of waste heat, excess humidity, and pollutants. Based on different production processes, many types of pollutants exist, having significant differences in their physical parameters. The emissions may be dozens of times greater than those of civil buildings, mainly including high-temperature flue gas, acid mist droplets, and harmful gases.

In commercial and residential buildings, the major heat sources include the human body, electronic equipment, and lighting equipment, and the major pollution sources are human activities. The heat and pollution sources in industrial buildings usually come from the industrial production process, and the release process of heat and pollutants is often instantaneous and periodic (Goodfellow et al. 2021). As industrial plants are mostly tall space buildings, pollutants will diffuse in large

spaces based on their properties, and may be deposited near the ground, suspended in the air, or accumulated at the top of the workshop (Han et al. 2020; Zhang et al. 2019). The effective elimination of these fugitive pollutants in industrial buildings has always been a difficult problem to ensure the indoor air quality of industrial buildings, as discussed below.

Control Demand. The indoor environmental control of industrial buildings needs to consider both the production process and the health and safety of workers, whereas the purpose of environmental control in civil buildings mainly satisfies the health and well-being requirements of residents. Many forms of industrial buildings exist, such as a clean plant with high requirements for temperature and humidity, and general plants that produce waste heat and other pollutants. Some of these are labor-intensive processing plants, high-level automation plants, totally enclosed plants, and open plants. Based on the different needs of production processes, the demand for industrial environmental control on indoor environmental parameters such as temperature, humidity, cleanliness, and airflow velocity would vary significantly, and may even require several orders of magnitude, much higher than that required in civil buildings. In addition, significant differences exist between industrial and civil buildings in terms of human demand. In civil buildings, the primary consideration is to create a comfortable and healthy environment for occupants, whereas in industrial buildings, the principal consideration is to create an acceptable work environment. Therefore, the difference in environmental control demand for these two types of buildings demonstrates not only their control index but also the assessment index. Workers in industrial buildings can perform high intensity labor leading to thermal stress irrespective of the environment. Thus, the evaluation of indoor thermal environment must aim to reduce its impact on human health. Various thermal stress indices can be used to evaluate thermal health and safety issues in workplaces (Belding and Hatch 1955; Wyndham et al. 1967; Yaglou and Minard 1957). Thus, this difference in the levels of physical exertion produces great differences in the need for environmental control between industrial and civil buildings due to their different control requirements to provide safe and productive workspaces.

Owing to the significant difference between industrial buildings and commercial and residential buildings, this chapter first introduces the characteristics and prediction methods of pollutants in industrial buildings, and then briefly introduce efficient industrial ventilation methods to improve the indoor air quality, and to improve the understanding of readers on the current situation and solutions of indoor air quality problems in industrial buildings.

Industrial Pollutants

Compared with civil buildings, the pollutants in high pollution industrial buildings are mainly the pollutants emitted in the production process, mainly including high-temperature particulate matter (flue gas), droplets, and gaseous pollutants. The emission mode and transmission mode of pollutants are significantly related to the process, with the characteristics of large emission and high concentration.

High-Temperature Particles

High-temperature particles are common contaminants in industrial plants. They are generated from various production processes, such as the liquid-metal pouring process, welding process, and sand-casting process. High-temperature particles with large concentrations can cause significant harm to the health of workers and indoor air quality. The dispersion of high-temperature particles in industrial plants is of great interest for chronic obstructive pulmonary disease and pneumoconiosis. Chronic obstructive pulmonary disease progresses slowly and is characterized by a gradual loss of lung function.

Based on World Health Organization statistics, chronic obstructive pulmonary disease accounts for 2.7% of all diseases globally (WHO 2017), and this percentage could be higher in developing countries with large populations. For example, by the end of 2020, over 17,064 cases of occupational diseases were reported in China, 84% of which were occupational pneumoconiosis (National Health Commission of the PRC 2020). Therefore, it is necessary to develop an energy-saving ventilation system to capture high-temperature particles and provide a solid understanding of the emission and migration characteristics of high-temperature particles.

Emission Characteristics of High-Temperature Particles

The high temperatures and gaseous and particulate pollutants generated in the metallurgy workshop can harm the health of workers. Contaminated airflows are frequently generated during various liquid-metal pouring processes. This airflow induced by liquid-metal pouring processes is generated intensely and dynamically. Commonly used ventilation design manual practices simplify the dynamic process of pollutants generation to a steady state. This results in either poor control of the polluted airflow or wastage of a large amount of the exhaust flow rate in the actual process. An accurate understanding of the flow field characteristics of the induced airflow during the pouring process can help match the exhaust flow rate in local exhaust ventilation with the dynamic generation of pollutants to refine the design of the ventilation system. The flow field characteristics of the induced airflow include flow velocity distribution, temperature distribution, and the distribution of polluted airflow found using the color schlieren image. Among these, the distribution of polluted airflow should be the primary focus because its identification can define the pollutant generation locations and estimate pollutant emission rates.

An illustration of the contaminated airflow generation during the pouring process is shown in Fig. 1. It was found that an eddy current composed of non-isothermal airflow was formed on the side near the pouring cup below the liquid column, which is called the air mass. The formation of air mass is related to the air pocket formed by the geometry of the fluid chain flow at the pouring cup outlet. Numerous contaminated airflows can be formed in the air pocket, which becomes the primary source of the air mass. When the air mass cannot remain stable, some contaminated airflow is emitted into the ambient environment. The air mass releases an enormous amount of contaminated air, which is the primary source of pollution during pouring. Throughout the pouring period, air masses will be formed in 60% of the entire period

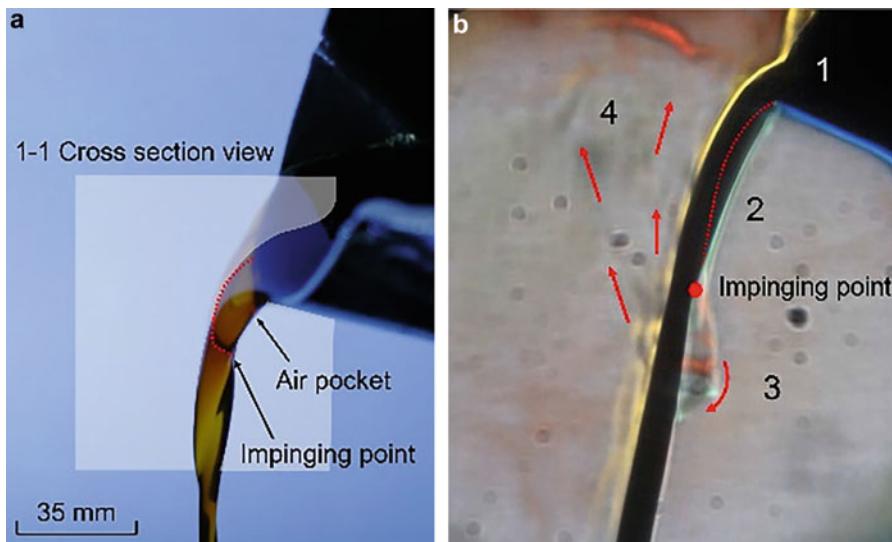

Fig. 1 Images of contaminated airflow generation during the pouring process ((1) Pouring liquid, (2) air pocket, (3) air mass, (4) contaminated airflow). (a) Image of the air pocket formed around the pouring cup outlet. (b) Schlieren image of contaminated airflow generation process (2-2 cross-sectional view)

(Huang et al. 2021a). Subsequently, the position and diameter of the air mass and the flow direction of the contaminated airflow released by the air mass during the entire liquid-metal pouring process were investigated.

Based on the quantitative analysis of the position and diameter of the air mass during the entire pouring process, it was found that the function types of the air mass position and diameter with the pouring time are approximately consistent with the variations of the trigonometric function, which rises first and then decreases rapidly. When the pouring flow rate is at its maximum, the air mass position and diameter reach a maximum (Huang et al. 2021a). Based on the position of the maximum air mass, it is suggested to strengthen the contaminated airflow control at a position 0.45 times the outlet radius of the pouring cup in the liquid column flow direction. Finally, when the pouring flow rate was the largest, the contaminated airflow released by the air mass flowed upward along the syncline away from the pouring cup at an angle of 85° in the horizontal direction (Huang et al. 2021a). This phenomenon differs from the vertical upward flow direction of an ideal thermal plume. In summary, the relevant conclusions can assist in the design of high-efficiency ventilation systems and in reducing energy consumption in industrial plants.

Some industrial processes, such as welding and spraying of large concentrations of high-temperature particles (Zimmer and Biswas 2001; Zimmer et al. 2002), result in significant harm to both indoor air quality and worker health. Therefore, an accurate understanding of the emission characteristics of high-temperature particles is important for achieving high-efficiency ventilation system design in industrial plants.

The transient discharge of high-temperature particles from industrial processes is usually accompanied or followed by high-temperature airflow; the initial airflow temperature significantly differs from the surroundings. Because high-temperature particles usually have small diameters, most studies have concluded that particles completely follow the airflow when moving. Here, airflow variations were considered, whereas the particle properties have not been studied. However, some recent studies (Duan et al. 2017; Huang et al. 2022) have shown that particles with different diameters are distributed differently in the same airflow field and may not always follow the airflow during the dispersion process. Along with the movement of high-temperature particles, the surrounding ambient air is heated. This leads to changes in the airflow field, which influences the particle dispersion mode.

Research has shown that ambient air is heated as high-temperature particles move; the variation in airflow velocity around the particles results in a nonuniform velocity across particles (Duan et al. 2017). The particle velocities near the centerline were larger than those far away from it. In addition, the dispersion mode of the particle population is determined based on the temperature and velocity variations in the airflow field and particles. Particles with higher initial temperatures and smaller particle diameters are associated with significant horizontal diffusion. This includes the movement of most particles within the upper space. Particles with either a larger diameter and higher initial temperature, or smaller diameter and lower initial temperature, experienced the least horizontal diffusion. Upward transport was limited, with most of the particles remaining at lower levels. Particles with moderate diameters and initial temperatures exhibited moderate horizontal diffusion. Most particles moved in the upper-middle space and spent the longest time in the vertical direction. These conclusions are necessary for future studies on the design of human protection and ventilation systems. Meanwhile, this will provide more reliable boundary conditions for future simulations and may reveal more parameters that impact particle dispersion modes.

Migration Characteristics of High-Temperature Particles

During the sand-casting process, the high-temperature molten metal liquid poured into a sand mold instantly heats the air in the cavity. This heated air volume expands and is then ejected at the sand exhaust port. This airflow, with a certain initial velocity and high initial temperature, can be regarded as a high-temperature buoyant jet. High-temperature buoyant jets usually contain dust particles; therefore, in industrial ventilation, to protect the health of workers, the canopy hood is often used to capture high-temperature buoyant jets.

Based on the recommendations in the industrial ventilation design manual, the installation position of the canopy hood should be set at the contracted section of the high-temperature buoyant jet. The contracted section had the smallest cross-sectional area and the largest flow velocity in the high-temperature buoyant jet. However, these industrial ventilation design manuals only provide the approximate location of the contracted section based on empirical formulas and do not discuss the formation of the contracted section, the temporal evolution process of the contracted section, or the influence of the initial temperature of the buoyant jet on the position of

the contracted section. Therefore, it is necessary to study these topics to improve the design guidelines for the installation of exhaust hoods at a suitable height, which can be used in high-temperature buoyant jets to achieve energy savings.

In the case of the high-temperature buoyant jet generated in industrial processes such as pouring and smelting, the emission characteristics of the high-temperature buoyant jet with an initial temperature of 303–473 K were introduced (Huang et al. 2021b). The initial temperature is an important factor that affects the transport characteristics of high-temperature buoyant jets. Because the diffusion angle and penetration distance of high-temperature buoyant jets increase with an increase in the initial temperature, the installation position of the local exhaust system for high-temperature buoyant jets should be as close as possible to the pollution source.

When the initial temperature is greater than or equal to 373 K, the flow field of the high-temperature buoyant jet produced a contracted section. The position of the contracted section was within two times the source diameter from the outlet of the pollution source. When the initial temperature increased, the position of the contracted section was closer to the outlet of the pollution source.

The contracted section is caused by the rupture of the vortex ring at the outlet of the pollution source, as shown in Fig. 2. The vortex ring is continuously generated within the range of 0.7 times the source diameter from the outlet. Outside this range, the vortex ring is broken and reorganized into a spiral vortex structure. The vortex ring can restrict the flow field diffusion of the high-temperature buoyant jet before the vortex ring ruptures, and the spiral vortex structure formed after the vortex ring ruptures and entrains a large amount of ambient air and expands. Therefore, it is suggested that the installation height of the canopy hood is within 0.7–2 times the source diameter from the outlet without affecting the operation process.

High-temperature buoyant jets usually carry particles of different diameters, and these particles driven by high-temperature buoyant jets exhibit different transport behaviors. In the case of the pulsating high-temperature particles produced in industrial processes such as forging and casting, the transport characteristics of pulsating high-temperature particles with an initial temperature of 1273 K and particle diameter of 5–30 μm are introduced. The pulsating high-temperature particles are driven by a high-temperature buoyant jet with a pulsed initial velocity and a short duration. The transportation process includes the supply, thermal energy attenuation, and kinetic energy attenuation stages.

Particles of different diameters present similar heating effects on the airflow at the edge of the flow field during the thermal energy attenuation stage. Therefore, the different distributions of particles in the horizontal direction are not mainly caused by the edge airflow heated by particles at the thermal energy attenuation stage but by the influence of the vortex structure on the particles at the kinetic energy attenuation stage.

During the transport of pulsating high-temperature particles, the vortex structure in the flow field was dominated by spiral vortex structures. The spiral vortex structure includes the vortex core regions, boundary regions at the edge of the vortex structure, and vortex braid regions between adjacent vortex structures. The vorticity of the vortex structure was transmitted to both sides, and a new vortex core was generated around the original vortex core. The attenuation of the vorticity leads to

Q Level=0.01

(Reprinted from Huang et al. (2021b), Copyright (2022), with permission from Elsevier)

the horizontal transport of particles in the spiral vortex structure. In addition, the horizontal transport of particles leads to variations in the particle concentration in the boundary regions of the vortex structure, which affects the shape of the small-scale vortex structure in the boundary regions. The increase in the particle concentration in the boundary regions increases the complexity and concentration of the small-scale vortex structure.

When the particle diameter is 5–30 μm , particles are transported from the inside to the outside of the work area, and 99% of the particles are suspended in the upper space outside the work area (Huang et al. 2022). The key capture area of the particles should be located in the upper space outside the work area. When the particle diameter is 50–70 μm , the particles suspended outside the work area are transported to the inside of the work area (Huang et al. 2022). The key capture areas of the particles should be located in the work area.

Droplets

Droplets, such as acid mist, oil mist, and water mist, are typical airborne contaminants in industrial indoor environments (Yang et al. 2019b). Their escape into indoor environments can harm human health or thermal comfort and cause equipment corrosion and construction damage (Wang et al. 2019). Field studies report that mist comprising droplets may severely hinder normal production and worker operation. The emission sources of the droplets are mainly from industrial processes (Fan et al. 2021). The surface treatment processes of steel and nonferrous metals mainly emit acid droplets, metal surface spraying mainly emits oil droplets, and water/spray cooling mainly emits water droplets. Although many industrial processes are involved in the emission of different droplet types, four main emission mechanisms exist, including direct spray, condensation, mechanical actions, and bubble burst, as shown in Fig. 3. Different emission mechanisms may generate droplets with different diameters and velocities.

Droplet transport may differ significantly from that of solid particles because evaporation changes their diameters (Yang et al. 2019a). Dispersion, deposition, and human exposure may exhibit more complex characteristics. When droplets are emitted into indoor environments, with the influence of the temperature and relative humidity of the ambient air, droplets evaporate during the motion. Evaporation leads to a constant change in the diameter of the droplets. As the diameter changes, forces such as gravity and drag force acting on the droplet also change, as shown in Fig. 4.

Different droplets have different diameter-variation tendencies owing to evaporation. Generally, pure water droplets evaporate rapidly. When it is a solution droplet, such as an acid droplet, the solute causes the water vapor pressure at the

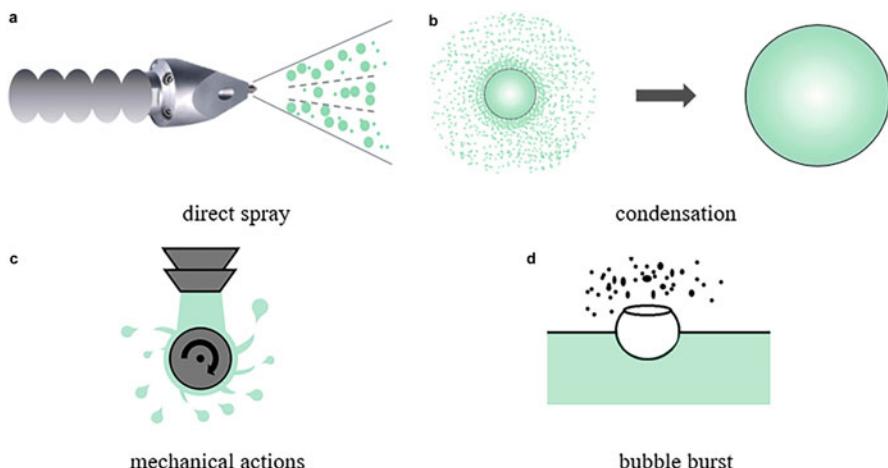

Fig. 3 Droplet emission mechanisms in industrial environments. (a) Direct spray. (b) Condensation. (c) Mechanical actions. (d) Bubble burst

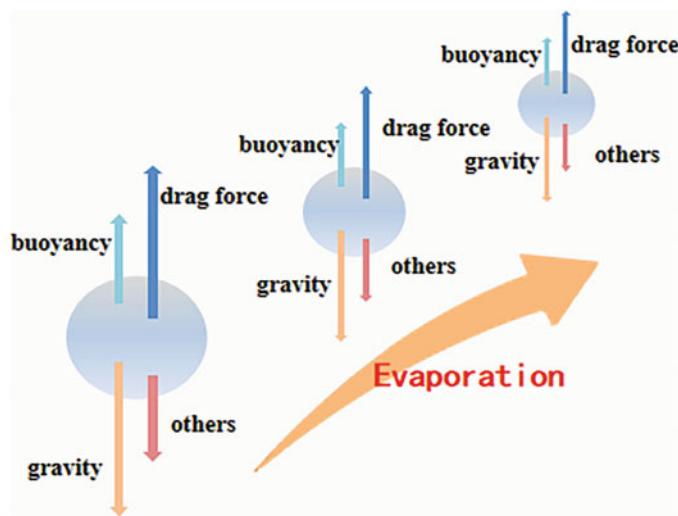

Fig. 4 Forces acting on the droplets change with evaporation

droplet to be lower than that of a pure water droplet, which is the solution effect. Thus, the evaporation of the solution droplet was slower. The strength of the solution effect on the water vapor pressure at the droplet surface mainly depends on the number of ions and the number of charges ionized by the solute.

Sulfuric acid (H_2SO_4) droplets and hydrochloric acid (HCl) droplets generated from the surface treatment processes of steel, such as pickling, electrolysis, and electroplating, are two common acid droplets in industrial environments. The evaporation of these two types of droplets differs from that of pure water droplets. For instance, at an ambient temperature and relative humidity of 25 °C and 50%, respectively, a pure water droplet of 100 μm needs approximately 12 s to evaporate completely, as shown in Fig. 5. For a sulfuric acid droplet, the diameter change owing to evaporation quite differs from that of a pure water droplet. It evaporates when the mass fraction of the solute is low. When the mass fraction of the solute is much higher owing to water loss, the evaporation almost stops, and it remains at a balanced diameter for a long time. The diameter evolution curve of a hydroelectric droplet is similar to that of a pure water droplet. As the mass fraction of a solute would not be much higher because HCl volatilized, it could evaporate completely. However, the duration of complete evaporation for a hydroelectric droplet is much longer than that of a pure water droplet under the same conditions (Yang et al. 2019a). This could be an important reason the acid mist could remain in industrial environments for a long time. With an increase in relative humidity, the sulfuric acid droplets evaporate more slowly, and the “balance diameter” of the sulfuric acid droplets increases. This is because the vapor pressure difference between the droplet surface and the ambient air decreases as the relative humidity increases, and the evaporation rate then slows down. With an increase in relative humidity, the evaporation rate of the hydrochloric acid droplets decreased. A longer time is

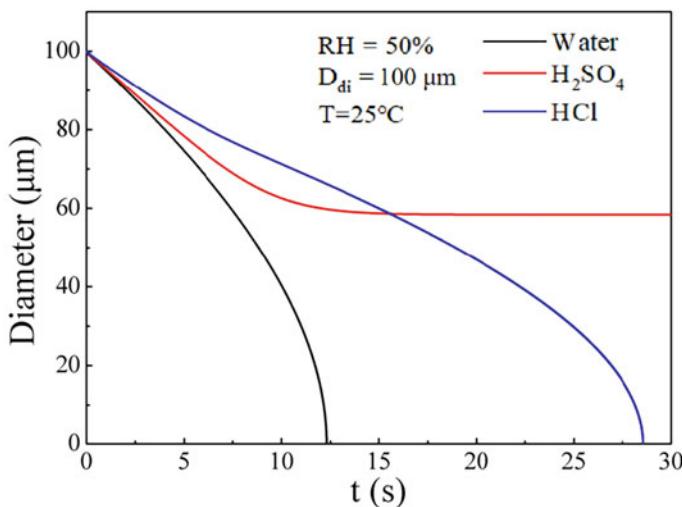

Fig. 5 Diameter variation of different droplets

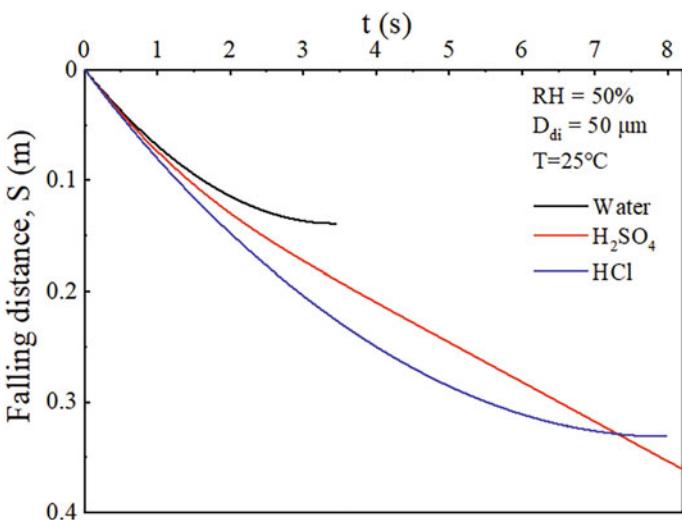

Fig. 6 Comparison of the falling distances of sulfuric and hydrochloric acid droplets

required for a hydrochloric acid droplet to evaporate completely in a higher-RH environment.

Different diameter variations lead to different droplets with different motion behaviors. As shown in Fig. 6, during the sedimentation process of a droplet, a pure water droplet quickly disappears after falling in a short time. A hydrochloric acid droplet with the same initial diameter could fall down a long distance and then disappear. In the case of a sulfuric acid droplet, because it could maintain a certain

diameter for a long time, it would fall to a very long distance. Initially, a hydrochloric acid droplet falls faster than a sulfuric acid droplet.

Gaseous Pollutants

Many types of gaseous contaminants are present in buildings. Many types of industries emit large amounts of hazardous gases. For example, the rubber industry emits pollutants such as vulcanizing heating fumes, toluene, and xylene. Dangerous hydrogen cyanide gas is emitted from the open surface tank processes in plating and metal-finishing shops. Harmful pollutants, such as tungsten fluoride and octafluorocyclobutane, are emitted by the semiconductor industry. Hydrogen leaks in the air can cause fires or explosions.

The concentration buoyancy is caused by density variations resulting from concentration differences. Gaseous pollutants are often considered as “passive” (Li et al. 1997; Liu et al. 2012) owing to their low concentration in civil building ventilations. However, in industrial facilities, the contaminant emission rates may be 10–100 times higher than those in civil building environments. Thus, concentration buoyancy should be considered in some circumstances.

Many studies have shown that concentration buoyancy may play an important role in the flow field and contaminant (or tracer) distributions. Ricciardi et al. (2008) and Gelain and Prevost (2015), both experimentally and computationally, showed that even in low quantities, the injection of gas of high density or low density compared with air can lead to stratification phenomena and thus create areas of high concentration. Many studies show similar results: the heavy gas may be deposited at the lower part of a space, whereas the light gas may be gathered in the upper region by the negative and positive concentration buoyancy. Niemela et al. (1991) revealed a difference in behavior between the three tracer gases of different densities using an experimental method. Zhou et al. (2018) showed that the concentration buoyancy effect is significant for tracer distribution with different tracer gases at a low velocity under isothermal conditions. In their investigation, three tracer gas concentrations were used, that is, the mass fractions of tracer gases were $Y_{0, \text{tracer}} = 0.001, 0.005$, and 0.01 . CH_4 represents a “light” tracer gas, and CO_2 represents a “heavy” tracer gas. Figure 7 shows the relative mass fraction distributions (Y/Y_0) of the supply air and tracer gases with different tracer gas concentrations under isothermal conditions with $u_0 = 1$ m/s. The tracer distributions were compared with the exact reference without a tracer. The comparison shows that the tracer distributions deviate from the exact reference as the tracer concentration increases. Moreover, even under isothermal conditions, the distributions of the tracer gas are up for the light tracer gas CH_4 and down for the heavy tracer gas CO_2 . This is because the density of CH_4 is lighter than that of air, causing a positive concentration buoyancy force and affecting the tracer gas distribution. However, the heavy tracer CO_2 causes a negative buoyancy force. Moreover, the tracer distribution deviation increased with an increase in the concentration of the tracer gas.

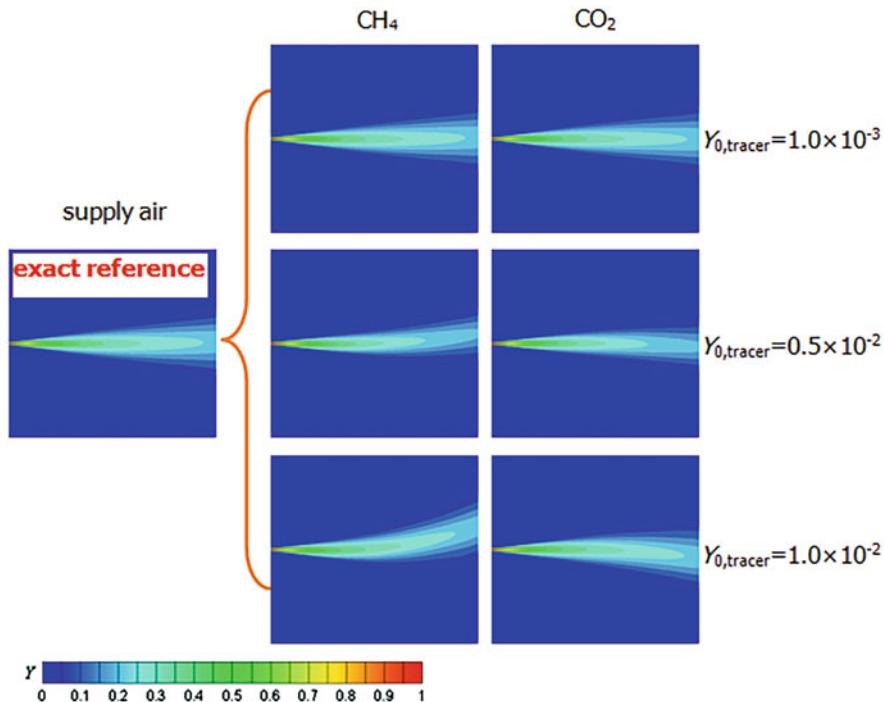

Fig. 7 Relative mass fraction distributions (Y/Y_0) of the supply air without tracer and the tracer gases with different tracer concentrations under isothermal conditions with $u_0 = 1 \text{ m/s}$

To quantitatively compare the effect of the tracer gas concentration on the tracer gas error, the relative tracer gas error is defined as:

$$Er = \frac{(Y/Y_0)_{\text{tracer}} - (Y/Y_0)_{\text{exact}}}{(Y/Y_0)_{\text{exact}}} \times 100\% \quad (1)$$

where Y/Y_0 is the relative mass fraction of the supply air, $(Y/Y_0)_{\text{tracer}}$ is the Y/Y_0 using the tracer method, and $(Y/Y_0)_{\text{exact}}$ is the Y/Y_0 using the self-label method.

Figure 8 shows the effect of the tracer gas concentration on the tracer gas deviation at the centerline of the jet under isothermal conditions. For $Y_{0,\text{tracer}} = 0.001$, and for both tracer gases, the tracer gas errors were close to zero. For $Y_{0,\text{tracer}} = 0.01$, and for both tracer gases, the tracer gas deviation is significantly larger. Moreover, the tracer gas deviation of CH₄ was much higher than that of CO₂. This is because the change in the density of CH₄ is larger than that of CO₂, thus increasing the additional concentration buoyancy force. The corresponding changes in the density are shown in Table 1.

Except for the concentration and contaminant (or tracer) type (light or heavy), flow velocity notably affects the distribution of concentration owing to the relative concentration buoyancy. Figure 9 shows the mass fraction distributions of the supply

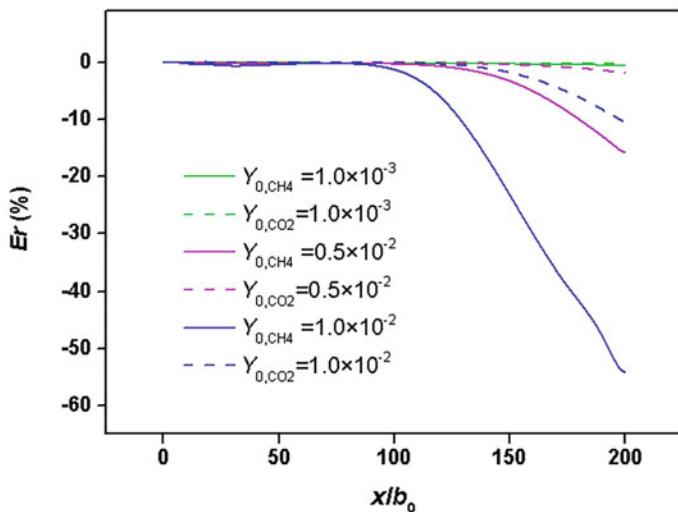

Fig. 8 Effect of tracer gas concentration on tracer gas deviation at the centerline of the jet under isothermal conditions with $u_0 = 1 \text{ m/s}$

Table 1 Parameters values related to the mixture density at the supply inlet

Tracer	Mass fraction, Y	Mole fraction, x_t	Tracer-mixture density, $\rho_{\text{mix-t}}$ (kg/m^3)	Change in density, $\delta\rho = \rho_{\text{mix-t}} - \rho_{\text{air}}$ (kg/m^3)	Ratio, $\delta\rho/\rho_{\text{air}} (\%)$
CH ₄	1.0×10^{-3}	1.80×10^{-3}	1.17573	-0.94×10^{-3}	-0.08
	0.5×10^{-2}	0.90×10^{-2}	1.17195	-4.72×10^{-3}	-0.40
	1.0×10^{-2}	1.79×10^{-2}	1.16727	-9.40×10^{-3}	-0.80

	0.5×10^{-2}	0.33×10^{-2}	1.17869	2.02×10^{-3}	0.17
	1.0×10^{-2}	0.66×10^{-2}	1.18071	4.04×10^{-3}	0.34

Note: $\rho_{\text{air}} = 1.17667 \text{ kg/m}^3$

air and tracer gases ($Y_{0, \text{tracer}} = 0.02$) with different air velocities under isothermal conditions. It can be seen that the mass fraction distributions deviate less from the exact reference as the air velocity increases for both CH₄ and CO₂. The tracer gas deviation decreased with an increase in supply air velocity. This is because with an increase in supply air velocity, the inertial force increases, thus decreasing the relative concentration of the buoyancy force.

In building environments, pollutants are often distributed under non-isothermal conditions. Thus, fluid motion and contaminant (or tracer) distribution may be induced not only by the concentration buoyancy but also by the thermal buoyancy, that is, double buoyancy owing to temperature and concentration differences. Laporte et al. (2001) found that differences in the stratifications of the tracer gas in hot air and cold air trials exist, indicating the heating or cooling conditions may affect the tracer gas distribution. Concentration buoyancy is positive for light

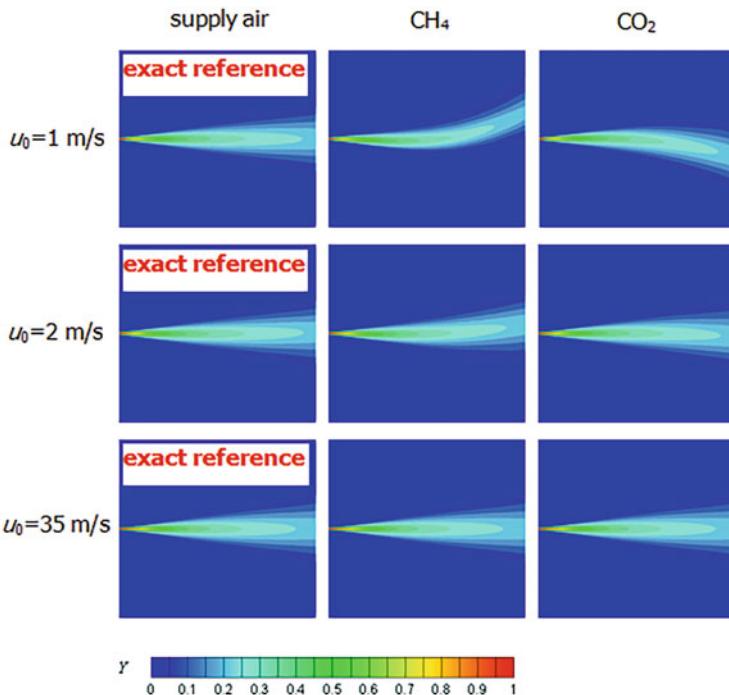

Fig. 9 Mass fraction distributions of the supply air and tracer gases ($Y_{0, \text{tracer}} = 0.02$) with different air velocities under isothermal conditions

contaminants and negative for heavy contaminants, and thermal buoyancy is positive under heating conditions and negative under cooling conditions. Therefore, the double buoyancy force was positive or negative. These factors still need to be investigated further.

Industrial Ventilation

General Ventilation with Zoning Environmental Control Strategy

Several production processes often exist simultaneously in an industrial workshop, and the emission of pollutants varies with location and environment in the workshop. For areas comprising a pollution source, it is necessary to capture as many pollutants as possible and avoid their spread. Owing to the huge volume of industrial plants, it is uneconomical and difficult to achieve the goal of increasing the airflow and improving the ventilation rate throughout the workshop. Consequently, it is necessary to divide the workshop into several parts based on the release location and diffusion characteristics of the pollutants and use different

ventilation strategies in different areas to use the minimum energy consumption to achieve the best indoor air quality. Generally, three modes for the zoning control of industrial buildings exist: natural zoning, physical partition, and airflow partition.

Natural Zoning

Natural zoning is a mode of zoning that fully utilizes the diffusion characteristics of pollutants. This mode does not need to consume too much energy; it only needs to set the vents as close to the pollutant deposition as possible, making zoning environmental control efficient. When the pollutant density is significantly higher than that of air and the pollutant release is not accompanied by thermal processes, the pollutants deposit near the ground. The best way to achieve this is to set the exhaust outlet near the ground, which not only ensures the safety of the working area but also ensures the highest pollutant concentration near the exhaust outlet and achieves the highest efficiency, as shown in Fig. 10a. When the release of pollutants is accompanied by a thermal process, the diffusion of pollutants becomes more intense and complex. Driven by buoyancy, pollutants move upward into the large space, then diffuse around the roof and accumulate in the upper part of the workshop, which is similar to the distribution of displacement ventilation. It is worth mentioning that when the temperature of pollutants accumulated in the upper part of the room decreases, pollutants may resettle and enter the work area, resulting in a wide range of pollution. Therefore, for the natural zoning control of pollutants in the upper part, it is necessary to set the exhaust outlet in the upper part of the room to remove the pollutants accumulated in the upper part of the room, as shown in Fig. 10b.

Physical Partition

The most efficient method of zoning is to use physical methods such as walls and partitions to divide industrial buildings into rooms, successively. This is difficult to achieve in industrial buildings, and some obstacles exist: production lines need to be set continuously, cranes are often set above industrial buildings, and the frequent handling of production materials also makes the setting of physical partitions difficult. Nevertheless, some physical isolation methods that minimize the impact on the process exist.

First, the partition can be set according to the deposition characteristics of the pollutants. For the lower deposition pollutants generated by grinding, spraying, and other processes, the working area can be surrounded by a semi-open grid to prevent the further diffusion of deposition pollutants in the room. For high-temperature pollutants driven by buoyancy, a continuous partition can be set on the roof directly above the pollution source, similar to the smoke vertical wall to prevent fire, to delay the horizontal diffusion of pollutants in the upper part of the room, and realize zoning, as shown in Fig. 11.

The other method is to use movable physical partitions, such as rolling shutters, automatic doors, and other devices that can be opened when they do not affect the

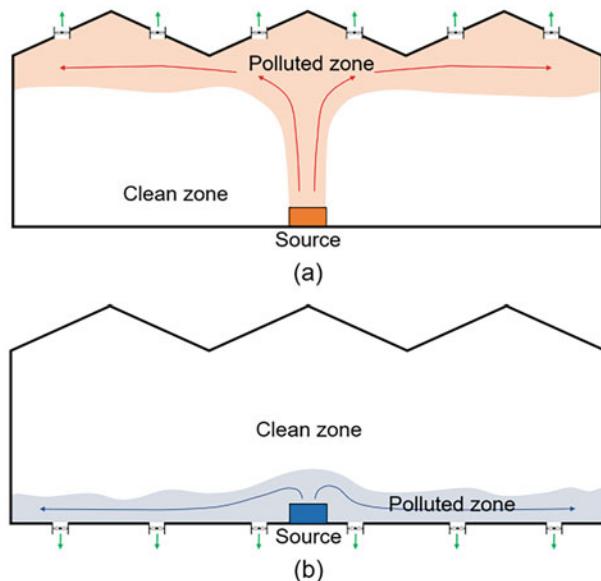

Fig. 10 Ventilation system setting under natural zoning

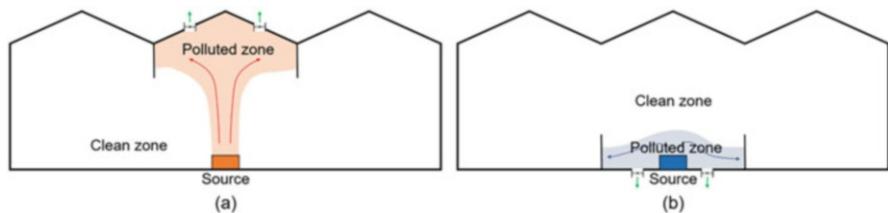

Fig. 11 Mode of ventilation system associated with physical partition: (a) upper partition and (b) lower partition

process to play the role of partition, while closing when they do, which can shorten the diffusion time of pollutants as much as possible.

Airflow Partition

When setting a physical partition is inconvenient, the airflow can also realize the partition function. The function of the airflow partition can be divided into two types: air curtain partition zoning and vortex airflow zoning.

The air curtain partition is widely used, which mainly blocks the airflow on both sides of itself through high-speed air, such as a gate air curtain. In an industrial plant, a wide range of air curtains can also be set to partition the space on both sides to maintain the difference in temperature, humidity, and pollutant concentration on both sides of the air curtain, as shown in Fig. 12.

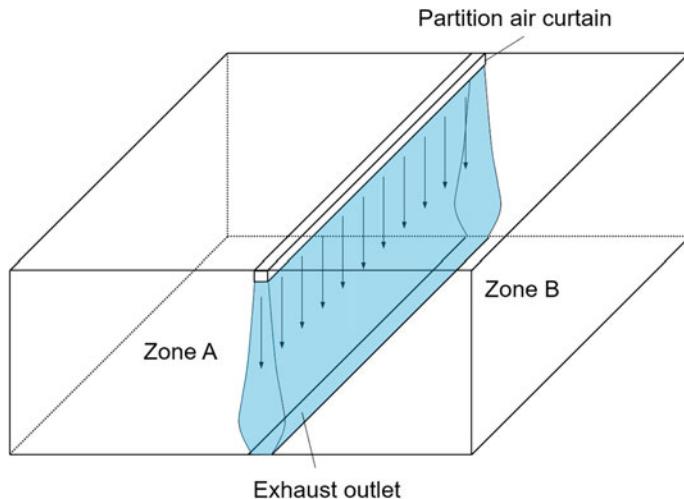

Fig. 12 Industrial workshop separated by an air curtain

The vortex airflow zoning mode is new and uses a tornado-like columnar air vortex to partition industrial buildings. The principle is that after generating vortex airflow in a large space, it mainly sucks pollutants inside the vortex zone, whereas less airflow movement occurs between the vortex ventilation system, the surrounding environment, and adjacent vortex ventilation systems. Thus, the effect of the zoning control was realized. When the pollution source is inside the vortex zone, the emitted pollutants are entrained by the vortex flow and transported to the roof exhaust outlet through the vortex pipe for elimination, as shown in Fig. 13. In industrial buildings with a large aspect ratio, multiple vortex ventilation systems can be set simultaneously to ensure the pollutants in each vortex ventilation system will not diffuse to other areas, as shown in Fig. 14.

Local Exhaust Ventilation Technology

Local exhaust is a common form of ventilation in industrial buildings. When concentrated pollution sources exist, first, we should consider setting local exhaust near the pollution sources to capture and control pollutants at the highest concentration just released, thus preventing pollutants from spreading into industrial buildings. The relevant contents of the local exhaust hood have been introduced in design handbooks (ACGIH 2010; HSE 2017). This section introduces several high-efficiency local exhaust modes suitable for industrial building environmental control.

Adjustable Exhaust Hoods

For local exhaust, the minimization of the contact area between the pollution source and the environment by enclosing as much as possible can not only reduce the

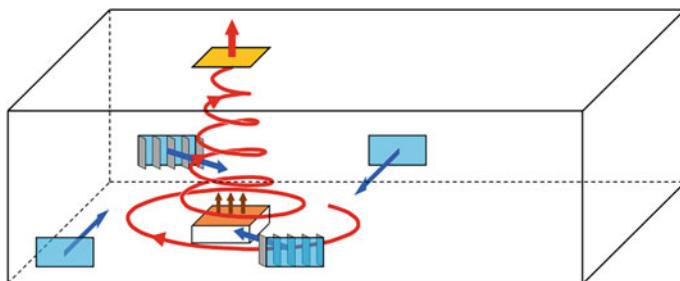

Fig. 13 Scheme of vortex ventilation in buildings with large space

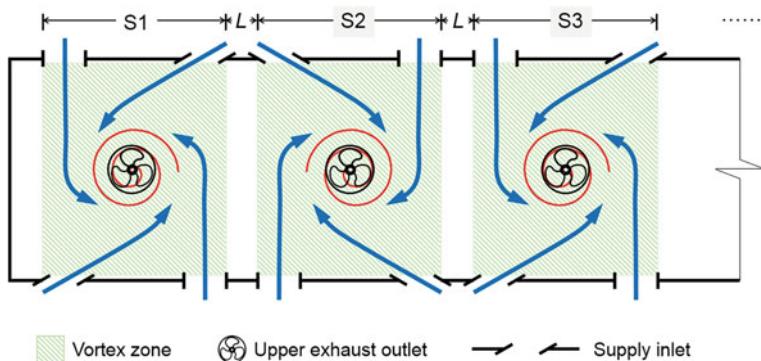

Fig. 14 Multi-vortex ventilation

possibility of pollutant diffusion but also reduce the entrainment of clean ambient air through the exhaust system, thus reducing the exhaust air rate. However, the setting of this enclosed hood is often limited by this process. Some production processes require frequent operations near the pollution source, resulting in an inability to effectively enclose the pollution source. Setting an adjustable exhaust hood is an effective alternative. The adjustable exhaust hood is often equipped with movable baffles, and the location of these baffles can be adjusted by the motor driving device to minimize the impact on the production process, as shown in Fig. 15. With an increase in the manufacture of cheap and accurate sensors in recent years, the adjustable exhaust hood can realize automatic operation, further reduce the operation cost, and improve work efficiency.

Movable Exhaust Hoods

In industrial buildings, sometimes the emission location of pollution sources is not fixed, such as cutting and grinding of large parts, welding, and spraying of large equipment. This challenges the setting of the local exhaust hood. If the local exhaust hood covers every location where pollutants may be released, the size of the exhaust

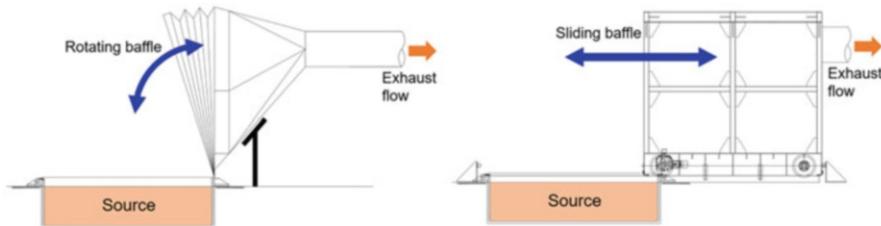

Fig. 15 Different types of adjustable exhaust hoods

Fig. 16 Multi-duct integrated movable exhaust hood used for spraying of a large airplane

hood is too large and the required air rate will be large; however, the efficiency is very low. Therefore, to solve the abovementioned pollutant capture problem of movable pollution sources, a movable exhaust hood can be used.

A movable exhaust hood means the air duct connected to the exhaust hood can move within a certain range through joints or hoses to adapt to the locations of pollution sources. The movable exhaust hood has been used in many chemical laboratories and automatic welding production lines, which significantly improves safety and operational convenience. For some extra-large movable pollution sources, such as surface spraying of large airplanes, setting a new integrated movable exhaust hood can effectively reduce the concentration of volatile organic compounds (VOCs) in the workshop through economical air rate without affecting the spraying operation, and effectively improve the indoor air quality of industrial buildings, as shown in Fig. 16.

Parallel-Flow Push-Pull Ventilation

Parallel-flow push-pull ventilation is an efficient local ventilation method that uses an air supply curtain with low turbulence intensity to shield the pollution source from the outside environment and prevent pollutants from escaping; it also uses the supply airflow to transport pollutants to the exhaust hood simultaneously. Owing to the low turbulence intensity of the supply airflow, the amount of mixing with the ambient air is very low in the process of transporting pollutants. Therefore, a good pollutant control effect can be achieved with a low air rate. Parallel-flow push-pull ventilation

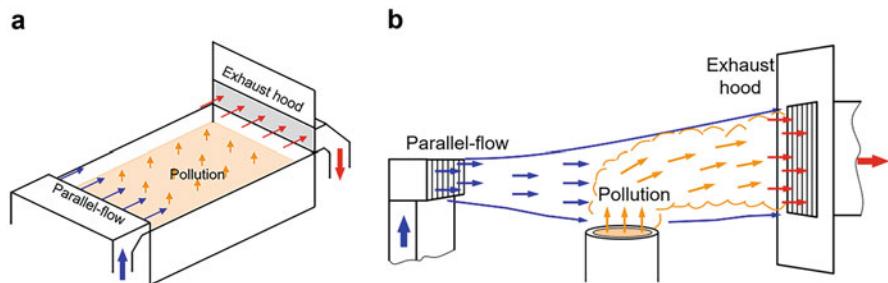

Fig. 17 Two types of parallel-flow push-pull ventilation: (a) above the open tank and (b) long-distance transportation of pollutants

systems are generally used in two application fields. One is used above the liquid surface of an open tank, and the other is to transport pollutants over a large range and long distance, as shown in Fig. 17.

Vortex Ventilation Hoods

The use of tornado columnar air vortex flow can achieve high-efficiency capture and control of pollutants in a certain indoor area. The vortex exhaust hood is a local exhaust hood that utilizes the vortex airflow, which can efficiently and quickly capture the pollutants released from pollution sources using tornado airflow. Owing to the strong control ability of vortex airflow, the vortex exhaust hood has strong adaptability to pollutants and has high capture and control performance for pollutants with high initial momentum and buoyancy flux.

The basic elements of the vortex airflow are the angular momentum air supply, the bottom plane, and the updraft. In the vortex exhaust hood, the angular momentum air supply can be provided by setting the air supply fan, and the updraft can be provided by the exhaust hood. The different control distances of the vortex exhaust hood can generally be divided into two types: bottom air supply type and total process air supply type. The angular momentum air supply devices of the bottom air supply type vortex exhaust hood are only arranged near the ground pollution source, whereas the total process air supply type vortex exhaust hood is equipped with angular momentum air supply devices between the pollution source and the exhaust hood, which can achieve a more stable vortex flow and a longer air supply distance, as shown in Fig. 18.

Assessment of Industrial Building Environment with High-Pollution Sources

For representative industrial buildings with high-pollution sources in the production process, including nonferrous metal smelting and calendaring, ferrous smelting and calendaring, and rubber products, a special Chinese building environmental assessment standard (CECS 2021) has been developed to assess the indoor environment of single industrial buildings.

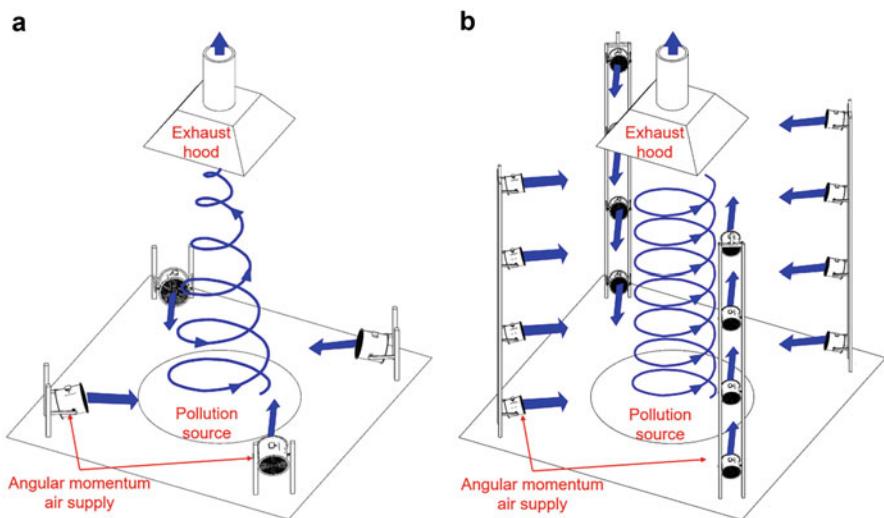

Fig. 18 Two types of vortex exhaust hood: (a) bottom air supply type and (b) total process air supply type

Divisional Principles for Environmental Assessment

Industrial buildings with high-pollution sources generally integrate many parts for different uses, including the parts for process production, offices, rest, etc. Each part has different environmental conditions, personnel residence times, and personnel health needs for the environment. In addition, to achieve precise control of the environment and industrial building energy conservation, it is necessary to design a reasonable cleaning and dust removal system for different environmental needs. Therefore, the standard divides single industrial buildings into three areas, including working, clean, and emissions areas, which would be more reasonable to assess the environment quality. The working area refers to the area where staffs often or quantitatively stay to observe and manage the production process, including the direct operation area of staff and the area of management, control, or scheduling. The clean area refers to the auxiliary office, rest, and other non-production areas. The emissions area refers to the unorganized emission area, excluding the working area and the clean area.

Environmental Parameters

The environmental parameters of industrial buildings with high pollution sources include common parameters and specific parameters. Common parameters refer to the indexes that all industrial buildings should meet the requirements of the indoor environment, such as temperature, humidity, and particle concentration. The

specific parameters proposed in the standard (CECS 2021) are based on the industry characteristics and the production situation of industrial buildings. The specific parameters should be assessed based on common parameters that meet the requirements.

Common Parameters

The common indexes in the working area include temperature, relative humidity, airflow velocity, and total particle concentration. Temperature, relative humidity, and airflow velocity should meet the current Chinese national health standards, and the total particle concentration should not be higher than 8 mg/m^3 (PC-TWA, permissible concentration-time weighted average). The common indexes of clean area include temperature, humidity, airflow velocity, and particle concentration, and each environment index should meet the requirements of Table 2. The common index of indoor emission area of industrial buildings with high pollution sources is the concentration of total suspended particles, which should not be higher than 5 mg/m^3 (time average value in 1 h).

Specific Parameters

The indoor specific parameter of nonferrous metal (lead-zinc) industrial buildings include sulfur dioxide, sulfur trioxide (sulfuric acid mist), lead and its compounds, and mercury and its compounds. The permissible concentrations of each parameter should meet the requirements of Fig. 19.

Table 2 Common parameters and the permissible values in indoor clean areas

Number	Parameters	Unit	Standard value	Seasons	Remark
1	Temperature	$^{\circ}\text{C}$	18~24	Winter heating	Time average value, time interval less than 30 min
			25~28	Summer air conditioning	
2	Relative humidity	%	/	Winter heating	
			40~70	Summer air conditioning	
3	Airflow velocity	m/s	0.2	Winter heating	
			0.3	Summer air conditioning	
4	PM _{2.5}	mg/m^3	0.075	/	Daily average value, time interval less than 1 min
5	PM ₁₀	mg/m^3	0.15	/	
6	Total suspended particles	mg/m^3	0.30	/

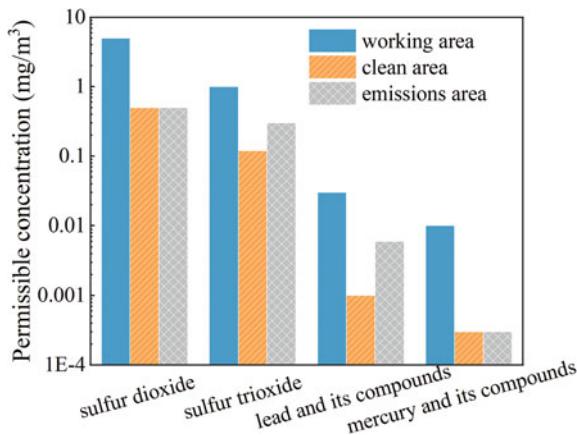

Fig. 19 Permissible indoor concentrations for specific parameters in different areas of nonferrous metal industrial building. Note: (a) Sulfur dioxide and sulfur trioxide are used as specific parameters in working area, sulfuric acid mist is used as specific parameters in clean area and emissions area. (b) Permissible concentrations for working area refer to PC-TWA, permissible concentrations for clean area refer to the time average value in 1 h, and permissible concentrations for emissions area refer to the time average value in 1 h. (Source: National Health Commission of the People's Republic of China (2019), National Institute of Environmental Health, China CDC et al. (2002), and CINF Engineering Co., Ltd et al. (2010))

The permissible concentrations of some indoor specific parameters of ferrous metal (calendering) industrial buildings, such as sulfur trioxide (sulfuric acid mist), hydrogen chloride, benzene, toluene, xylene, should meet the requirements of Fig. 20.

The permissible concentrations of some indoor specific parameters of rubber products industrial buildings, such as benzene, toluene, xylene, hydrogen sulfide, and ammonia, should meet the requirements of Fig. 21.

The principles for formulating the permissible indoor concentrations generally consider factors such as human health effects, economic feasibility, and technical feasibility. Some permissible concentrations only consider human health effects, while in some countries and regions, the determination of permissible concentrations should consider the overall level and economy of the industry at the same time. Thus, for a given environmental parameter, the value is not always the same and not comparable between different standards.

Prediction Methods of Environmental Parameter Values

Different methods can be used to obtain the value of environment parameters of industrial buildings with high pollution sources at different stages. For the existing industrial buildings with high pollution sources, the measurement method that determines the values through site tests and can truly reflect the

(Source: National Health Commission of the People's Republic of China (2019), National Institute of Environmental Health, China CDC et al. (2002), and Baoshan Iron and Steel Co., Ltd et al. (2012))

indoor environment. For the industrial building environments in the design stage, the environmental indexes can be predicted to access whether the environments meet the requirements by analogy method, model experiment, or numerical simulation.

Analogy Method

The analogy method is commonly used in the prediction of occupational hazards (CECS 2021). It predicts the environment of to-be-assessed buildings by field investigation and indoor environmental parameter tests of the production process and indoor environment of the same or similar projects. When the analogy method is adopted, appropriate analogy items and data should be selected, and the feasibility analysis of the analogy between the two items should be performed.

When the industrial building to be assessed is an extension project, the original industrial building project can be selected as an analogy project. If the industrial building to be assessed is the expansion project of the original industrial building, the design scale, production process, production equipment, raw and auxiliary materials, protection facilities, and occupational health management of the industrial building

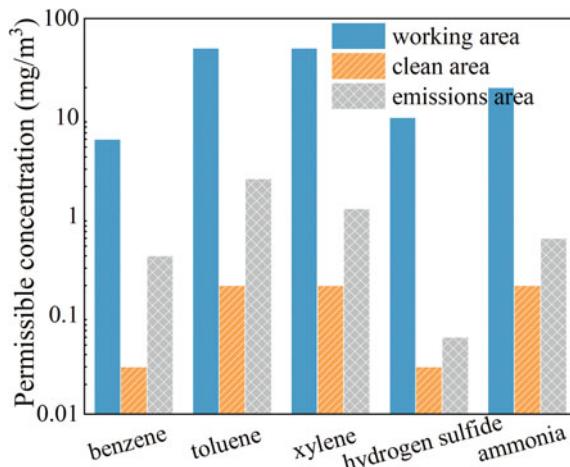

Fig. 21 Permissible indoor concentrations for specific parameters in different areas of rubber products industrial building. Note: Permissible concentrations for working area refer to PC-TWA, permissible concentrations for clean area refer to the time average value in 1 h, and permissible concentrations for emissions area refer to the time average value in 1 h. (Source: National Health Commission of the People's Republic of China (2019), National Institute of Environmental Health, China CDC et al. (2002), and Tianjin Academy of Environmental Sciences et al. (2011))

are probably completely or basically the same as those of the original industrial building. Here, the analogy project has strong comparability and is more suitable for the analogy method.

When the industrial building to be assessed is a new project, similar enterprises in the same industry and industrial buildings with similar processes can be selected. If the project and the project to be assessed are in the same province or city, and the assessment of the analogy project is also completed by the same institution, the environmental parameter data can be obtained from those of previous industrial buildings. If the project is in another province, city, or abroad, but belongs to the same owner as the construction project, the information required for assessment can be provided by the owner. If the project is in other provinces, cities, or abroad, and belongs to different owners of the construction project, it is necessary to obtain analogy information through group companies, industry associations, or other assessment agencies.

Model Experiment

It is a method to restore the airflow and characteristics of the indoor environment of the building in the actual project under laboratory conditions, based on the similarity theory (Huang et al. 2021c). It should be based on the process and environmental conditions of industrial buildings to determine the appropriate number of similarity criteria. The model design should be based on geometric similarities. The determination of an appropriate geometric scale should consider the scale of industrial buildings, test sites, equipment, and other conditions. The boundary conditions of

the model experiment should be set according to the conversion results of the wind tunnel test or design parameters based on the similarity criteria. In the model experiment, if different velocities and temperature differences are involved, the values with large changes in the dimensionless criterion number should be selected. When the initial temperature of the airflow in the model is high, the initial velocity can be adjusted to reduce the initial temperature of the airflow while ensuring the same number of criteria. To avoid large measurement errors, the adjusted initial velocity must be significantly greater than the ambient airflow velocity. The results of the model experiment should be converted to actual values based on the similarity criteria.

Numerical Simulation

Numerical simulation is an environmental prediction method based on computational fluid dynamics (ANSYS 2011). It should be performed based on the basic idea of “analysis of actual industrial building environments – proposal of the physical problems – selection of a mathematical model to describe.” The geometric model, including the shape, size, relative position of the space, and relative position of each component in the space, should be determined based on practical projects. The established model can be simplified based on the actual situation of industrial buildings, and a simplified basis should be provided. The mesh division, initial and boundary conditions, calculation methods, and convergence criteria should meet the corresponding requirements to ensure the accuracy of the calculation. Meanwhile, the calculation model and calculation method used in the numerical simulation should be verified experimentally.

Conclusions

The indoor air quality of industrial buildings with high pollution sources is closely related to the production process, which needs to be controlled through efficient industrial ventilation technology based on the characteristics of pollution sources. With the continuous emergence of new environmental requirements and production processes, the indoor air quality control of industrial buildings is facing new problems, which are mainly reflected in the expansion of industrial buildings and their indoor production scale, the reduction of emission capacity, and the improvement of healthy environmental requirements, which pose a higher challenge to ventilation technology.

In recent years, industrial ventilation technology has made great progress. A series of research results on refined industrial building ventilation technology have been proposed and have been successfully used in industrial buildings with high pollution sources, such as the new ventilation air distribution model based on parallel flow and vortex flow, the efficient control and cleaning technology of high-temperature particles, droplets, and harmful gases. The research on ventilation technology of industrial buildings also shows that with the progress of experiment and numerical simulation technology, it has great potential to improve the effect of

pollutant control and reduce energy consumption and carbon emission by deepening the level of cognition. Facing the low-carbon goal and ultra-low emission demand, there is a long way to go to improve the indoor air quality of industrial buildings with high pollution sources. Meanwhile, it also provides a good opportunity for the significant improvement of relevant technical development. The indoor air quality of many industrial sectors needs to be further improved, and more in-depth and systematic basic research is urgently needed to make a new breakthrough in efficient and low consumption industrial ventilation technology.

Abstract

Solid fuels like coal and biomass fuels are still frequently used for daily cooking, heating, and lighting, especially in rural areas of developing countries. Low-efficient burning of these solid fuels in residential stoves produce significant amounts of air pollutants into not only ambient but also indoor air, resulting in high air pollution exposure and various diseases associated with household air pollution (HAP) exposure. With longer time spent indoors, indoor air pollution contributes significantly to the total air pollution exposure and related adverse

health outcomes. The HAP issue has been attracting growing interests and high concern. This chapter focuses on main research progresses in HAPs in developing countries. Pollutant emissions, exposures, health risks, and needs in future studies are analyzed and discussed. Fugitive emission from home stoves is one main source of indoor air pollution. Due to influencing factors like different stove-fuel combinations and highly variable operational behaviors, both pollutant emissions and indoor air pollutant levels have very high inter- and intra-variations uncertainties in residential pollutant emissions and the associated impact assessment results are relatively high. Significant differences in the inhalation exposure dose were generally observed among different fuel-stove users and gender difference is often found. Contributions of household solid fuels on the energy consumption, pollutant emission, air pollution exposure, and health risks amplified, indicating obvious health benefits in reducing air pollution from household solid fuel use in rural areas.

Household air pollution · Solid fuels · Indoor combustion · Fugitive emission · Exposure · Clean intervention

Introduction

It was estimated that globally there were nearly 2.8 billion people relying on traditional solid fuels like biomass and coals for daily cooking, with most from less developed or developing countries with relatively low socioeconomic status (Bonjour et al. 2013). Besides cooking, solid fuels are important energy sources for heating, resulting more people exposing to air pollutants from the solid fuel combustion (Chen and Zhao 2022; Du et al. 2018a). Solid fuel burning in residential stoves often has low efficiencies and produces high emissions of products of incomplete combustion (PICs) such as carbon monoxide (CO), PM_{2.5} (particles with a diameter of <2.5 μm), black carbon, and polycyclic aromatic hydrocarbons (Du et al. 2018a; Garland et al. 2017). Indoor solid fuel combustion affects not only ambient air pollution but also directly to severe indoor (household) air pollution (Smith et al. 2014; Shen et al. 2019). Since most people spend ~80% or more time indoors, serious indoor air pollution and long residence time indoors cause high exposures to PICs associated with solid fuel use. Exposure to household air pollution (HAP) from solid fuel use has been recognized as one leading environmental risk factor causing more than 1.6 million premature deaths globally in 2017, including ~0.27 million in China and 0.48 million in India (GBD 2019).

Household Air Pollution (HAP) Definition

The problem of air pollution associated with residential combustion has been widely recognized as household air pollution (HAP). The concept of indoor air pollution

(IAP) is well-known and studied. According to the US EPA (2021), IAP refers to air pollution within and around buildings and structures, caused by various sources like fuel-burning combustion, tobacco products, building materials and furnishings, products for household cleaning and maintenance, personal care, or hobbies, central heating and cooling systems and humidification devices, excess moisture, and some outdoor sources. That is, besides solid fuel combustion sources, IAP has other sources including non-combustion processes. Meanwhile, HAP is defined as air pollution arising from inefficient combustions of solid or nonsolid fuels used for domestic cooking, lighting, and/or heating (Smith et al. 2014). The term involves not only indoor but also near residences and in the ambient air (Clark et al. 2013; Du et al. 2018a). When household ventilation is poor or absent, indoor HAP could be more serious than outdoor air. Note that in some studies, HAP is used as the abbreviation of hazardous air pollutants, which is different from the issue discussed here.

Therefore, the differences between IAP and HAP, from their definitions, are obvious (Smith et al. 2014). Compared to IAP, HAP sources are more specific and explicit. The term “HAP” emphasizes the health risk of the exposure to the definite source from cooking, lighting, and heating, not food, spreading to any space. While the term “IAP” covers the health risk of exposure to all sources contributing to the indoor. Some researches use the term “indoor air pollution from household use of solid fuel” to express the air pollution from domestic cooking fuel burning (Smith et al. 2014). However, this term *“neglects the near-household environment, which is the main site of health-relevant air pollution exposure”* and *“the term indoor implies that an effective chimney or other venting would solve the problem entirely, when the basic problem is dirty combustion, thus confusing the attribution of risk and assessment of appropriate interventions unless it is specified which household uses are being considered.”* In rural areas, there are also indoor air pollution issues like hazardous pollutants from furniture, decorations, building materials, and cleaning products that are not limited to urban homes. IAP issues associated with other common indoor sources like cooking fume, furniture, and building materials have been covered in other chapters (Bond 2022; Torkmahalleh 2022; Zhang et al. 2022), and in this chapter, we focus on household air pollution associated with indoor energy use.

Household Air Pollution (HAP) Sources

As mentioned above, HAP here refers to air pollution associated with household fuel use. Therefore, major sources of HAPs are indoor combustion processes and outdoor air pollution via indoor-outdoor air exchange (Chen and Zhao 2022). Efforts have been made to alleviate HAP by promoting clean household energy such as natural gas, liquid petroleum gas, propane, and electricity (Anenberg et al. 2013). Installation of vented facilities like chimney and fans and optimization of stove designs are also purposed as effective countermeasures to lower HAP, especially before utilization of modern energies like electricity and gaseous fuels. Emission smokes from unvented stoves enter indoor environment directly contributing HAP. Some field

studies revealed health benefits after the adoption of improved stoves with chimney (Guarnieri et al. 2015), but some did not find significant improvements (Mortimer et al. 2017). Although chimneys can effectively remove indoor smokes to outdoor, the emission contributes to neighborhood or village pollution, which in turn would influence indoor air quality to some extent. High indoor levels of PICs are still often reported in households burning coal or biomass in chimney stoves (Hartinger et al. 2013; Jiang and Bell 2008; Qi et al. 2019; Qiu et al. 2019). For instance, the kitchen PM_{2.5} in rural Peru homes using improved chimney stoves was as high as 148 (88–208 as 95% confidence interval) $\mu\text{g}/\text{m}^3$ (Hartinger et al. 2013). The wintertime kitchen PM₁₀ concentrations in a rural village were reported at about $100 \pm 203 \mu\text{g}/\text{m}^3$, with a maximum concentration of $1570 \mu\text{g}/\text{m}^3$, though stoves used were equipped with outdoor chimneys (Jiang and Bell 2008). A recent study in rural southern China found that daily average kitchen PM_{2.5} concentration in homes burning solid fuels in brick chimney stoves was $101 \pm 56 \mu\text{g}/\text{m}^3$ (Qi et al. 2019).

High indoor pollution levels in homes with vented stoves are thought to be associated with reasons like leakages (also known as fugitive emissions from stoves) into indoor air, and/or short-circuiting resulting from improper design (Smith et al. 2011). These are two important sources of household air pollution (Johnson et al. 2011; Ruiz-Garcia et al. 2018; Smith et al. 2011). While outdoor air pollution impacts via indoor–outdoor air exchange has been recognized and discussed extensively, fugitive emissions are significantly underappreciated (Shen et al. 2020; Luo et al. 2021). The proportion of fugitive emissions into indoor environment in the total emissions from the combustion process is defined as the fugitive emission fraction. There are significant gaps in data and understanding for this important parameter as very few experiments and modeling studies are available.

Indoor Combustion Emissions and Air Quality

Indoor Combustion Emissions

Emissions of air pollutants can be estimated based on emission factors (EFs) and fuel consumptions. Reported EFs in literature often vary several orders of magnitude and most used to be from tests in developed countries rather than the real-world conditions in rural developing countries, leading to high uncertainties and potential biases in emission inventory development (Lei et al. 2011; Wang et al. 2012). Significant differences are reported between the EFs from laboratory chamber tests and those measured in real kitchens, and between the EFs under controlled conditions and those in field (Roden et al. 2009; Zhang et al. 2011). For example, a study from uncontrolled in-field measurements in Ghana (Coffey et al. 2017) showed the fuel-mass-based carbon monoxide (CO) and particulate matter (PM) emission factors were generally higher in field compared with in laboratory. Roden et al. (2009) found that PM emissions measured in field were on average three times higher than those measured in laboratory tests. Garland et al. (2017) reported that laboratory tests generally had lower black carbon (BC) emission factors but higher BC/PM ratios

compared with field tests. Laboratory experiments allow investigators to repeat the process under controlled conditions to assess influencing factors, pollutant formation kinetics, and mechanisms (Jetter et al. 2012; Zhang et al. 2011). As such, laboratories are suitable for testing a variety of stove/fuel combinations operated under different conditions. Even so, direct field measurements are preferable in developing inventories, because they are more realistic and may cover emissions from stoves operated at random conditions that are difficult to reproduce in laboratory. However, field measurements are much more difficult in sampling and financially expensive compared with the laboratory tests. In recent years, with the development of portable emission testing system, more and more field tests and important data are available. There are more studies in developing countries including China and India.

Indoor Fugitive Emission

While short-circuiting of air pollution is recognized as one source of indoor air pollution from solid fuel combustion, the source of fugitive emissions has been underappreciated. There are very few experimental measurements of fugitive emissions nowadays. Four studies evaluated fugitive emissions, and two of them were laboratory-based tests. At the US Environmental Protection Agency (US EPA) household energy research facility, a well-built system has been developed to evaluate efficiency performance and emissions for stoves with or without chimneys (Jetter et al. 2012; Shen et al. 2017). The facility can quantify chimney and fugitive emissions separately by fully capturing emission exhaust in two separate fume hoods. For a 60 L institutional stove fueled with wood, a study found that fugitive emissions were approximately 2.0–2.7% and 1.0–1.9% of the total emissions for PM_{2.5} and CO, respectively (Jetter 2016). In another laboratory study, Ruiz-Garcí'a et al. (2018) found that fugitive emissions from Plancha-type chimney stoves were only $5 \pm 3\%$ and $1 \pm 1\%$ for PM_{2.5} and CO, respectively.

In the development of the World Health Organization (WHO 2010a) guidelines for indoor air quality (IAQ): household fuel combustion, because of the absence of direct measurement of fugitive emissions prior to that time, it was assumed that for vented stove emissions, the fraction of PM_{2.5} and CO into the kitchen was approximately $25 \pm 10\%$ (range of 1–50%) of those for unvented stoves. This assumption was conservatively based on comparison of the decrease in the concentration of indoor air pollution between homes using stoves with or without chimneys from the two field campaigns (Cynthia et al. 2008; Johnson et al. 2011; Smith et al. 2010). The assumed 25% and the normal distribution were further adopted in models to simulate and to set indoor emission rate targets (Johnson et al. 2011). The value of 25% was far different from the results of the two laboratory studies mentioned above. It has been widely recognized in pollutant emission studies that due to factors like different operator behaviors and burning conditions, there are substantial differences between lab- and field-based pollutant emission factors, with usually higher values and larger variations in the latter (Roden et al. 2009). Given the importance of fugitive emissions and recognizing gaps in data and knowledge, researchers are calling for

evidence-based experiments on fugitive emission characterization, especially under real-world conditions.

Shen et al. (2020) developed a new field fugitive emission study method and quantified field-based fugitive emission fractions (Luo et al. 2021; Shen et al. 2020). The fraction of fugitive CO emissions to the total emissions ranged from $10.9 \pm 9.2\%$ for corn cob burning to $21.6 \pm 17.1\%$ for wood combustion, with an average fraction of $13.5 \pm 10.3\%$. For PM_{2.5}, the average fugitive emission fraction was $27.9 \pm 13.7\%$, ranging from $12.1 \pm 4.0\%$ for corn cob burning to $36.7 \pm 15.0\%$ for wood combustion. An ANOVA result showed that differences among fuel types were statistically insignificant. The fugitive fractions of PM_{2.5} were significantly higher than those of CO ($p < 0.05$), as found in past laboratory tests (Jetter 2016; Ruiz-Garcia et al. 2018). Ruiz-Garcia et al. (2018) thought that the higher fractions for PM_{2.5} may be due to greater fractions of PM_{2.5} escaping during lighting or due to emissions from larger fuel pieces sticking out of the fuel chamber (Ruiz-Garcia et al. 2018). Different dispersion and transport abilities between fine particles and gases like CO may also result in the fugitive fraction difference.

The field-based fugitive fractions presented here are much higher than those in the previous two lab studies, which were $<5\%$. Besides the stove and fuel differences, different testing conditions and quantitative approaches may have caused the discrepancy. There may be similar differences in fugitive emissions and the fraction of fugitive to total emissions between lab- and field-based measurements (Fig. 1). In comparison with the default value of 25% used in the development of WHO guidelines for IAQ: Household fuel combustion, the CO fugitive fraction found ($13.5 \pm 10.3\%$) was much lower ($p < 0.001$), but the fugitive fraction for PM_{2.5}

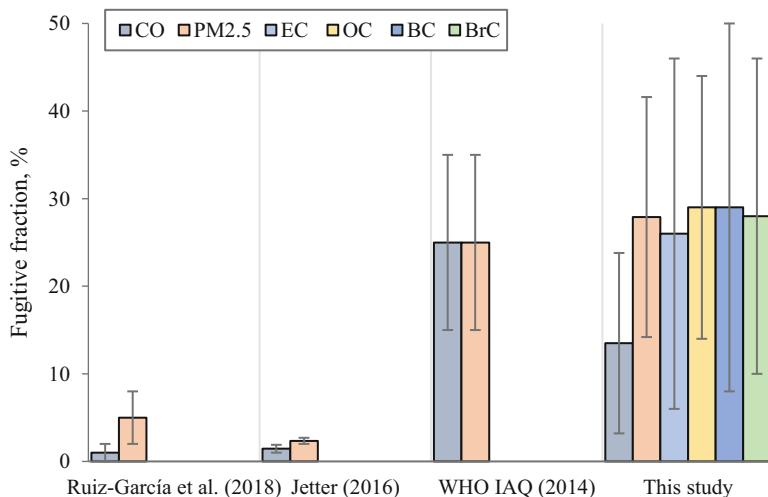

Fig. 1 Comparison of fugitive fractions in two previous lab studies, the default values used in the development of guidelines for IAQ: Household fuel combustion, and values from the field-based study presented here

($27.9 \pm 13.7\%$) was not significantly different from 25% ($p > 0.05$). There was no significant correlation between CO and PM_{2.5} fugitive fractions. The fractions of fugitive emissions of EC and OC were recorded as $26 \pm 20\%$ and $29 \pm 15\%$, respectively, with no significant differences found across different biomass fuels. Average fractions of fugitive values for BC (black carbon) and BrC (brown carbon) were $29 \pm 21\%$ and $28 \pm 18\%$, respectively.

Using a single-zone model (Johnson and Chiang 2015) and assuming that cooking activities occur 3 times a day (for 30 min in the morning and at noon and for 1.0 h in the evening), modelled increments for 24-h-averaged PM_{2.5}, EC, and OC concentrations reached as high as 342 (interquartile range of 251–623), 9.46 (3.59–18.4), and 42.4 (23.9–96.1) $\mu\text{g}/\text{m}^3$ with peak concentrations of 5880, 163, and 728 $\mu\text{g}/\text{m}^3$, respectively. Noted that these indoor concentrations estimates are highly variable, depending on the emission rates and indoor-outdoor air exchange rates. The results here were only semi-quantitatively, but show the high indoor pollution concentrations from the fugitive emissions from vented stoves. While the modelled results are associated with relatively large variations, a few previous field monitoring studies have reported hundreds of $\mu\text{g}/\text{m}^3$ in daily PM_{2.5} with peaks of tens of mg/m^3 for rural households (Qiu et al. 2019), indicating strong indoor air quality contributions and consequently significant adverse health impacts of solid fuel combustion. These studies clearly demonstrate that the simultaneous measurement of indoor and outdoor emissions and air quality is crucial to understanding mechanisms of the environmental impacts of indoor combustion sources. It is necessary and important to evaluate the fugitive emission impacts on indoor air quality in future work.

Household Air Pollution

For most air pollutants in rural homes using solid fuels, HAP in kitchen is often more severe than that in living room and ambient air. Utilization of clean modern energies can reduce HAP effectively for most air pollutants. However, large variations in pollutant concentrations are often reported from the different household structures, various stove-fuel types, meteorological factors, and spatiotemporal conditions (Du et al. 2018a).

CO is one typical gaseous pollutant from incomplete combustion processes. Most HAP studies measured CO. CO was generally higher in winter than that in summer, although the difference might be statistically not significant in some cases (Du et al. 2018a) due to high variations. The kitchen CO in literature ranged from 0.1 to 35 mg/m^3 in summer in homes using solid fuels, and from 0.4 to 30 mg/m^3 in winter. The concentration was generally lower in bedroom than that in kitchen. However, Edwards et al. (2007) observed higher CO concentrations in the bedroom than the CO in the kitchen in the winter of 2002–2003 in rural Shanxi Province, northern China. Data compiled from the literature showed that the difference between homes using solid and nonsolid fuels was statistically not significant, when the comparison was not adjusted for other influencing factors. For homes using gaseous fuels, the

kitchen CO ranged from 2.8 to 12 mg/m³, while in homes using traditional solid fuels, CO had a larger variation across different studies (Du et al. 2018a).

SO₂ contamination is a serious issue particularly in homes burning coal. Indoor SO₂ concentration in rural areas vary largely in 2–3 orders of magnitude, ranging from several to a few thousand µg/m³. The contamination is considerably higher in kitchen compared to the bedroom and outdoor air. The wintertime SO₂ was often reported to be higher than that in summer, and explained by more coal uses for space heating in cold days. SO₂ was also detected in homes using nonsolid fuels, with relatively lower levels compared to that in solid fuel use homes.

TSP or PM₁₀ are often studied in early years, and now, there are more concerns on fine particles (PM_{2.5}, PM_{1.0}) and even ultrafine particles. High wintertime levels, in both indoor and outdoor air, were often reported. For the site difference, there were generally higher concentrations in kitchen than that in bedroom, and lower concentrations in outdoor air. Studies from China showed that the outdoor PM₁₀ in rural areas ranged from 23 to 770 µg/m³, with an arithmetic mean of 261 µg/m³, which was nearly 1.7 times the China National Air Quality Standard of 150 µg/m³, and more than 17 times the new standard of 15 µg/m³ (WHO 2021). The PM_{2.5} ranged from 10 to 460 µg/m³, often exceeding the standards of 15 µg/m³ (WHO 2021). The indoor levels from homes using clean fuels like gas and electricity were lower than those using solid fuels, but serious HAP issue with PM_{2.5} exceeding the standard by several times did still exist in many gas-use households, due to the neighboring effect, unignorable emissions from gas burning, and short-circuiting of air pollution.

Polycyclic aromatic hydrocarbons (PAHs) consist of numerous individual compounds with multiple aromatic rings, existing in either gaseous or particulate phases, but a number of studies reported only particulate PAHs. High indoor pollution levels than the outdoor concentration appeared to be much more significant for PAHs compared to other pollutants, as well as the difference between winter and summer. PAHs are largely produced from the burning of solid fuels, and residential coal and biomass burning is a major source of PAHs globally in many developing countries. The indoor BaP concentration was significantly lower in homes burning LPG compared to that in homes burning solid fuels, but even in those using clean household energies, the indoor BaP levels can exceed the standard of 1.2 ng/m³ set by the WHO (2000), causing adverse health outcomes. Most studies are confined to only the US EPA's designated 16 priority PAHs, or 15 priority PAHs excluding naphthalene as it is volatile and has large measurement uncertainties compared to other PAHs. Chen et al. (2016) measured 28 PAHs including 16 priority PAHs and 12 non-priority ones, in rural Shanxi Province, northern China. Although the mass concentrations of the 12 non-priority ones comprised only about 16%, 8%, and 1% of targeted 28 PAHs in the kitchen, bedroom, and outdoors, respectively. Some of the non-priority compounds are more toxic than the priority ones. Besides parent PAHs, there are concerns on PAHs derivatives like nitrated and oxygenated PAHs which might be more toxic compared to the parent ones. Contamination, transformation, and impacts of these toxic non-priority PAHs in rural areas should be investigated.

Measurements of other pollutants, including but not limited to OC, BC, EC, fluoride, heavy metals, and NOx, led to the following conclusions: higher

concentrations in summer than in winter; higher in indoor than in outdoor; higher in bad ventilation than in good ventilation; more severe in kitchen than in bedroom; and coal > fuelwood > LPG/biogas.

Indoor-Outdoor Ratio

The indoor/outdoor ratio (I/O) is often calculated as an indicator to exchange direction and strength of the exchange between indoor and ambient environments (Chen and Zhao 2011). The I/O value is influenced by many factors, such as stove/fuel combinations, ventilation, the type of air pollutants, and so on.

Studies on I/O ratios of PMs indicated strong impacts of internal sources in rural areas (Huang et al. 2017). The PM that leaked from the cookstoves increased the indoor PM concentrations, which then became concentrated due to the low air exchange rates between the indoor and outdoor air during the local cold winter. Alternatively, diffusion and dilution of particles in outdoor air were usually much stronger than that in indoor air, leading to lower outdoor concentrations of PM. In urban areas, however, the concentrations of indoor PM were generally lower than those outdoors, and a few cases with elevated indoor concentrations were mainly attributed to the infiltration of outdoor PM (Diapouli et al. 2011), which supports the role of rural indoor burning of solid fuels to produce higher concentrations of PM indoors. Du et al. (2017a) reported that for homes using clean fuels, outdoor air pollution is an important contributor to indoor air pollution, while for homes using traditional solid fuels, indoor combustion sources are the main sources of both indoor and outdoor pollution.

I/O ratios larger than 1.0 were also reported for other pollutants including OC, EC, and PAHs. For example, Du et al. (2017b) reported the indoor/outdoor ratios (I/O) for EC, OC, PM_{2.5}, and TSP in homes burning coal were 4.1 (1.1–10 as range), 3.3 (1.9–6.0), 4.6 (1.6–12), and 4.5 (1.9–10), respectively, while for homes burning wood, they were 1.7 (0.93–3.1), 2.5 (0.85–4.4), 2.2 (1.9–3.5), and 2.4 (1.5–4.0), respectively, suggesting significant contributions from indoor sources. The average I/O value for PAH in rural Shanxi, north China, was reported to be 1.8 (0.5–3.8), and was 2.6 (0.9–7.1) in Guizhou, south China (Du et al. 2018b). Although in many studies, stoves were equipped with outdoor chimneys, fugitive emissions may still lead to considerable amounts of air pollutants into indoor air directly.

Exposure and Influencing Factors

Quantification of Exposure

Inhalation exposure is one main pathway of the air pollution. The overall exposure depends on not only outdoor air pollution, but indoor air quality and exposure activities like time spent in different microenvironments and respiratory rates. Some studies estimate time-weighted exposure concentrations based on measured

indoor and outdoor air pollutant concentrations and the time spent in these environments (Mestl et al. 2007). Despite relatively high price of individual samplers and the need of high levels of cooperation from the residents, personal portable samplers are expected to have a more accurate assessment on daily inhalation exposure and have gained popularity in more recent studies. Because of temporal variations in area concentrations (e.g., peak concentrations during a cooking period) and numbers of different microenvironments, there are considerable biases and uncertainties in this indirect estimation approach compared to the direct measurement using personally carried samplers. For instance, a summertime study in rural Shanxi Province by Huang et al. (2017) found that the calculated time-weighted PM average was generally positively correlated with the direct measurement, but the former was ~30% lower. Shen et al. (2014) also found that the inhalation exposure to BaPeq calculated from area concentrations was underestimated by 31–65% compared to the concentration from the personal samplers.

Contribution of Indoor Exposure

As mentioned above, there could be large differences in air pollutant concentrations between the indoor and outdoor air. In the case of no strong internal sources, outdoor air pollution could be a significant source of indoor air pollution, which is known as ambient-originated indoor pollution. In this case, if only using the outdoor pollution concentration in assessing exposure and health risks, the overall exposure would be overestimated. Xiang et al. (2019) estimates that indoor exposures accounted for 66–87% of the total exposure to PM_{2.5} originating outdoors and consequently contributed up to three-quarters of the PM_{2.5}-associated premature deaths in urban China in 2015. Li et al. (2016) reported in an urban area from the northwest China, where coal, gas, and electricity are used for cooking and heating, 75% of the total exposure was attributed to indoor PM_{2.5} exposure. High indoor levels and indoor exposure contributions were observed in the heating period compared to the non-heating period. In case of strong internal sources like solid fuel combustion in rural areas, high indoor pollution concentrations and longer time spent indoors result in high contributions of indoor exposure to the total exposure. For example, in Shanxi Province, Huang et al. (2017) reported that the kitchen PM_{2.5} was the highest ($376 \pm 573 \mu\text{g}/\text{m}^3$), nearly 3 times of the bedroom concentration of $114 \pm 81 \mu\text{g}/\text{m}^3$, and significantly higher than that outdoors at $64 \pm 28 \mu\text{g}/\text{m}^3$. In another study in rural southwestern China, the PM_{2.5} difference between kitchens ($101 \pm 56 \mu\text{g}/\text{m}^3$) and living rooms ($99 \pm 46 \mu\text{g}/\text{m}^3$) was not significant, but both were much higher than the ambient air pollution (Qi et al. 2019). The field study by Huang et al. (2021) reported that the indoor PM_{2.5} exposure for the population using biomass fuels contributed to over 80% to the total exposure in the Eastern Tibetan Plateau area. Recently, a nationwide modeling study in rural China demonstrated that indoor PM_{2.5} inhalation exposure ($80 \mu\text{g}/\text{m}^3$) occupied 95% of the total exposure ($84.5 \mu\text{g}/\text{m}^3$). The higher contribution was more significant for the rural population (94%) where the indoor PM_{2.5} concentration ($95 \pm 34 \mu\text{g}/\text{m}^3$) was much higher than

that in urban areas ($58 \pm 23 \mu\text{g}/\text{m}^3$) because of the strong dependence on solid fuels as household energy sources (Yun et al. 2020). Therefore, compared to outdoor exposure, indoor inhalation exposure contributes largely to the weighted total exposure.

Influencing Factors

Personal exposures varied largely depending on various factors like fuel-stove systems used, activity patterns like time spent indoors and outdoors, and indoor-outdoor air exchanges which are affected by factors like household structure, window-opening, etc. In countries like China and Mongolia, the highest exposure concentrations were generally in cold seasons when home heating was needed and solid fuels like coal and wood are burned. For example, Du et al. (2017a), using personal carried samplers, estimated that the daily exposure to PM_{2.5} were $451 \pm 301 \mu\text{g}/\text{m}^3$ for the population from the north where traditional solid fuels were used for daily cooking and heating, and the concentrations were twice the exposure to PM_{2.5} among the population who do not heat homes by burning solid fuels. Compiled data on HAP exposure in rural China showed that the overall geometric means of exposure to PM_{2.5} among the rural residents of northern and northeastern China in summer ($121 \mu\text{g}/\text{m}^3$) were nearly one-third of that in winter ($359 \mu\text{g}/\text{m}^3$), and in the southwestern regions, the daily exposure concentrations were 160 and $69 \mu\text{g}/\text{m}^3$ in winter and other seasons (spring, summer, and fall), respectively (Du et al. 2018a).

The gender difference in HAP exposure was observed in rural areas. In many developing countries, women often undertake housework, such as cooking, and spend more time in kitchen. Exposure concentrations for the children are also high because of longer time indoors. Therefore, the exposure concentrations are generally in the sequence of women > children > men (Li et al. 2017). The wintertime study by Pan et al. (2001) in rural Anhui Province, eastern China, also found that the daily inhalation exposure to PM₁₀ for males ($556 \pm 535 \mu\text{g}/\text{m}^3$) was lower than that for the females ($659 \pm 646 \mu\text{g}/\text{m}^3$). The exposure to BaP eq was nearly twice as high for the cook compared to the non-cook (Shen et al. 2014).

Exposure could vary largely among the population using different fuel-stove systems. Shen et al. (2016) reported the inhalation exposure concentrations to air pollutants for the rural residents using wood gasifier burners were significantly lower than those burning wood in traditional built-in brick stoves, and comparable to those using LPG and electricity.

Recently, Shupler et al. (2020) measured household and personal PM_{2.5} exposures in 120 communities in 8 countries (including Bangladesh, Chile, China, Colombia, India, Pakistan, Tanzania, and Zimbabwe). As seen from Fig. 2, the exposure concentration for the population using clean energies (e.g., gas and electricity) is much lower than those using dirty fuels (e.g., coal, crop waste, wood, animal dung, and shrubs/grass). However, there were no significant differences between males and females in their PM_{2.5} and black carbon exposures across the

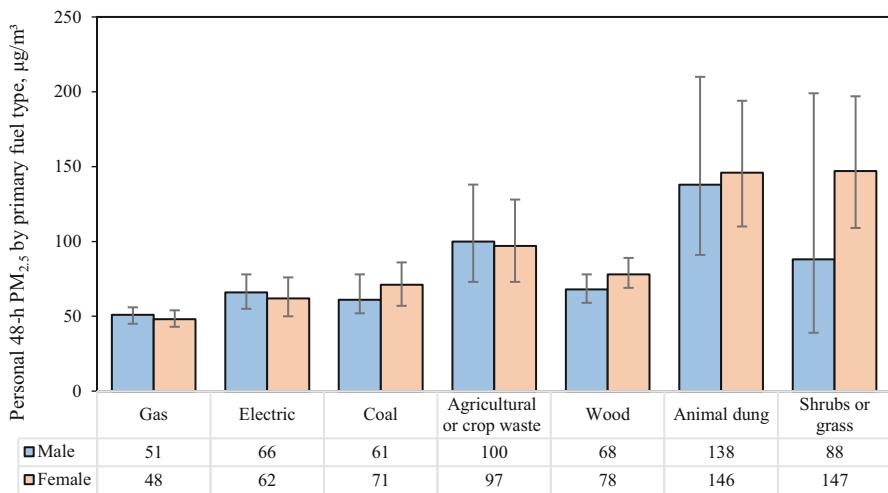

Fig. 2 Summary of 48-h average $\text{PM}_{2.5}$ personal exposures by the primary fuel type. Data was from a study in 120 communities in 8 countries by Shupler et al. (2020)

eight countries. In Bangladesh and Pakistan, where biomass fuels are widely used, females had higher $\text{PM}_{2.5}$ and black carbon exposure were much higher compared to the exposure for males. In populations using clean energies like gas and electricity, the exposure differences between the male and the female are small.

Health Risks Associated with HAP

Estimates of HAP-Related Health Impacts

Adverse health outcomes associated with household air pollution have been reported in mounting empirical studies, and some provides valuable exposure-dose relationship which is critical in accurately quantifying the outcomes. For example, Alim et al. (2014) conducted a cross-sectional survey in Bangladesh and compared the occurrence of respiratory symptoms between adult women using biomass fuels in rural areas and adult women using gas fuels in urban areas. The prevalence of respiratory symptoms and diseases investigated in biomass users was significantly higher than that among the gas fuel users. Albers et al. (2019) studied the association between latent tuberculosis infection (LTBI) and household fuel use in Nepal. Among the population aged 18–70 years, cooking with biogas reduced LTBI compared to cooking with wood and LPG. Kerosene is still used for cooking or lighting in some developing countries. Arku et al. (2020) found the risk of cardiovascular and respiratory mortality for kerosene users was 20–47% higher than that for solid fuel users.

Using low-cost sensors and cause-specific mortality database in China, Dong et al. (2020) found that an increase of $10 \mu\text{g}/\text{m}^3$ in the time-averaged $\text{PM}_{2.5}$ exposure was associated with increased daily mortality estimates of approximately 0.44–0.69% for the total non-accidental causes, cardiovascular diseases, coronary heart disease, stroke, respiratory diseases, chronic obstructive pulmonary disease, respectively. The study also showed that the risk would be underestimated if only ambient $\text{PM}_{2.5}$ exposure was considered.

Premature deaths and disability-adjusted life years (DALYs) are usually estimated to quantitatively evaluate the burden of disease. DALYs for a disease or health condition are the sum of the years of life lost (YLL) due to premature mortality in the population and the years lost due to disability (YLD) for incident cases of the health condition: $\text{DALY} = \text{YLL} + \text{YLD}$ (WHO 2010b). The Global Burden of Disease Study shows that in 2019 (GBD 2019), premature deaths associated with exposure to $\text{PM}_{2.5}$ from solid fuel use were 2.3 million. The DALY was 91,474,469 that was nearly 9 times of that caused by exposure to ambient particulate matter pollution (18,215,374). Adverse health outcomes were mostly in developing countries, including China, India, and the African countries, attributed to dirty fuels, stoves with low thermal efficiency, poor indoor ventilation, and large populations using solid fuels.

The health impacts of HAP exposures for the sensitive group like the infants, children, pregnant women, and the old requires more attention. Bates et al. (2013) found the increase in acute lower respiratory infection (ALRI) in the childhood was associated with the use of biomass stoves, kerosene stoves, and gas stoves, as opposed to electric cooking. Compared with no heating or clean heating (gas or electricity), the use of dirty fuels like wood, kerosene, or coal for heating was also associated with higher ALRI. Persistent cough in the first year of infant life are related to gas stoves and wood-burning stoves (Belanger et al. 2003). Alexander et al. (2017) investigated the influence of clean cookstoves intervention on blood pressure for the pregnant women, in which they found that before the intervention, 8.8% of the kerosene users had hypertension, while 1.8% of the ethanol users ($p = 0.029$). After the intervention, ethanol cookstoves reduced diastolic blood pressure and hypertension during pregnancy.

Amplified Contribution and Clean Household Energy Transition

Based on the updated emissions from on-site emission measurements and a new database of household energy, Yun et al. (2020) estimated that in China, although the residential sector contributed only 7.5% of total energy consumption, the sector contributed 27% of primary $\text{PM}_{2.5}$ emissions; 23% and 71% of the outdoor and indoor $\text{PM}_{2.5}$ concentrations, respectively; 68% of $\text{PM}_{2.5}$ exposure; and 67% of $\text{PM}_{2.5}$ -induced premature deaths in 2014, showing a progressive order of magnitude increases from sources to receptors. The study also found that biomass fuels and coal had comparable contributions to the adverse health impacts. Rural populations are suffering more from severe household air pollution compared to urban populations.

To reduce adverse health outcomes, also in response to climate impacts of climate-relevant pollutants like BC from the residential sector, clean household energies like electricity and gas fuels are being promoted for cooking or heating. Shen et al. (2017) evaluated PM_{2.5} and UFP emissions for 11 fuel-stove combinations, finding that LPG and alcohol combustion emitted $\sim 10^{11}$ particles per useful energy delivered (particles/MJ_d), and burning of kerosene had $\sim 10^{13}$ particles/MJ_d, while solid fuels, including pellet, wood, charcoal, and rice hulls, had higher UFP emissions by 2–3 orders of magnitude (10^{14} – 10^{15} particles/MJ_d). PM_{2.5} EFs, on the basis of useful energy delivered, are also much lower for the liquid and gas fuels: alcohol < LPG < kerosene < solid fuels. For EC and PAHs, the emissions from clean fuels are also lower (Shen 2015).

However, in some studies, the use of clean fuels did not always reduce health risks. A case-control study by Bates et al. (2019) showed that the women using LPG stoves had higher pulmonary tuberculosis risks than those who used wood or biogas stoves, which might be explained by more ultrafine particle emissions. Amaral et al. (2014) suggested that the gas cooking may cause the increase of bronchial responsiveness compared with electricity.

Generally, with the socioeconomic development, many households are switching to clean energies, but fuel and stove stacking are common since one single fuel or stove cannot meet all household energy consumption demands. Zhu et al. (2019), based on a national survey of household energy, pointed out that the stacking phenomena is more and more obvious. The number of household energy types increased significantly between 1992 and 2012, especially in northern areas where there is a need for heating. The number of household energy types was positively correlated with the heating degree days, and negatively with the household income. The mixed use of fossil fuels and biomass may result in more energy consumption (about 20–40%). Because of the common “stacking” approach, the proportion of coal use may be underestimated if only the main energy source was counted in household survey. In addition, the transition rates are different between the cooking energy and heating energy, and there are large spatial differences. Clean transitions first appear in more developed areas, followed by a clean transition in inland provinces after 5–10 years in rural China.

To fight against high wintertime air pollution from widespread space heating burning coals in northern China, China launched a clean heating campaign (CHC) in “2 + 26” cities. Although CHC-1 aims to reduce outdoor air pollution, it had a positive impact on improving indoor air quality (Meng et al. 2020). It was estimated that if the goal of clean heating was achieved by 60%, the primary PM_{2.5} emissions and outdoor PM_{2.5} concentration will be reduced by 70% and 60%, respectively, and meanwhile indoor PM_{2.5} concentrations would be reduced from 209 $\mu\text{g}/\text{m}^3$ to 125 $\mu\text{g}/\text{m}^3$. Consequently, the overall exposure would decrease from 140 $\mu\text{g}/\text{m}^3$ to 78 $\mu\text{g}/\text{m}^3$. If the clean substitution targets were all met, the population exposure concentration would be further reduced to 61 $\mu\text{g}/\text{m}^3$. The clean heating campaign usually requires a fixed proportion of clean heating in each region, but in fact, the realization of the situation in each city is very different. The differences are related to

socioeconomic differences as well as geographical conditions across the region. If differentiated clean heating goals were set according to the actual situation in different places, there would be greater health benefits. The differentiated target could have prevented 30,000 (23,000–34,000) premature deaths in the region, compared to 26,000 (21,000–31,000) premature deaths averted by a fixed clean heating ratio (Meng et al. 2020).

Conclusions

Indoor solid fuel use is an important source of indoor air pollution, especially in many rural areas. Though transition to cleaner modern household energies like electricity and gaseous fuels did occur in many places, especially for cooking, high indoor pollution levels and adverse health outcomes associated with indoor exposure are still often reported. In homes relying on traditional solid fuels, high indoor-outdoor ratios indicated significant impacts of internal combustion sources on indoor air quality and human health. Indoor air pollutant concentrations in literature vary largely across different studies, because of various influencing factors like fuel-stove systems, household characteristics, and meteorological conditions.

Indoor exposure can account for >80% of the total exposure, due to high indoor pollution levels and longer time spent indoors for most population. Exposure to PM_{2.5} associated with indoor solid fuel use causes millions of premature deaths every year, with high deaths in developing countries in east and south Asia, and Africa. Adoption of cleaner household energy and improved low-emission stoves has been demonstrated to lower health risks.

Access to affordable modern household energy is an important part of sustainable development. Indoor air pollution in rural areas, not only from indoor solid fuel use but also other indoor sources, is also concerned in environmental health equality. Adoption of cleaner energies and improved stoves should be encouraged, but it is always not just a technical issue. Future studies are called to evaluate enablers and barriers in clean fuel and stove adoption and sustainable use. Consequent impacts on health and regional climate need to be assessed. It would be also interesting and vitally important to link the health outcomes associated with HAP exposure with unique biomarkers and epidemiological studies. Such studies would enrich our understanding on the adverse impacts of HAP in support of decision-making (Samet et al. 2022; Kinney 2022).

Abstract

There is now unequivocal evidence that the climate is rapidly changing due to the accumulation of anthropogenic warming pollutants (e.g., carbon dioxide, methane) in the Earth's atmosphere. Climate change may affect indoor air quality and associated health impacts via increases in indoor temperatures, higher or lower emissions of pollutants from indoor sources, changes in ambient air pollution driven by climate change, changes in building construction and operations that alter ventilation rates, and changing activity patterns and behaviors, including use of windows and air-conditioning. These changes will be driven not only by climate change itself, but also by efforts to adapt to or mitigate climate change, and will occur in parallel with other societal trends, such as population growth and urbanization, that could impact the built environment and IAQ. Those most vulnerable to climate-related changes in the indoor environment likely include the poor, the elderly, and children. While the challenges posed by climate change for IAQ are not qualitatively new, the pace and complexity of future changes will offer new challenges, as will the societal transformations needed to transition to a

net zero carbon if we are to avert more severe climate change. Since the residential indoor environment is where individuals who are most vulnerable to climate change are and will continue to be found in the largest numbers, it is critical that policy makers and technology developers focus their efforts on finding ways to keep those places as healthy as possible to all members of society in the face of climate change.

Introduction

Substantial changes in the global climate have been evident since about 1960, and evidence from the past few decades demonstrates accelerating warming and increasing intensity of heat waves, extreme precipitation events, and periods of extreme draught. While the trends are clear on a global basis, these changes exhibit strong regional differences. Models tell us that climate change will continue to accelerate over the next several decades, regardless of societal efforts to mitigate, due to the long-term increase of carbon dioxide (CO_2) in the atmosphere and the inherent inertia in the climate system. This highlights the need for large-scale efforts to adapt to the changing climate. It is important to note that the extent of future climate change depends critically on mitigation actions we take now to reduce societal impact on the climate. Strategies to adapt to or mitigate climate change will likely to be important implications for indoor air quality. For example, in addition to their long-term benefits for reducing climate change, mitigation strategies will likely alter indoor and outdoor air pollution sources, as well as building ventilation characteristics. Finally, it is important to recognize that vulnerability to climate change, as well as the benefits of adaptation and mitigation efforts, will vary substantially across populations due to such factors as income, age, the built environment, and social/governance structures (IOM 2011).

Because we spend most of our time indoors, the majority of people will experience climate change to a large extent through its impacts on the indoor environment. This is especially true for the elderly, infants, and those with chronic illnesses, who spend more time at home and are highly vulnerable to environmental health risks. In addition to direct effects of climate change on rising temperatures, humidity, and precipitation, there are several ways in which climate change could affect indoor air quality and associated health impacts. These include increased indoor temperatures, higher emissions of volatile organic compounds (VOCs) from indoor materials, changes in ambient air pollution driven by climate change and/or by efforts to mitigate it, changes in building construction and operations that alter exchanges between indoor and outdoor air, and changing activity patterns and behaviors, including use of windows and air-conditioning. Some of these changes will be

driven by efforts to adapt to higher temperatures and more intense precipitation events, and others will be driven by efforts to become more energy efficient as society transitions to a low-carbon future. In addition to climate change and society responses to it, there will be simultaneous challenges related to increases in population and urbanization, and related changes in the built environment, particularly in developing countries. Figure 1 illustrates the main drivers and linkages among these diverse factors.

While climate change is likely already affecting the indoor environment, there has been relatively little empirical research so far on IAQ in the context of climate change. Nazaroff notes that the question of how IAQ will be affected by climate change involves a complex system (Nazaroff 2013). While the system as a whole has not been studied, he notes that we do have a good understanding of individual system components and their connections with each other. Based on that understanding, we can make useful inferences about how the system may continue to evolve in a changing climate. In this chapter, we make use of several recent reviews and reports which have explored this complex but important topic (IOM 2011; Spengler 2012; Nazaroff 2013; Vardoulakis et al. 2015).

We begin by summarizing some of the key aspects of climate change, drawing from the 2021 report of the IPCC (IPCC 2021). This is followed by a series of subsections summarizing key pathways by which climate change may impact IAQ. Finally, we consider climate change adaptation and mitigation from the perspective of IAQ.

Key Aspects of the Changing Climate

The fact that the global climate is changing due to anthropogenic drivers is no longer in doubt. In its 2021 report on the physical science basis of climate change, IPCC stated that “It is unequivocal that human influence has warmed the atmosphere, ocean and land,” the most definitive statement ever from this body comprised of leading climate experts from around the world (IPCC 2021). Widespread and rapid changes have occurred, including a rise in global mean surface temperature of 1.09 °C for 2011–2020 as compared to 1850–1900, with substantially larger increases over land than water. From 1970 to 2020, global temperature rose faster than in any other 50-year period for at least the past 2000 years. In addition to temperature change, heavy precipitation events have become more frequent as well as intense. Compound climate events where more than one climate-rated extreme occurs in close proximity in space and/or time have also increased in recent decades. The magnitude of these myriad climate changes is unprecedented over many centuries to many thousands of years, based on the best available science.

Along with climate change, rising CO₂ concentrations in the atmosphere are also striking. IPCC concludes that CO₂ concentrations are higher now than at any time in the last 800K years at least, and the amount of change since 1750 is similar in magnitude to the variations observed between glacial and interglacial periods over that time frame. Given the rate of GHG emissions and the inertia of the earth/climate

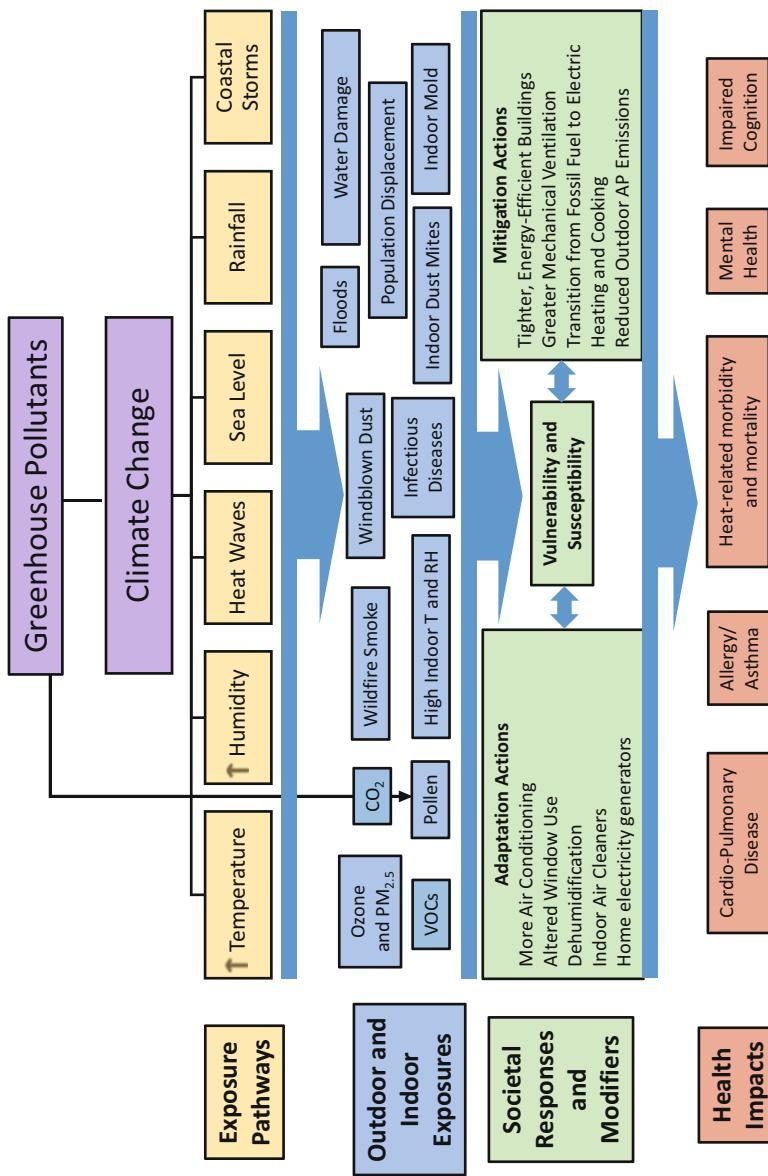

Fig. 1 Key pathways linking climate change to indoor air quality and health

system, scientists expect that temperatures will continue to rise rapidly for several decades this century, with the rate of change and end point being determined by the ability of countries to adhere to ambitious carbon reduction targets. IPCC anticipates additional global warming through 2100 of between 1.4 and 4.4 °C, depending on emission reduction policies. Many of the other climate events, e.g., heat waves, intense storms, droughts, flooding will increase in proportion to the temperature change. Similarly, sea level is virtually certain to continue to rise, by between 0.3 and 1.0 m by 2100 depending on the global GHG emissions trajectory. Unlike temperature, sea level rise is now committed to rise for several centuries to millennia due to the inertia in the earth/ocean/ice systems. We usually talk about climate change in terms of changes in the average state of the system. Superimposed on these gradual trends will be substantial variability across years and decades due to natural drivers and internal variability in the climate system, for example, due to the El Nino Southern Oscillation (the magnitude of which is itself expected to be enhanced by climate change). This is important because many of the effects of climate change on human society are felt most significantly in connection with extreme events in the tails of the distributions of extreme climate events.

Impacts of CC on the Indoor Environment

Climate change involves a long-term trend towards higher temperatures as well as more intense and longer duration heat events in summer, larger and more intense storms and droughts, altered patterns of large-scale atmospheric circulation, and rising sea levels. These direct impacts lead to a range of downstream changes, including higher humidity and declining soil moisture, rising risk of wildfires, higher concentrations of ambient ozone and fine particles (in the absence of emission changes), longer pollen seasons, and more intense dust storms. All of these changes in outdoor environmental conditions have implications for IAQ. We review some of the most well documented in the following sections.

Climate Extremes: Climate change involves both gradual changes in average conditions as well as increases in the frequency and/or severity of extreme events such as heat waves and storms. Extreme climate events, made more intense and in some cases more frequent by climate change, can put people at risk via a range of pathways. In particular, extreme climate events often lead to infrastructure disruption, including loss of power due to floods, wind/tree damage, or the effects of extremes of temperature. Climate extremes can damage homes so severely that families become displaced. When this happens, there can be a wide range of adverse effects due to the living conditions in the new or temporary housing, with potential adverse impacts on several health outcomes including mental health.

Loss of power can lead to greater reliance on portable generators to supply backup power. Portable generators burn liquid fuels such as gasoline or diesel fuel and emit a range of harmful pollutants including carbon monoxide gas (CO), PM, and others. If used in or near enclosed spaces, use of portable generators can lead to deadly exposures to CO (Hampson and Stock 2006; Damon et al. 2013). While the

transition to a low-carbon economy should eventually lead to greater reliance on batteries for backup power, in the near term, it is likely that CO exposure from fuel-based backup generators will continue to be common following power failures. Resulting indoor exposures are more likely in high-density neighborhoods where homes are closely spaced and yards are small, as is common in low-income urban communities. Indoor space heating using fuel-based stoves or heaters poses similar risks, as can indoor cooking with charcoal or wood stoves. People with limited financial resources can be expected to be at higher risk of these effects. During power outages, household exposures to air pollution can also occur due to cooking with gas or charcoal grills. Chen and colleagues found a large and significant increase in CO-related exposures and poisonings reported to the NYC poison control center in the 2 weeks following Hurricane Sandy in 2012, compared to years 2008–2011 (Chen et al. 2013). Most were due to indoor grilling or use of generators.

Moisture Changes: Climate change will result in higher moisture levels in the atmosphere, as well as changing patterns of precipitation, with more rain in some areas and less in others. Higher moisture, alone or in combination with climate-induced sea level rise and coastal flooding, could cause IAQ problems. The 2011 IOM report highlighted the extensive literature linking indoor moisture to adverse respiratory health effects (IOM 2011). For example, Fisk et al. (2007) estimated that one in five of asthma cases in the USA could be attributed to indoor moisture. Moisture-related building material damage promotes bacterial and mold growth, and can release chemical contaminants, such as phthalates from vinyl floor coverings (IOM 2011). Higher temperatures and relative humidity both can affect off-gassing emissions from building materials. Many studies and reports have highlighted the importance of indoor mold (fungi) as a source of health risk indoors (WHO 2009; Brambilla and Sangiorgio 2020). Tighter building envelopes without ventilation and moisture management to keep water activity of surfaces below thresholds for spore germination can lead to IAQ problems.

Many biological agents that are sensitive to temperature or humidity can have profound impacts on human health. Respiratory viruses in particular are of special concern. For example, seasonal respiratory viruses like influenza contribute to morbidity and mortality throughout the world. In the USA, influenza outbreaks occur mostly in the winters. Evidence suggests that low absolute humidity promotes higher infection rates and may be at least partially responsible for observed seasonality (Shaman and Kohn 2009). Low vapor pressure may hasten the evaporation of exhaled respiratory droplets, allowing virus particles to remain airborne for longer periods. The COVID-19 pandemic also exhibited seasonality but was not limited to the cold season. Rising ambient temperatures and humidity may influence future transmission of respiratory viruses; however, those changing ambient conditions will mainly be relevant for human exposure and health to the extent that they influence indoor conditions, where people spend the vast majority of their time. More time spent indoors in air conditioned spaces in a warmer, more humid world could promote spread of disease even if ambient conditions would appear unfavorable for virus survival.

Ambient Air Quality: Climate change and outdoor air quality are closely related. Many GHG sources, such as power plants and motor vehicles, are also key emitters of health-relevant pollutants and/or precursors for PM and ozone. At the same time, warming temperatures and changing weather patterns can alter air pollution emissions, transport, and atmospheric chemistry. Since IAQ is influenced in part by ambient AQ, if outdoor concentrations change, indoor concentrations may too.

Over the past two decades, research has shown how climate change can make it more difficult to achieve ambient air quality objectives. Higher temperatures and changing weather patterns tend to make ozone pollution worse in places where it is already a problem, with adverse consequences for human health (Knowlton et al. 2004; Bell et al. 2007; Kinney 2018). This is of concern both due to direct health effects of ozone on health, as well as from the potential for ozone to oxidize indoor co-pollutants such as VOCs. Recent work has shown that both PM_{2.5} and ozone concentrations in the continental USA could worsen over the current century due to climate change, even with further air pollution emission controls (Fann et al. 2021). Evidence shows that anthropogenic emissions of ozone and PM_{2.5} precursors play a dominant role in future trajectories of ambient AQ, and suggest that the “climate penalty” could be surmounted by more stringent emission controls. However, because ozone chemistry is complex, and depends on the ratio of VOC to nitrogen dioxide (NO₂) in the atmosphere, there are some regions and regimes in which ozone control is especially challenging. The ozone challenge is compounded by potential increases in biogenic VOC emissions as temperatures rise. Indeed, while ambient PM_{2.5} has shown improving trends in recent years, ozone is trending upwards in many locations, including in China (Li et al. 2020) and the eastern USA (Squizzato et al. 2018; Blanchard et al. 2019).

Penetration of outdoor pollutants indoors depends on air exchange between the indoor and outdoor environment. If, in response to a changing climate, homes become tighter and more energy efficient, this may lead to decreased ventilation by outdoor air and reduced penetration of ambient pollution. Mechanical ventilation with air cleaning can enable higher ventilation by clean outdoor air, counteracting the negative consequences of tighter buildings for exposures to pollutants of indoor origin, including CO₂. Recent studies have explored the potential impacts of climate-driven changes in ambient air quality to affect IAQ, with or without changes in building ventilation. For example, Dionisio and colleagues used the EPA APEX exposure model to simulate future ozone exposures for people living in each of 12 large US metro areas (Dionisio et al. 2017). Under a climate change scenario, personal exposures to ozone were predicted to rise, especially for a high climate change scenario. These changes were driven by climate-induced increases in ambient ozone. This study did not take into account changes in home ventilation changes that might occur as a function of climate, which should be included in future studies. Salthammer and colleagues evaluated scenarios of climate change and ambient and indoor air quality in Germany (Salthammer et al. 2018). They concluded that there will likely be higher ambient background concentrations of ozone, but decreasing concentrations of NO₂ and PM_{2.5}, and that with “intelligent manual ventilation behavior, adjusted to suit the conditions of the day, it is unlikely that concentrations

which are critical in terms of health aspects will be attained in indoor areas through infiltration.” On the other hand, they anticipate significant challenges related to keeping indoor temperature and humidity within healthy limits (Salthammer et al. 2018). See the section “[Implications for IAQ of Climate Adaptation and Mitigation Actions](#)” on adaptation responses for related research findings.

Anthropogenic PM_{2.5} is likely to continue to decline in coming decades in the USA and many other parts of the world, following current trends, and accelerated by the transition to a low carbon energy system. This will be especially true for motor vehicle related PM in more urbanized areas, which has a disproportionate impact on local PM exposure, including indoors near roadways, and will be highly sensitive to the trend towards electrification of the vehicle fleet, a trend that is already accelerating. However, “natural” sources of PM, including from wildfires, dust storms, and pollen, are expected to rise with climate change, though with strong regional and temporal heterogeneity. This could change the size and chemical characteristics of PM, its dosimetry, and potential effects on different adverse health outcomes. For example, an increase in secondary organic aerosol could enhance oxidative stress and inflammation leading to both respiratory and cardiovascular morbidity. Also, dust and pollen are risk factors for asthma and other respiratory diseases.

Climate change promotes wildfire risk for several reasons. Higher temperatures draw water vapor into the atmosphere, lowering available soil moisture, which increases the likelihood of fire. Temperature, water, and insect stress in a warming climate also increases the risk of disease-related morbidity and mortality of trees. In a 2008 study, Westerling and Bryant modeled how fire risk in California may be influenced by climate change through this century (Westerling and Bryant 2008). Their analysis suggested that higher temperatures would increase fire risk in wetter, forested regions, but could decrease fire risk in places where lower precipitation might reduce the amount of fuel available to burn in the longer run. More recently, Neumann et al. modeled the potential future impacts of climate change on wildfire-related PM_{2.5} and mortality across the continental USA (Neumann et al. 2021). They found that climate change could increase wildfire pollution emissions by about 38% between 2006 and 2100 under a lower GHG emission scenario, and about 67% over the same period under a high GHG emission scenario. Their model further showed that wildfire PM_{2.5} concentrations could more than double by the end of the century, with substantial impacts on premature mortality among exposed populations.

In addition to PM_{2.5}, wildfires also increase ambient concentrations of ozone, CO, NO₂, formaldehyde, acetaldehyde, and other pollutants. Fisk (2015) estimates, based on a 50% infiltration rate, 90% of time indoors, and typical at-rest breathing rates, that adults may receive about 65% of total wildfire smoke exposure indoors and children about 50%. To protect people from exposure and health risks from wildfires when they occur, he recommends spending more time indoors with windows and doors closed, and to operate particle filtration systems. The latter can reduce indoor PM by 50% or more, which would reduce risks from wildfire smoke as well as from general PM for people living in high pollution areas.

As large-scale regional smoke exposure becomes more common due to persistent fires, there will be a growing need for information on how best to mitigate IAQ

impacts in affected areas. Burke and colleagues analyzed a range of social media and other data sources to shed light on current impacts of wildfire smoke on household behaviors and exposures (Burke et al. 2021). The authors noted that protection from wildfire smoke is currently treated as a private responsibility in the USA – i.e., encouraging staying indoors, closing windows, and/or using air filtration devices. However, there are likely large differences in the ability of people to implement protective measures. Using cell phone location records, the authors showed that fire smoke days with PM_{2.5} concentrations above 50µg/m³ lead to about a 10% increase in average time spent indoors. This effect was higher for high income versus low income populations, potentially because lower income people have less options to work from home and/or less ability to control IAQ. The study also analyzed data from indoor low-cost PurpleAir sensors used in the San Francisco Bay area and compared the PM_{2.5} to outdoors when fire smoke is present. The average I/O ratio was about 0.15, but was lower at higher ambient concentrations, probably due to protective behaviors. Infiltration varied substantially across households. The highest quartile infiltration versus lowest had 3.5x higher indoor PM_{2.5} concentrations, meaning that population exposure to wildfire smoke varies markedly across the population. Interestingly, the study observed no income gradient in penetration, but the authors note that users of low-cost sensors tend to be more wealthy than average.

Results from this study make the point that exposures to fire smoke depend only partially on outdoor airborne pollutant concentrations, but also on such factors as knowledge about risks, ability to shelter at home, and the ability to modify the indoor environment in ways that reduce exposure and risk. Those attributes will likely vary across the population. Education can help with the first part. Government assistance programs can help with the second. However, there is likely to be a dichotomy in agency between owners and renters.

Rising CO₂: CO₂ concentrations outdoors have risen steadily for several decades, as clearly demonstrated by the continuous series of CO₂ measurements at the Mona Loa observatory since 1958. As of December 1, 2021, CO₂ concentrations there had reached 416 ppm. Rising CO₂ concentrations (as well as warmer temperatures) are leading to longer and potentially more severe pollen seasons in North America, with adverse impacts on allergy and asthma (Anenberg et al. 2017; Neumann et al. 2018; Anderegg et al. 2021). Laboratory studies in which common ragweed was grown under different CO₂ concentrations demonstrated dose-related increases in both the amount, and the potency, of the pollen generated (see, e.g., USGCRP 2016). Similar findings were reported for ragweed grown in downtown Baltimore, where mean CO₂ concentrations were 30% higher than in a comparison plot grown in a rural location (Ziska et al. 2003). Authors reported that “ragweed grew faster, flowered earlier, and produced significantly greater above-ground biomass and ragweed pollen at urban locations than at rural locations.” Recent analyses of ambient pollen trends demonstrate that pollen seasons are getting longer in response to climate change (Anderegg et al. 2021). Although pollen grains tend to have large physical diameters, their low density gives them much smaller aerodynamic diameters, which enhances their penetration into indoor spaces.

In addition to its impacts on plant biology, CO₂ can be problematic indoors for human health and well-being. CO₂ can reach very high concentrations indoors due to respiration of human occupants. Concentrations well above 1000 ppm are routinely observed in conference and classrooms. Studies have shown a range of adverse effects of concentrations about 1000 ppm, including reduced cognitive performance on standardized tests. Tighter buildings and reduced interior volumes aimed at efficient use of energy will make it difficult to keep CO₂ at healthy concentrations.

While CO₂ is often used as a tracer for poor ventilation, evidence on the direct health effects of CO₂ itself remains sparse. Since CO₂ indicates inadequate ventilation, health effects observed in field studies may also be due to the increases in concentration of indoor contaminants as a consequence of a poor ventilation. However, emerging evidence from carefully controlled studies suggests a range of direct effects at CO₂ concentrations of 1000 ppm and above (Jacobson et al. 2019). The American Society of Heating and Air-Conditioning Engineers (ASHRAE) recommends indoor CO₂ below 700 above ambient to ensure comfort, which would translate to an indoor concentration in the neighborhood of 1100 ppm. However, ambient concentrations are rising, and urban areas are already higher than the global mean, and more people are moving to urban areas. In the future, the urban CO₂ dome will diminish in intensity as we transition to renewable energy sources for transportation and building energy needs. Like other indoor-source pollutants, smaller spaces and lower ventilation as energy savings measures will tend to increase CO₂ concentrations resulting from occupant respiration. Satish and colleagues carried out an experimental study in which 22 subjects were exposed to CO₂ for 2.5 h at each of three CO₂ concentrations: 600, 1000, and 2500 ppm in an enclosed office-like space. Performance on decision-making tasks (assessed by computer) diminished modestly but significantly at 1000 ppm compared to 600 ppm, and quite substantially at 2500 ppm, for most of the decision-related sub-domains (Satish et al. 2012). Implications are uncertain but reinforce the target of staying below 1000 ppm indoors.

Household Air Pollution from Solid Fuel Combustion: Cooking and/or heating with biomass fuels such as wood, dung, charcoal is a daily reality in much of the world where access to clean fuels is limited by cost and/or technical constraints (see chapter “Cooking/Heating”). Biomass fuel use is highly prevalent in rural regions of Africa, Asia, and South America. This combustion leads to very high concentrations of PM, CO, and many carbonaceous compounds in the indoor environment, and presents substantial health risks, especially for women and children. Climate change could influence biomass-related IAQ through several mechanisms. Heating demand would likely go down with warmer winters, lowering indoor impacts. Also, higher ambient temperatures and dry conditions could lead to more cooking outdoors or in better-ventilated structures, potentially leading to lower personal exposures. However, other trends not directly related to climate change could have more profound impacts, including urban migration, economic development, and national clean-fuel initiatives aimed at providing greater access to LPG, electricity, or other clean options. While there have been substantial efforts over several decades to develop cleaner-burning stoves using biomass fuels, and some have shown promising results,

in general they have proven unable to sustainably reduce exposures sufficiently to avoid adverse health impacts (Chillrud et al. 2021).

Changes in Activity Patterns Due to and in Parallel with Climate Change

Another important trend affecting exposures to IAQ is time spent indoors in various microenvironments: home, work, transit, and school. All are likely to change as society transitions to a zero-net-carbon future. Historically, people spent 60–70% of time at home and 80–90% of time indoors (IOM 2011) (see ► Chap. 37, “Time-Activity Patterns”). The COVID-19 pandemic in 2019–2021 led to major shifts in allocation of time across these modes, with substantial increases time spent indoors at home. After the pandemic receded, there is evidence of some shift back part way in the direction of pre-pandemic time allocation. However, it is unclear to what extent society will fully return to the old way of life. Moreover, zero-net-carbon implies reducing unnecessary energy use for commuting and climate control in office buildings, which will be an added pressure in that direction. An additional relevant factor, not directly related to climate, is the shift away from brick and mortar commerce as online retail continues its rising dominance. This will reduce the need for in-person shopping and favor time spent at home. It is unclear though whether climate change itself will result in addition pressure to shift spent at home versus other locations (see p. 43 of (IOM 2011)).

Vulnerability

Effects of climate on IAQ likely vary for different segments of the population due to differences in housing type and quality, owner versus renter, economic resources, knowledge of the issue, language, local microclimates, location in relation to the urban heat island, baseline health status, age, etc. (Fisk 2015; Vardoulakis et al. 2015). This diversity of impacts calls for extra effort on the part of policy makers to level the playing field by targeting interventions to those most affected and/or unable to take action on their own. Groups vulnerable to climate-related extremes affecting the indoor environment include the poor (low energy security; poor housing quality; lack of resources and/or knowledge to respond to extreme events; lower baseline health status), the elderly (chronic illnesses; limited mobility/homebound; cognitive deficits; limited social and economic resources; less physiologically able to acclimate to heat waves), and children (more time spent at home, especially for infants). Lower income individuals are less likely to be homeowners. Renters have less control over their indoor environment. They may be more likely to rely on windows for ventilation, and also more exposed and less able to protect from extreme heat or storm events. Also, income gradients lead to differential ability to respond to extreme events including heat waves and storms, and the ability to repair damage and get back to normal versus being displaced and/or exposed to mold or chemicals

for longer periods. What little is known about vulnerability and IAQ is mainly based on research in North America and Europe. Fisk (2015) points out that this makes it difficult to draw conclusions for other, potentially more vulnerable, world regions.

Implications for IAQ of Climate Adaptation and Mitigation Actions

IAQ is likely to be affected not only by climate change itself but also by societal responses to climate change, including strategies to both adapt to climate change and/or mitigate (reduce or eliminate) GHG emissions. Adaptations are actions taken to reduce the impacts of a changing climate, for example, to maintain indoor thermal comfort in response to higher ambient temperature, or to avoid penetration by water in the event of floods or extreme rainfall. Mitigation involves actions to reduce GHG emissions, or enhance sinks, in an effort to minimize our impact on the future climate. Since the building sector is a major contributor to carbon emissions, it will also be an important target of mitigation actions aimed at improved energy performance and for shifting from fossil-fuel based fuels to renewably generated electricity.

Indoor air quality depends on the joint influence of indoor sources, ventilation with outdoor air, and concentrations of pollutants in outdoor air. Both adaptation and mitigation efforts in buildings are likely to result in tighter buildings with less natural ventilation. Thus, along with energy efficiency and thermal comfort measures, it will be important to identify and reduce indoor pollution sources related to building materials, consumer products, and cooking, and, where necessary to incorporate air cleaning or local ventilation to reduce impacts of indoor sources. Meanwhile, mitigation of GHG emissions more broadly, as well as air quality regulations, should lead to a continued trend towards lower ambient air pollution concentrations.

There is increasing recognition that the climate is changing at an accelerating rate, and that both adaptation and mitigation responses will be necessary to both build resilience to climate extremes in the near term and to limit our impact on future climate change. Rising temperatures will have important implications for indoor thermal comfort. As ambient temperature rises, the seasonal and geographic patterns of window use and air-conditioning will evolve to maintain internal thermal comfort. While hard to predict, and very location specific, these changes are likely to affect indoor concentrations of pollutants of both indoor and outdoor sources.

A recent study in Atlanta illustrates how warming temperatures could affect home ventilation and indoor/outdoor penetration of ambient PM over the course of the seasons (Liang et al. 2021). The researchers measured I/O infiltration ratios for PM_{2.5} sulfate in 60 Atlanta homes between 2016 and 2017. They observed seasonal variations in I/O infiltration ratios, with ~20% lower values in summer when A/C use was highest compared to spring and fall (see Fig. 2). The seasonal pattern was stronger in homes without HVAC systems. They then developed prediction models for infiltration ratio based on ambient temperature, and then used those models to

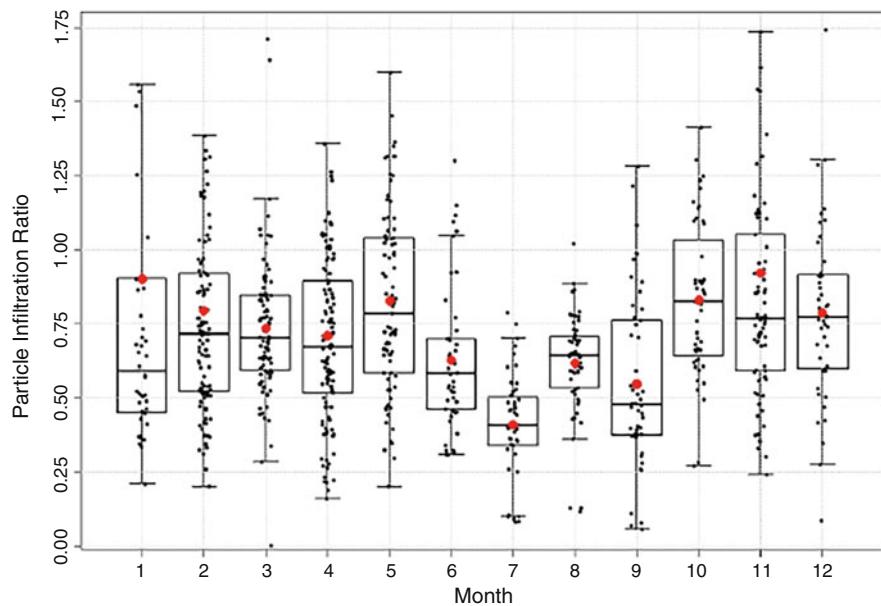

Fig. 2 Distribution of particle infiltration ratio by month in 60 houses in Atlanta. (From Liang et al. 2021)

estimate future I/O infiltration ratios under climate change scenarios in 2046–2065 as compared to a baseline climate period of 1981–2000. With 2.1 °C warming in Atlanta, they estimated there could be a 4% *increase* in infiltration ratio during cooler months and a 6% *decrease* in warmer months. While these results for Atlanta cannot be generalized directly to other locations, they do illustrate the bidirectional impact of seasonal changes in ventilation on indoor exposures to PM of outdoor origin and how those could shift in a future, warmer climate. Figure 2 shows the distribution of particle infiltration ratios by month from that study.

Ilacqua and colleagues used a model for building infiltration that is driven by indoor versus outdoor temperature differences, which partly drives infiltration, for nine US metro areas (Ilacqua et al. 2017). By mid-century, annual mean infiltration went down about 5% based on T output from eight climate models. But seasonal differences were noted, with some locations experiencing increases of 20–30% in summer.

Air-conditioning is an effective way to reduce indoor exposure to heat and to protect from adverse health effects during heat waves. However, prolonged use of A/C among inactive residents prevents physiological adaptation to even moderate increases in heat, putting people at greater risk if they must leave the A/C space for whatever reason or during power outage. Also, extensive A/C use increases load on grid and can be a reason for blackouts, contribute to the urban heat island, and lead to higher CO₂ emissions if the electricity comes from a power plant fueled by coal, oil, or gas.

On the mitigation side, increasing commitments by local and regional government bodies to achieve a net zero carbon economy by mid-century implies that we are embarking on a rapid trend towards an all-electric energy system based on renewable energy sources like solar and wind (Steinemann et al. 2017). This in turn implies lower ambient air pollution (at least for NO₂ and PM), no indoor gas cooking emissions or space heating emissions, and tighter building envelopes for energy efficiency.

Mitigation-related efforts to reduce energy use in buildings could lead to lower volume structures with less ventilation with outdoor air, leading to higher impacts of indoor sources, including cooking and heating, emissions from materials, furniture, cleaning products, etc. As indoor volume and air exchange are reduced, indoor sources will have a larger impact on IAQ unless the sources themselves are mitigated through elimination, substitution, or focused ventilation. Because exhaust fans have a more difficult time drawing air outdoors when there is high back pressure due to a tight building envelope, this tendency would need to be counteracted with engineered retrofits. As a general matter, space heating energy needs will gradually diminish worldwide as mean global temperature rises. There could also be pressure for greater use of renewably sourced wood-based fuels, which could have adverse impacts in IAQ if not burned efficiently and fully ventilated outdoors. In addition, it is possible that there will be some northward migration of populations as new communities are established in cooler regions closer to the poles.

There will be strong pressure to maximize energy efficiency as we transition to a net-zero carbon economy. Conditioning of indoor temperature and humidity is a major factor in building energy use and will thus be an important target for energy efficiency measures. These could lead to lower ventilation rates, which might in turn lead to higher concentrations of pollutants generated indoors (CO₂, combustion-related PM and gases, VOCs and semi-volatile VOCs), while also reducing penetration of ambient pollution.

There is a growing literature examining the interplay between energy efficiency, climate change, and IAQ. For example, based on a systematic review of literature since 2000, Levasseur and colleagues recommend a holistic approach to IAQ management, incorporating knowledge about how to reduce contaminants at the source (referring to both indoor sources and infiltration of ambient), ensuring adequate ventilation, and purifying indoor air if needed, taking into account ambient conditions (Levasseur et al. 2017). They note that because buildings are getting tighter due to concerns of energy and carbon emissions, there is a growing need for complementary ventilation to maintain adequate IAQ. Heat recovery and energy recovery ventilators are increasingly being used to deliver fresh air while maintaining indoor thermal and moisture comfort, without introducing condensation problems. However, to operate effectively, proper calibration and ongoing maintenance are needed. Natural ventilation is another option and is modifiable via window opening by occupants. There is a potential interaction of hot weather, window opening, and the presence of high outdoor pollution due to climate-related ozone, pollen, or wildfire pollution. Encouraging more natural ventilation at night could help since pollution concentrations tend to be lower (at least for ozone and

anthropogenic PM) and temperatures tend to be cooler (though less so in a warming climate).

A potentially important new direction in IAQ under climate change will be development and application of adaptive, active intelligent control ventilation systems which monitor occupancy, indoor/outdoor T, RH, CO₂, and possibly PM, and adjust infiltration of fresh air to maximize comfort and IAQ as well as being as energy efficient as possible (Laverge et al. 2011). During extreme air pollution episodes, whether from wildfires or other sources, the ability to minimize infiltration, accompanied by some filtration could help to preserve IAQ while the event is ongoing. Based on their analysis, Laverge et al. suggest that demand-controlled mechanical exhaust ventilation in residences can reduce indoor CO₂ concentrations and save 25–60% of heat loss during the heating season as compared with conventional systems. In another study, Carbonare and colleagues evaluated a ventilation system that learns based on user behavior and adjusts indoor CO₂ and RH (Carbonare et al. 2021). The idea is to provide comfort and IAQ where and when it is needed, rather than in all places at all times, providing good IAQ at reduced energy cost.

Improved source controls or elimination will also be critical in tighter, more energy-efficient homes to maintain adequate IAQ. Air cleaning may be needed when IAQ problems cannot be addressed with ventilation or source controls. Air cleaners can be effective, but may require frequent maintenance to be most efficient, and need to be scaled to the volume of the space, taking into account air exchange (Davison et al. 2021). Cleaning close to the source of indoor pollution is usually most effective.

Fisk (2015) suggested that we should prioritize indoor environmental quality in residential settings, where vulnerable people are most likely to be exposed. He highlights the value of passive thermal control measures – insulation, window shading, better windows, reflective roofs – because they do not result in ongoing CO₂ emissions, unlike A/C use. However, A/C use with the windows closed substantially reduces indoor concentrations of ozone. Ozone episodes often coincide with heat waves, so air-conditioning can provide a double benefit. Evidence also suggests that health effect associations for ambient air pollution are lower for homes with A/C, likely due to lower exposures indoors.

Moreno-Rangel and colleagues note that the building sector is responsible for a substantial amount of energy use and GHG emissions currently, and thus will be an important target for mitigation actions on the path to a zero-carbon future (Moreno-Rangel et al. 2020). This paper surveyed the literature on IAQ characteristics of passivhaus dwellings. These are highly energy-efficient buildings that provide thermal comfort using mechanical ventilation to supply fresh air from outdoors with heat recovery. They found relatively little data on IAQ in relation to energy efficiency, but what is available suggests that homes meeting passivhaus standards have generally better IAQ than conventional homes, including new energy-efficient homes, probably because of the greater supply of fresh air. However, this finding points out the need for filtration of inlet air stream using appropriate methods, in locations or at times when ambient pollution concentrations are high, as well as the

importance of indoor source elimination or controls to maximize IAQ. They reinforce the value of keeping ventilation rates above 0.5 h^{-1} along with indoor source controls and air cleaning where needed. This review suggests that highly energy-efficient dwellings, when properly designed and maintained, have the potential to provide good IAQ while also achieving substantial energy reductions. But proper functioning requires adequate knowledge among building occupants.

Conclusions

Climate change is and will have increasing impacts on society, including via the indoor environment. Impacts, both negative and beneficial, may be felt due to longer and more intense heat waves, milder winters, more intense storm events, coastal flooding, rising concentrations of ambient pollen and smoke from wildfires, reduced anthropogenic air pollution, the low-carbon energy transition, energy efficiency measures, and other direct or indirect pathways related to climate change. The mechanisms by which IAQ may change due to these factors are ones that building scientists have been studying for decades: changes in indoor sources; technology for air cleaning; impacts of ventilation by fresh air, etc. Thus, the toolkit available to confront these changes will be similar to what we are already familiar with. However, the pace and complexity of changes will offer new challenges, as will the societal transformations needed to transition to a net zero carbon if we are to avert more severe climate change. Since the residential indoor environment is where individuals who are most vulnerable to climate change are and will continue to be found in the largest numbers, it is critical that policy makers and technology developers focus their efforts on finding ways to keep those places as healthy as possible to all members of society in the face of climate change.
