Though there are some measurements for indoor SVOCs concentration, only one complete experiment in a real indoor environment was found in the literature to obtain the dynamic concentrations in different phases including gas, particle, dusts, and surfaces. The experiment was conducted in a test house located at the University of Texas at Austin as shown in Fig. 14a (Bi et al. 2015), which is a three-bedroom, two-bathroom, 110 m² residential building built in 2008. In the house, 2-month periodical measurements of total airborne (i.e., gas and particle phase) and dust phase BBzP (benzyl butyl phthalate) were taken together with the concentrations on various surfaces including stoneware dish plates and mirrors in the test house at the controlled temperature (21 ± 0.8 °C). Then, based on the estimated or experimentally measured parameters used in the model presented above, the SVOC concentrations were predicted and compared to the measured concentrations as shown in Fig. 14b–e. The model is able to predict the dynamic variation of indoor BBzP concentration in different media with acceptable uncertainty.

Estimating Partition Coefficients of SVOCs Between the Gas Phase, Airborne Particles, Settled Dust, and Surfaces

Due to low vapor pressure, SVOCs tend to adhere to indoor surfaces including airborne particles, settled dusts and walls, which is very different from VOCs and is substantial to indoor SVOC concentrations. In common, the equilibrium partitioning between different compartments is characterized by partition coefficients defined by Eqs. (45), (46), and (47) (Weschler and Nazaroff 2010; Liang et al. 2019).

$$K_p = \frac{C_{part}}{TSP C_{gas}} \quad (45)$$

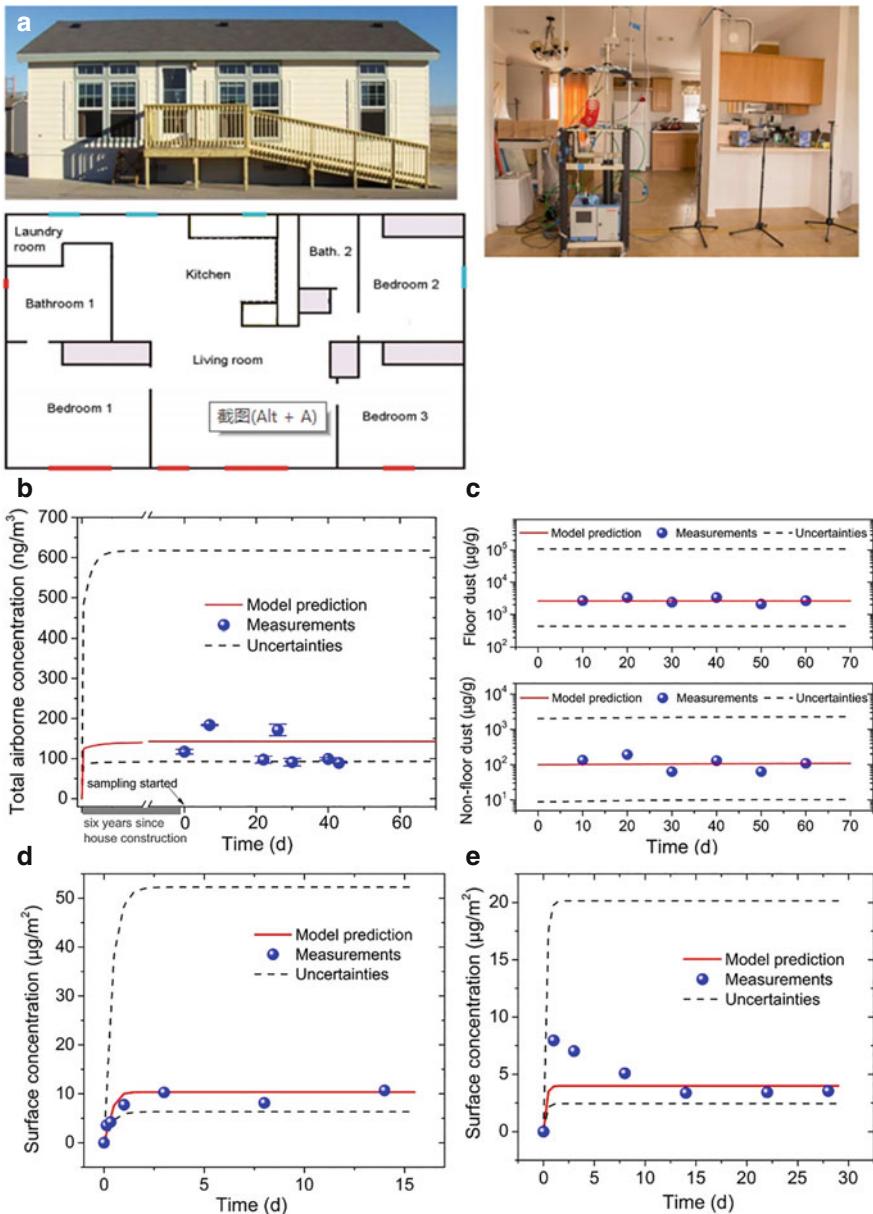

Fig. 14 Predicted results by the model and comparison with experimental data. (a) UT test house at University of Texas at Austin. (Reprinted from Bi et al. (2015) Copyright 2021 with permission from American Chemical Society); (b) suspended airborne BBzP concentration; (c) settled dust phase BBzP concentration; (d) plate surface phase BBzP concentration; and (e) mirror surface BBzP concentration. (Reprinted from Liang et al. (2019) Copyright 2021, with permission John Wiley and Sons)

$$K_{dg} = \frac{C_{dust}}{C_{gas}} \quad (46)$$

$$K_{sg} = \frac{C_{surface}}{C_{gas}} \quad (47)$$

where C_{part} is the particle phase concentration in the air ($\mu\text{g}/\text{m}^3$); TSP is the average particle concentration in the air ($\mu\text{g}/\text{m}^3$); C_{gas} is the gas phase concentration in the air ($\mu\text{g}/\text{m}^3$); C_{dust} is the dust phase concentration in the settled dusts ($\mu\text{g}/\text{mg}$); $C_{surface}$ is the surface phase concentration ($\mu\text{g}/\text{m}^2$). Thus K_p , K_{dg} , and K_{sg} are not dimensionless and their units are $\text{m}^3/\mu\text{g}$, m^3/mg and m , respectively.

Based on the assumption that the affinity of an SVOC for sorbed organic matter is similar to its affinity for octanol, Weschler and Nazaroff (2010) estimated partition coefficients by Eq. (48).

$$K_{SVOC,m} = f_{om,m} K_{oa} \quad (48)$$

where $K_{SVOC,m}$ is the medium-air partition coefficient in the respective compartment, $f_{om,m}$ is the fraction of organic matter in the medium, and K_{oa} is the octanal-air partition coefficient of the SVOC. On indoor impermeable surfaces, similar organic films are likely to be ubiquitous on indoor surfaces (Weschler and Nazaroff 2017), $f_{om,m}$ can be approximated to 1. Further information on organic films on impermeable surfaces can be found in Weschler and Nazaroff's paper (2017).

Considering the difference between octanal and organic matter, K_{part} can be estimated by the following equation (Finizio et al. 1997).

$$\log(K_p) = \log(K_{oa}) + \log\left(1.22 \times 10^{-12} \times f_{om} \times \frac{M_o}{M_{om}} \times \frac{\gamma_o}{\gamma_{om}}\right) \quad (49)$$

where M_o (g/mol) and M_{om} (g/mol) are the molecular weights of octanol and the mean molecular weight of the organic matter phase, respectively, and γ_o and γ_{om} are the activity coefficients of the chemical in octanol and in the organic matter phase, respectively. The model expressed as Eq. (49) is called single parameter model because it considers only the sorption of SVOCs by organic matter in particles.

K_p can also be estimated based on the vapor pressure of the SVOC of interest at different temperature, as shown in Eq. (50) based on Pankow's partitioning theory (Pankow 1994; Wei et al. 2019b).

$$K_p = \frac{f_{om}RT}{10^6 M_{om} \gamma_{om} p_b T_b^{(1-\frac{T_b}{T})} e^{\frac{\beta}{R}(1-\frac{T_b}{T})}} \quad (50)$$

where p_b is the SVOC vapor pressure at the boiling point (Pa); T is the absolute temperature (K); T_b is the absolute temperature at the boiling point (K); and β is a constant. From Eq. (50), the effect of the temperature on partition coefficients may

be found and can also be simplified as shown in Eq. (51) (Wei et al. 2016), which was validated with experimental data (Wei et al. 2016; Zhou et al. 2021).

$$\log(K_{p,T}) = \frac{A}{T} + B \quad (51)$$

Because some of the parameters in the theoretical models are difficult to obtain, the following empirical correlations with the sub-cooled vapor pressure p_L and the octanol-air partition coefficient K_{oa} are often used to estimate particle-gas partition coefficients.

$$\log(K_p) = m_p \log p_L + b_p \quad (52)$$

$$\log(K_p) = m_o \log K_{oa} + b_o \quad (53)$$

where m and b are the empirical parameters that were obtained by fitting the measured data into Eqs. (52) and (53). m and p also correlate with the air temperature t , $\log(K_{oa})$, and $\log(p_L)$ (Qiao et al. 2021).

$$m_o = -m_p = 0.011t + 0.263 \quad (54)$$

$$b_o = -(0.135t + 5.006) \quad (55)$$

$$b_p = -(0.054t + 3.101) \quad (56)$$

$$m_o = \frac{1}{a-b} [\log(1 + 2.4f_{om}^{-1}10^{10-b}) - \log(1 + 2.4f_{om}^{-1}10^{10-a})] \quad (57)$$

$$b_o = -11.38m_o - 1.53 \quad (58)$$

$$m_p = 1 - \frac{1}{c-d} [\log(1 + 1.20f_{om}^{-1}10^{-d-4}) - \log(1 + 1.20f_{om}^{-1}10^{-c-4})] \quad (59)$$

$$b_p = 4.92m_p - 1.53 \quad (60)$$

where a and b are the maximum and minimum values of $\log(K_{oa})$ of SVOCs for the sampling event/events, respectively, and c and d are the maximum and minimum values of $\log(p_L)$ of SVOCs for the sampling event/events, respectively. The above equations are applicable in the range from -40°C to 38°C .

In most models, only the organic fraction of particles is assumed to sorb SVOCs. Dachs and Eisenreich (2000) indicated that elemental carbon fraction of particles should also be considered as potentially adsorbing SVOCs. Therefore, the following two-parameter model was proposed:

$$K_p = f_{om} \times \frac{M_o}{M_{om}\rho_{oc}} \times \frac{\gamma_o}{\gamma_{om}} K_{oa} + f_{ec} \times \frac{a_{ec}}{a_p\rho_{ec}} \times K_{sa} \quad (61)$$

where ρ_{oc} and ρ_{ec} are the density of the organic matter and elemental carbon, respectively ($\mu\text{g}/\text{m}^3$); f_{ec} is the mass fraction of elemental carbon; a_{ec} and a_p are the specific areas of elemental carbon and the aerosol particles, respectively (m^2/g); and K_{sa} is the elemental carbon-air partition coefficient.

Under consideration of the sorption to the inorganic fraction of the particles, the two-parameter model was improved and a three-parameter model was developed (Zhou et al. 2020):

$$K_p = f_{om} \times \frac{M_o}{M_{om}\rho_{oc}} \times \frac{\gamma_o}{\gamma_{om}} K_{oa} + f_{ec} \times \frac{a_{ec}}{a_p\rho_{ec}} \times K_{sa} + f_N \frac{K_N}{\rho_{ec}} \quad (62)$$

where f_N is the mass fraction of the inorganic material in the particle ($1-f_{om}-f_{ec}$); K_N is the inorganic material-gas partition coefficient, and ρ_N is the density of the inorganic material ($\mu\text{g}/\text{m}^3$).

All of the above models originated from Junge and Pankow's partitioning theory (Pankow 1987 1994) and the estimation of K_p was based on K_{oa} or p_L . After applying the Junge-Pankow equation for estimating indoor gas/particle distribution, Salthammer and Schripp (2015) found that the K_p values estimated by the models can result in substantial error for indoor scenarios. Therefore, the method of pp-LFER (Poly Parameter-Linear Free Energy Relationships) was applied to estimate the partition coefficients of SVOCs between different phases as a promising alternative. In the method, particle/gas partition coefficient K_p can be predicted using Eq. (63) (Goss 2005).

$$\log(K_p) = s \cdot S + a \cdot A + b \cdot B + l \cdot L + v \cdot V + c \quad (63)$$

where S , A , B , and V are compound-specific Abraham descriptors. S is the polarizability/dipolarizability, A is the hydrogen bound acidity (donor), B is the hydrogen bond basicity (acceptor), L is the logarithmic hexadecane/air partition coefficient (a surrogate for van der Waals term) and V is the McGowan volume. These parameters can be obtained from databases (Ulrich et al. 2017) or QSPRs (Quantitative Structure Property Relationships) (Huang and Jolliet 2019). s , a , b , l , and v are particle-specific parameters, which together with constant c are obtained by multiple-linear regression using experimental $\log(K_p)$ values.

Based on theoretical analysis, Weschler et al. suggested for SVOCs with high K_{oa} values that SVOCs sorbed to airborne particles and settled dust may not have sufficient time to equilibrate with the gas phase (Weschler and Nazaroff 2008, 2010). Liu et al. (2013) performed a further analysis on the dynamic mass transfer of SVOCs from the gas phase into airborne particles based on a normalized mass-transfer model. It is found that for SVOCs with a lower vapor pressure, it may take more than several hours to reach equilibrium between gas and particle phase. Comparing with the residence time of particles in the indoor environment, the assumption of instantaneous equilibrium between gas-phase and airborne particle-phase SVOCs in the indoor environments is not a feasible, especially for SVOCs with lower vapor pressure. Thus, the particle-gas partition coefficient measured from

particle- and gas-phase SVOC concentrations may not be the actual partition coefficient, but may instead vary with time and can be designated as apparent partition coefficient, $K_{p,a}$. It is correlated with K_p as Eq. (64) and will reach to K_p for enough time (Liu et al. 2013).

$$K_{p,a} = K_p \left(1 - e^{-\frac{6v_t t}{d_p TSP K_p}} \right) \quad (64)$$

v_t is the effective gas/particle mass-transfer coefficient (m/s); d_p is the diameter of the particles (m); t is time (s); TSP is the concentration of total suspended particles ($\mu\text{g}/\text{m}^3$). Based on Eq. (64), the concept of particle age was proposed to consider the effect of nonequilibrium partitioning (Cao et al. 2018).

In contrast to K_p , SVOC partitioning between impervious surfaces and air has received little attention to date. Weschler et al. (2008) proposed that SVOC partitioning to surfaces is affected by a thin organic film covering indoor surfaces and that the film will grow over time (Weschler and Nazaroff 2017). Hence, surface-air partition coefficients are often approximated using K_{oa} and thus different surfaces have identical K_s value close to K_{oa} , which was verified in experiments (Wu et al. 2017). In the only existing models, equilibrium partitioning was assumed and experiments showed that the roughness of indoor surfaces plays an important role for partitioning between surface and gas phase SVOCs, but further research needs to be done (Wu et al. 2017).

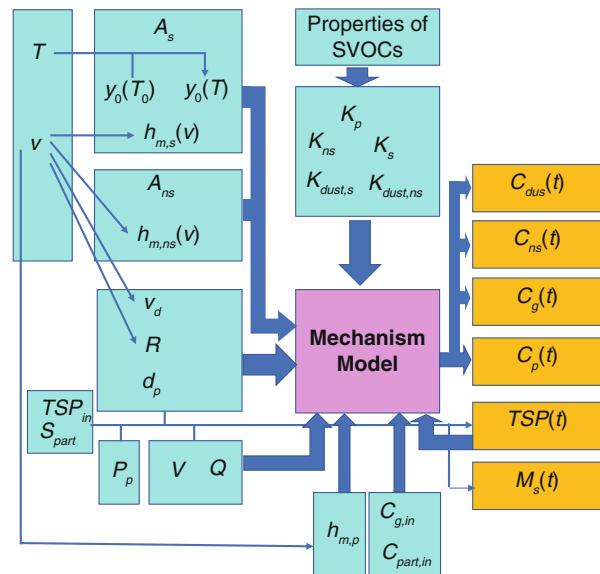

Challenge to Accurate Prediction of Indoor SVOC Concentration in Complex Indoor Environment

Figure 15 shows the flow chart for employing the models with some determined parameters to predict indoor SVOC concentrations in complex indoor environment accurately. Accuracy of the prediction may be affected by each step. Hence, it is a challenging task to predict indoor SVOC concentrations with small uncertainty.

Firstly, because emissions of SVOCs from the source and adsorption by some sinks are both sensitive to indoor environmental parameters including temperature and velocity of indoor air (Xu and Zhang 2011), variation of indoor environmental parameters can greatly affect emission rates of SVOCs so that accurate prediction of emission rates must be based on accurate prediction of indoor thermal environment. Due to all kinds of random factors such as meteorological conditions, it is difficult to predict indoor thermal environment accurately. Prediction bias of indoor thermal environment may lead to large uncertainty for prediction of indoor SVOC concentrations. In common, indoor temperature is not predicted in most of simulation cases and is often set as one constant or several constants for different period. Thus, large uncertainty will be brought in.

Secondly, ventilation is a key factor influencing indoor SVOC concentrations by exchanging indoor and outdoor air and also affects emission rate of SVOC from the sources (Lyng et al. 2015). Air exchange rate of mechanical ventilation is easy to

Fig. 15 Flow chart to predict indoor SVOC concentrations

obtain but that of natural ventilation is much more random depending on meteorological conditions. Because of random of natural ventilation, the unchanged ventilation rate or estimated average ventilation rate is set as an inputting parameter, which may result in some bias from practical concentrations. In addition, for some SVOCs originating mainly from indoor articles, outdoor concentration may be regarded as zero and it will not bring in large effect on indoor concentration prediction. But the sources of some SVOCs such as PAHs may also lie outdoors and the concentrations of outdoor SVOCs may greatly affect indoor SVOCs. Accurate inputting of outdoor SVOC concentrations will be key to predict indoor SVOC concentrations. It will be a challenging issue to obtain accurate outdoor SVOC concentrations.

Thirdly, partitioning plays an important role for indoor fate and transportation of SVOCs; accurate determination of partition coefficients is key to prediction uncertainty. It is difficult to measure these coefficients and must rely on theoretical estimation. However, because theoretical estimations are often based on some assumptions or empirical parameters, large deviation from the practical values may be produced, which depends on the theoretical models. Accurate estimation of partition coefficients is a challenge by itself.

Last but not least, the models mentioned in section “[Two Types of Models for Predicting the Fate and Transport of SVOCs in Real Indoor Environments](#)” are also based on some assumptions, which may also result in some uncertainty. The assumption of well mixing is a general assumption for both VOCs and SVOCs.

Because the fate and transport of SVOCs are often sensitive to local environmental factors, the deviation deriving from the well mixing for SVOCs may be larger than for VOCs. Field investigation showed different dust-phase phthalate concentration in different position in a house (Liu et al. 2020) and revealed large deviation of well mixing from practical conditions. Up to now, there is no measurement to validate the assumption of well mixing for indoor airborne SVOCs. The non-uniform distribution of indoor SVOCs may challenge the accurate predictions by the existing models.

Conclusion

The fates of VOCs/SVOCs are very complex due to various dynamic emission sources, interactions between different surfaces and potential chemical reactions. The prediction of VOC/SVOC concentrations in complex indoor environments must rely on some known information such as emission characteristics from the sources, ventilation scheme, kinetic physical parameters for physical adsorption or absorption by surfaces, and chemical parameters for indoor chemistry. With determined or estimated parameters, the physical models in the literature can predict VOC concentrations with an acceptable accuracy. However, the emission profiles from various indoor sources are often absent and need to be measured in chamber experiments. The mentioned methods in previous chapters can help to determine the key parameters for VOC emissions from the sources rapidly. Another challenge is the existence of indoor ozone originated from outdoor air or indoor sources, which may increase the complexity of the prediction due to chemical reactions between some VOCs and ozone. The recently developed physical-chemical model in literature was introduced to characterize the indoor ozone-initiated chemistry, which made the prediction of indoor VOC concentrations with indoor secondary reactions possible. In contrast to VOCs, it is more difficult to predict indoor SVOC concentrations. As emerging indoor pollutants, emission characteristics for SVOC emissions from indoor sources have been studied only for less than 20 years and study on the fate of indoor SVOCs is much less than VOCs. And some mechanism on the interactions between different SVOC phases is still being studied. In addition, not enough continuous measurement of indoor SVOC concentrations in practical indoor environment provided support for developing the models to predict indoor SVOC concentrations. These factors may affect the effectiveness for the accurate prediction of the indoor SVOC concentrations. Nevertheless, the study is still in progress. This chapter introduces a general model in literature with understanding indoor SVOC fate and also reviews some methods to estimate the key partition coefficients between different phases of SVOCs. The model seems to be successful to predict SVOC concentration in a test house with an acceptable agreement with the measured data. Certainly, more research are still needed to develop some simpler methods suitable for engineering applications.

Abstract

Indoor chemistry is a complex topic that has received much research attention in recent years. This section offers chapters that cover the following topics: comparing chemistry occurring indoors and outdoors; indoor gas-phase chemistry; indoor photochemistry; indoor surface chemistry; occupant emissions and chemistry; analytical tools in indoor chemistry; and indoor chemistry modeling. After reading this section, those interested in indoor chemistry research will have a strong grounding in indoor chemistry fundaments and the current state of the field, and they should be able to identify future directions for fruitful research.

Introduction

This indoor chemistry section offers chapters related to the study of indoor chemical transformations and processes. This topic is very broad in scope including research that spans from fundamental to application-based scale. It is a growing field that is continuously accommodating new researchers. In this introductory chapter, we outline and offer a brief description of the chapters in this section. Supporting references are not included here but are available in the individual chapters themselves.

Comparing Chemistry Occurring Indoors and Outdoors

The chemical reactions occurring indoors are largely the same as those occurring outdoors but differ in their extent due to the availability and intensity of sources, surfaces, and driving forces such as sunlight. The contemporary study of indoor chemistry, therefore, benefits from the accumulated knowledge and techniques developed as the result of nearly a century of research on outdoor atmospheric processes. Indeed, recent intensive application of experimental methods, technology, and modeling have rapidly advanced the field of indoor chemistry.

Like outdoor air, indoor environments are subject to complex sources and drivers. To understand this complexity, the authors suggest drawing parallels with outdoor processes and identifying simplifying characteristics where possible. For example, what has been learned about the biogeochemical processes occurring within the Sea Surface MicroLayer may be valuable in understanding thin films, complete with their own unique microbiome, on indoor surfaces. Similarly, outdoor “dark chemistry” is more relevant to indoor spaces due to limited input of strong UV light. Unlike the ambient atmosphere, indoor environments are much easier to control and perturb to unravel processes including source strengths, interactions of chemicals with indoor compartments, particle formation, and so forth. Recent perturbation experiments have revealed the presence of surface reservoirs that store acids and SVOCs as strong buffers against efforts to reduce air concentrations by controls such as increased outdoor air exchange. Introduction of controlled trace species reveals the path air takes when passing through homes, knowledge key to understanding its chemical history. In all, collaboration among experts in atmospheric physics and chemistry, building science, surface science, microbiology, and related modeling will be necessary to advance the science of indoor air chemistry in the face of 50 years of regulatory neglect.

Indoor Gas-Phase Chemistry

The indoor environment is rich in volatile organic compounds (VOC) that are emitted from building materials and activities such as cleaning, cooking, or using personal care products. These VOCs can undergo oxidation reactions in the

gas-phase. The primary drivers of indoor VOC oxidation are reactions with ozone (O_3) and the hydroxyl radical (OH), though VOC reactions with nitrate radicals (NO_3) and chlorine radicals can sometimes be important. Whether a particular gas phase reaction is important indoors depends on whether it occurs on a timescale that is competitive with the residence time of indoor air, which is set by the outdoor air exchange rate of the building (also called the ventilation air exchange rate).

This chapter reviews that state of knowledge of indoor air gas phase chemistry, with a strong focus on oxidation reactions with VOCs. Indoor ozone is typically due to outdoor-to-indoor transport, with indoor concentrations often at a factor of 0.2–0.7 of outdoor concentrations. Most indoor oxidation is initiated by reactions of ozone with one or more double bonds in alkenes, including compounds such as terpenoids and squalene. Ozone reactions with alkenes follow the well-established Criegee mechanism. First, ozone adds to the double bond forming a primary ozonide that rapidly decomposes to form stable carbonyls as well as Criegee Intermediate (CI) radicals and hydroxyl radicals (OH). These ozone-alkene reactions are often the dominate source of OH indoors, although photolysis of nitrous acid (HONO) has recently emerged as a second important source. While ozone reacts only with double bonds in alkenes, OH has the potential to react with almost any VOC at a fast enough rate to affect product concentrations. Reactions of VOCs with ozone and OH also generate peroxy radicals (RO_2), which can undergo further reactions to yield peroxydes, organic nitrates, peroxyacetyl nitrates, carboxylic acids, alcohols, and carbonyls. Oxidation of VOCs by the nitrate or chlorine radical can also generate peroxy radicals that behave similarly to those produced by ozone or OH reactions. The products generated by VOC oxidation have a large range of volatilities from very volatile to weakly volatile in nature. Products with low to semivolatility can partition to the organic aerosol phase, acting as a meaningful source of secondary organic aerosol (SOA) in indoor environments. This process is especially important for ozone-terpene reactions indoors.

Indoor Photochemistry

Outdoors, light from the sun initiates much of the chemistry that is responsible for ambient air pollution. Although light levels are generally much lower indoors, photochemistry still occurs and can meaningfully drive chemistry in special situations and locations where light is intense enough and of the right wavelength.

This chapter provides a detailed description of the range of chemistry and chemical products resulting from photochemistry. Photochemistry begins when a molecule absorbs light, then reacts. Energetic radicals that are common products of photolysis can then go on to react with other nearby molecules. Major reactions discussed include photolysis of nitrous acid that generates the hydroxyl radical (OH) that can then initiate oxidation of organics and other species. Other species of interest include photolabile aldehydes, hydrogen peroxide, chlorine dioxide (used in fumigation), and hypochlorous acid (a product of bleach cleaning). The intensity and spectrum of light near windows and near certain artificial light sources are

sufficient to raise radical concentrations significantly above indoor background levels. Heterogenous photochemistry has been observed to take place on indoor surfaces. For example, light-induced generation of nitrous acid on paint has been ascribed to photocatalysis of nitrogen dioxide. Some researchers have proposed that photochemistry over long time periods may expose occupants to small congener photolysis products of brominated flame retardants. Advanced models that combine computational fluid dynamics (CFD) with photochemistry predict that chemical concentrations can vary by one or more orders of magnitude throughout indoor environments subject to spatially nonuniform light flux. Although historically neglected in indoor air research, photochemistry deserves more attention especially in identifying chemicals and conditions where photochemistry meaningfully alters occupant exposure to harmful products. Understanding the impact of this chemistry has become even more important as more photo-reactive precursors are added to indoor environments (disinfectants and fumigants), as photocatalysts are included building materials, and as we increase our use of ultraviolet light for air and surface disinfection.

Indoor Surface Chemistry

Buildings are rich in surfaces available for chemical interactions. Considering only the geometrically projected area of building surfaces and furnishings, the surface area-to-volume ratio of the indoor air volume is much greater than outdoor air. The internal surfaces, such as the surface of textile fibers or pores within drywall, can increase the available surface area by one or more orders of magnitude. Early researchers recognized that surfaces were responsible for the observation that the concentrations of ozone indoors were much lower than outdoors. Over time, other chemical reactions and interactions were identified that were supported by indoor surfaces.

Indoor surfaces can act as chemical reservoir, extending the time to interact and react with other chemical species. For example, indoor materials and the films that coat their surfaces can hold onto very large amounts of semivolatile organic compounds as well as volatile acids and bases. These surface reservoirs act to stabilize air concentrations, limiting the effectiveness of controls such as periodic “airing out” by opening windows. Fragrance compounds, oils, and many other unsaturated organic compounds can be adsorbed to (or absorbed within) indoor materials for sufficient time to allow ozone to collide and subsequently react with their double bonds, forming aldehydes, ketones, carboxylic acids, and other volatile and semivolatile oxidized species. Surfaces support the formation of nitrous acid from nitrogen dioxide, conversion of amines to carcinogenic nitrosamines, hydrolysis of phthalates, and many other chemical processes. Not only does surface chemistry alter the composition of the air we breathe, but also it alters the composition of the surfaces themselves. Therefore, indoor surface chemistry influences our intake of pollutants by both air and surface-mediated exposure pathways.

Occupant Emissions and Chemistry

Human malodor is among the earliest drivers of active building ventilation. Occupants are a major source of indoor chemicals that can lower air quality directly or through their subsequent chemical transformations. Breath, skin, and intestinal gases contribute meaningfully to the total volatile organic compound concentration in an occupied building (by mass). While generally considered nontoxic, occupant emissions may affect cognitive performance or be respiratory irritants.

In addition to CO₂, breath contains numerous products of metabolism including acetone, isoprene, nitric oxide, and products of oxidative stress. The composition of breath can be influenced by intake of exogenous chemical from exposure to smoke, solvents, and other nonnatural species present indoors. Skin emissions include glandular secretions, often quite malodorous, as well as products of the metabolism of microflora on skin. The skin is a major sink for the photochemical pollutant ozone. While lowering indoor air levels of ozone, this chemistry generates a host of notable products that themselves can participate in chemistry to form irritants and contribute to aerosol mass. Skin flakes, skin oil, and other secretions are also deposited on indoor surfaces and can act as a further sink for oxidants and source of emissions to indoor air. Personal factors, including age, sex, physical activity, metabolism, menstruation, diet, clothing, and use of personal care products can influence emissions. As a building factor, ventilation not only dilutes occupant emissions but also introduces outdoor pollutants that can increase the production rate of some reaction products with skin and breath compounds. Temperature and relative humidity can also alter the yields of ozonolysis products from skin and clothing.

Analytical Tools in Indoor Chemistry

The indoor environment contains meaningful concentrations of many organic and inorganic species that exist in the gas, aerosol, or surface phases. Due to their sheer number and chemical complexity, identifying and quantifying these compounds is a great challenge. Moreover, these compounds often must be measured at high time resolution, since building-relevant timescales such as residence time are short, and sources and sinks often vary over orders of minutes or even seconds. Current and emerging analytical instruments that were originally intended for outdoor air quality measurements have recently been brought indoors. This chapter discusses chemical measurement principles, addressing issues such as selectivity to measure target compounds and sensitivity to measure changes in concentration. Different strategies for measuring indoor compounds are reviewed, including bulk versus compound-specific; offline versus online; chemical versus physical analysis; low-cost sensors versus research instrumentation; and analytical chemistry approaches for different types of measurements.

Inert gases like carbon dioxide are relatively easy to measure, while reactive gases range from relatively easy (like ozone) to very difficult to the point of only a few labs having the capability (like hydroxyl or nitrate radicals). Volatile organic compounds

(VOC) and semivolatile organic compounds (SVOC) were traditionally measured in an offline manner using combinations of gas-chromatographs and detectors. Newer instrument methods such as proton-transfer reaction mass spectrometry (PTR-MS) and chemical ionization mass spectrometry (CIMS) have enabled fast detection and quantification of a multitude of indoor VOCs. When these instruments are equipped with time-of-flight (TOF) mass analyzers, their resolving power is orders of magnitude higher than quadrupole-based predecessors. For particles, scanning mobility particle sizers (SMPS) allow precise quantification of size distributions, while aerosol mass spectrometers (AMS) and aerosol chemical speciation monitors (ACSM) have been used in indoor experiments to detect changes in bulk chemical composition. Although the AMS-type instruments fragment aerosol components, soft ionization techniques that minimize fragmentation and provide molecular level information are also available.

Indoor Chemistry Modeling of Gas-, Particle-, and Surface-Phase Processes

Modeling of indoor chemical processes can be used to effectively predict indoor concentrations and exposure as well as to investigate certain processes not practical experimentally or to test the completeness of our understanding of process. Early indoor model development came in the 1980s when Nazaroff and Cass used concentration balances to predict the fate of chemically reactive pollutants in a museum setting, considering effects of ventilation, filtration, surface reaction, emission, and chemical reactions. A few years later, the same authors offered a similarly robust, size-resolved particle model. In the decades afterward, a host of indoor models and techniques were developed, some of which are as follows.

Early gas-phase reaction models used limited chemistry schemes, for example, to indicate the importance of ozone-alkene reactions on indoor hydroxyl radical (OH) concentrations, which were previously thought to be negligible indoors. Subsequently, indoor gas-phase reaction models were developed that incorporated detailed reaction mechanism, and they later included gas-to-particle partitioning based on vapor pressures of predicted compounds to predict formation of indoor secondary organic aerosol (SOA) from ozone or OH reactions with volatile organic compounds (VOC). A second class of models was also developed to predict indoor SOA using a mass yield framework within the volatility basis set (VBS), which organizes numerous SOA forming compounds generated by VOC oxidation into bins separated by volatility and then predicts partitioning. The two-dimensional VBS has also been used to further allow tracking of later generation oxidation reactions and organic aerosol density, water uptake, and phase state. The transformation of ammonium nitrate upon transport indoors has also been simulated. Finally, surface reactions have been modeled using the parameter of the deposition velocity, which is a mass transfer coefficient that includes information on reactive uptake and boundary layer transport. The deposition velocity can be used with surface yields to predict indoor air concentrations. Kinetic models have also been used to simulate

ozone reactions with human skin, and computational fluid dynamics have predicted heterogeneous concentrations of indoor byproducts due to ozone reactions with skin and also indoor OH concentrations.

Conclusion

As this introductory chapter demonstrates, indoor chemistry topics are widely variable in their scope. They include a range of issues such as outdoor to indoor transport, indoor chemical transformations among different phases indoors, and building and mechanical system processes. Researchers that study indoor chemistry utilize both sophisticated instruments as well as consumer grade sensors in lab and field campaigns and also develop detailed models to understand and inform observations.

Indoor Air Quality Through the Lens of Outdoor Atmospheric Chemistry

Abstract

Outdoor atmospheric chemistry and air quality have been the topic of research that intensified in earnest around the mid-twentieth century, while indoor air quality research has only been a key focus of chemical researchers over the last 30 years. Examining practices and approaches employed in the outdoor atmospheric chemistry research enterprise provides an additional viewpoint from which we can chart new paths to increase scientific understanding of indoor chemistry. This chapter explores our understanding of primary chemical sources, homogeneous and multiphase reactivity, gas-surface partitioning, and the coupling between the chemistry and dynamics of indoor air through the lens of

outdoor atmospheric chemistry. The means to mitigate degraded air quality outdoors are heavily rooted in public policy actions, while the commercial sector mainly promulgates solutions for indoor air quality, making practical and actionable outcomes to research essential for prompt improvements to indoor environments. Indoor and outdoor environments have many important scientific distinctions, but a shared vision for healthy environments motivates both research communities in the same way.

Introduction

Air quality has been of general public awareness for centuries but only became clearly codified over approximately the last 150 years. In the late nineteenth century, actions to address public health during intense urbanization were based, at least in part, on the human sense of smell in the waning years of adherence to the miasma theory (Kiechle 2017). The notion that exposure to “bad air” was a risk for contracting disease was broadly replaced by the germ theory. Modern understanding of infectious disease, indeed, includes the possibility that a subset of known infectious diseases can be spread through exposure to airborne biological particles. However, a general sense of healthfulness continues to be connected with our sense of smell as a detector of air quality, both indoors and outdoors. Important health effects of poor air quality are also associated with exposure to *chemical* agents, rather than just biological ones; poor air quality is associated with various noncommunicable diseases and is a leading global health risk factor (Murray et al. 2020).

Scientific understanding of outdoor air quality has grown significantly since the mid-twentieth century. Tracking radiogenic isotopes released from atomic bomb detonations allowed for new insights on long range transport (Burton and Stewart 1960). Around the same period, smog formation represented an intense health and safety problem in major cities like Los Angeles and London; similar air quality problems persist to varying degrees to this day in urban environments around the globe. Arie Haagen-Smit’s discovery of the photochemical processes that created smog and recognition that ozone played a central role in urban air pollution (Haagen-Smit and Fox 1956) were critical achievements in establishing the importance of chemistry in atmospheric phenomena that degraded air quality. Following growing scientific understanding, along with dedicated efforts to communicate these findings, government regulations and public policy have been used to address outdoor air quality problems to impressive effect (Hand et al. 2020). Key advancements in chemical analysis technology continue to allow for an ever-increasing level of detail in our understanding of atmospheric chemistry through increases in sensitivity, portability, spatial/temporal coverage, and chemical specificity to target measures that will help to mitigate poor air quality.

Building science and indoor air quality have also advanced dramatically since the mid-twentieth century. Specific studies of indoor chemistry began in the 1970s and have been accelerating especially since the mid-1990s (Weschler 2011). In the same period, however, improvements to building technology and energy efficiency have advanced more rapidly than methods to thoroughly understand and address indoor air quality from a chemical perspective. It remains critical to increase our understanding of indoor chemistry and clearly communicate new knowledge to the public. Significant progress has been made in elucidating the chemistry that occurs in both the gas phase and on surfaces indoors. More recent applications of highly sensitive, specific, and rapid online chemical measurements of the gas phase, aerosol particles, and surfaces have continued to enhance our depth of understanding (Farmer 2019). Since improvements in indoor air quality are promulgated by the building industry, researchers need to continue to develop a clear and predictive understanding of the processes that lead to degraded air quality along with solutions for practitioners to implement. Therefore, the outcomes and goals of indoor chemistry studies differ slightly from outdoor air, where changes in public policy are often a more crucial element of effective solutions.

In this chapter, we seek to unpack the approaches of outdoor atmospheric chemistry research with an eye toward their application to future studies of indoor air chemistry. The objective within each topical section is to explore several ways in which outdoor atmospheric chemistry has been conducted; examples have been chosen such that they shed light on the way that indoor chemistry is currently studied or could be studied in the future.

Primary Chemical Sources

Introduction of outdoor air is an important chemical source for indoor air. At the same time, mounting evidence shows the growing importance of indoor activities and emissions of volatile chemical products on outdoor air quality (McDonald et al. 2018). Processes that add chemical constituents to the air are important controlling factors in atmospheric chemistry and often represent the most viable opportunity for mitigating poor air quality. Considering only primary (i.e., direct) emissions, sources are often categorized as “natural” or “anthropogenic,” although the line can be blurred in some cases, like agriculture, wildfires, or land-use change. Each source has its own chemical signature, including but not limited to: a wide variety of volatile and semi-volatile organic compounds (VOCs and SVOCs: hydrocarbons, carbonyl compounds, organic acids, amines), including compounds that are considered to be persistent organic pollutants; oxides and/or oxoacids of sulfur (SO_2 , H_2SO_4), nitrogen (NO , NO_2 , HNO_2 , HNO_3 , organic nitrates), or carbon (CO , CO_2); inorganic acids (HCl , H_2S , HCN) and bases (NH_3); and aerosol particles of organic, inorganic, biological, mineral, or mixed composition (Finlayson-Pitts and Pitts 2000). The source signatures of many types of anthropogenic sources can be replicated in laboratory settings if they are associated with engineered systems (e.g., combustion engines). However, deviations in emission strengths or chemical composition

between controlled laboratory operating conditions and less-controlled field operation can be important (Frey et al. 2003; Gentner et al. 2017). Natural sources of aerosols and gases to the outdoor environment can be more challenging to simulate and study in a controlled manner. Emission processes can be the result of nuanced couplings between physical, chemical, and biological processes, along with a wide variety of spatial (nanometer to kilometer) and temporal (second to year) scales.

To account for couplings between ambient environmental conditions and emission source signatures, field experiments are targeted for strategic or opportunistic sampling of the atmosphere. Anthropogenic sources can be probed over timescales in which variations in activity are either predictable or known externally, such as weekday/weekend studies or episodic shutdowns/reductions of source activity, like the public response to the COVID-19 global pandemic (Kroll et al. 2020). Field experiments, in some cases, yield less specific chemical information than is achievable in laboratory studies due to various confounding environmental factors but provide key constraints and guidance for more fundamental study and continued model development. Improvements in transportable and field-deployable chemical measurement technology have enabled major advances, allowing for online measurement approaches to field campaigns that were previously restricted to laboratory studies or offline operation (Laskin et al. 2018). Supplementing field observations with controlled laboratory experimentation using emission source simulators can yield a greater depth of fundamental understanding but are often subject to a variety of their own caveats. However, coordinated combinations of field measurements, laboratory studies, and modeling have provided significant insight on complex atmospheric chemistry topics (Burkholder et al. 2017; Ault et al. 2020).

It is possible for indoor air quality to bridge the gap between field and laboratory studies more readily than outdoors as perturbations to the indoor environment can be made deliberately. Two key approaches to perturbing indoor air composition are available: enhanced ventilation or air cleaning to rapidly reduce concentrations of compounds that are more abundant indoors than outdoors, and source modulation that can provide episodic additions of chemical constituents to indoor air. Each of these approaches can yield important insights about emission rates and rapid post-emission processes like chemical reactions or phase partitioning that act as sinks for aerosol particles or traces gases of interest. At the same time, care must be taken to understand the realism of the perturbation strength. Comparison of deliberate perturbations to indoor air composition and chemical processes should be compared against measurements of opportunistic perturbations due to non-prescribed occupant activity or normal building system operations. Modulation of HVAC operating status (cooling and heating cycles), window opening, day/night temperature and light cycles, and occupant cooking or cleaning activities are key opportunities for study.

The concept that source emission and physicochemical processes near to the chemical source can respond to the environment has been noted indoors in the context of relative humidity (RH) and temperature (T) for some gases (Parthasarathy et al. 2011) and aerosol particles (Xie et al. 2007; Salimifard et al. 2017). Emission source behavior studies in realistic environments are important to perform, despite being subject to complication by interfering chemical signals or poorly constrained

sink processes that influence airborne constituent concentrations. Complementary use of controlled source characterization studies in the laboratory environment using smaller or more controllable chambers allows for deeper inspection of fundamental principles, while implementation of similar experiments in more complex, realistic indoor environments allows for an accounting of rapid interactions between the source and/or freshly emitted material with the realistic surroundings, providing an “effective” source strength.

Additional complexity beyond varying RH and T are possible. Studies of biosphere-atmosphere coupling in the outdoor environment require careful accounting for biogeochemical processes in terrestrial or marine environments. For instance, chamber studies of biogenic VOC production from plants may constrain emission rates, which can then be juxtaposed with emission estimates derived from ambient measurements of the same VOCs in or near a forest canopy outdoors. The field studies of ambient air may, for instance, make clear that measurements that account for stress responses, including those arising from herbivory or disease, are necessary (Faiola and Taipale 2020). In addition, meteorological conditions can influence the behavior of biological systems that drive emissions, and atmospheric conditions also influence the chemistry that may occur. For some biological systems, atmospheric deposition of limiting nutrients can drive productivity, which affects the fluxes and/or compositions of gases and particles emitted to the atmosphere (Mahowald et al. 2009).

One approach to understanding biosphere-atmosphere interactions is to make a large suite of measurements near to (or within) a major biogenic source of emissions, such as the Amazon rainforest. This permits source signature characterization and studies of the reactivity as emissions are transported away from the source or interact with other atmospheric constituents (see section “Reactivity”). The GoAmazon project involved a multi-platform field campaign that built upon a longer time series of chemical measurements from a tall tower in the Amazon (Martin et al. 2017). The study sampled a “clean” biogenic signature from the highly productive rainforest and juxtaposed those biogenic emissions with episodic influence from a major urban area (Manaus, Brazil). The indoor environment bears perhaps unexpected similarity to the GoAmazon study and other forested regions: the building and its contents are major sources of VOCs with their own emissions behavior. Indoor air composition is influenced by the “natural background” of the building, with occupant activity or other time-dependent source behavior (e.g., cooking, cleaning, changes in outdoor air composition and introduction rate) superimposed on top. It becomes clear that a broad view of the building, its behaviors, and chemical signatures is important to gain a more holistic understanding of indoor air quality.

A different approach to understanding a highly complex and coupled system is exemplified by approaches to understanding ocean-atmosphere exchange. The ocean is home to a large and diverse biomass that participates in chemical exchange with the atmosphere. Deposition of inorganic material (e.g., iron, nitrate, phosphate) and uptake of CO₂ provide nutrients for primary production and carbon fixation by microalgae (Emerson and Hedges 2008; Mahowald et al. 2009), but changes in microbiological activity of the near-surface ocean can drive major changes in the

water-to-air fluxes of both particles and gases (Wurl et al. 2017; Collins and Grassian 2018). Recognizing the effects of microbial succession on the organic composition of the surface ocean (Prather et al. 2013) has provided key insights into the aerosols and gases that arise from differences in biological activity (Wang et al. 2015; Mayer et al. 2020) that naturally occur on month-long and kilometer scales (Dall’Osto et al. 2019). At the same time, the physical processes that control material fluxes across the air-sea interface occur on the micrometer length scale and involve nuanced (bio)chemistry that occurs in a thin gelatinous film on the ocean surface called the sea surface microlayer (SSML) (Cunliffe and Murrell 2009). Biogeochemical processes occurring within the SSML can be sources of trace gases, but the physical properties of the SSML also physically mediate air-sea gas transfer in both directions (Frew 1997; Wurl et al. 2017). In addition, the air-exposed film may participate in multiphase chemistry, leading to the reactive uptake and/or production of various trace gases (Wurl et al. 2017; Collins and Grassian 2018; Schneider et al. 2019). In the indoor environment, significant effort on the microbiology of the built environment has been initiated (Gilbert and Stephens 2018). Treating the indoor microbiome in a manner analogous to the microbiome of the surface ocean could yield important new insights. It could be important to treat the bidirectional exchange of material on microbially colonized indoor surfaces with care, as a recent study has shown that the gut microbiome can respond to the chemical environment to which a person is exposed (Gardner et al. 2020). Do bidirectional feedbacks and/or important couplings exist between the microbial communities and the chemistry of the air within a building?

Reactivity

The strength and nature of the sources that supply reactive compounds to the atmosphere impart an important control on the overall amount and type of reactivity observed in the air. Most gaseous and aerosol reactions in the outdoor atmosphere are driven by a cascade of energy from ultraviolet (UV) light in the Sun’s spectrum. Although the most energetic photons are removed in the stratosphere, sunlight with wavelengths in the near UV range penetrates to the ground. Through photochemistry, OH radicals are formed, which then oxidize VOCs and lead to the formation of O₃ when NO_x is present. This flow of energy from the Sun also drives nocturnal chemistry, with O₃ formed during the day reacting in the dark with alkenes, also forming radicals (Finlayson-Pitts and Pitts 2000). The implicit approach in atmospheric chemistry is to attempt to define the dispersal of photochemical energy: Which oxidants form? What are their sinks? What oxidation products arise? Large field campaigns are organized around simultaneous, *in situ* measurement of short-lived radicals and their precursors along with assessments of radical loss mechanisms (Carlton et al. 2018). Photochemical models, which include representations of fundamental gas-phase chemistry and are constrained by observations from field studies, embody our understanding of the energy cascade from sunlight into more oxidized species.

The same questions arise with the chemistry of aerosol particles and cloud droplets, requiring detailed chemical characterization of the condensed-phase component of the atmosphere. Such multiphase chemistry involves the coupled chemical and mass transfer interactions of atmospheric gases with the surfaces and interior of aerosols, cloud droplets, and ground materials (Ravishankara 1997). In particular, the gaseous products of oxidation reactions may partition to aerosol particles (see section “[Partitioning](#)”), giving rise to secondary aerosol formation. In aqueous aerosol particles and cloud droplets, it is important to evaluate the degree to which condensed-phase oxidants such as H₂O₂ react with dissolved constituents, giving rise to more oxidized and water-soluble species. This is how one important component of acid rain, sulfuric acid, forms.

We can also track the Sun’s input, along with generated oxidants and their impacts, to the indoor environment. Although sunlight penetrates windows, the shortest, most photochemically active wavelengths are attenuated by glass and the total indoor volume illuminated by direct sunlight is generally low. As well, most indoor lighting is a weak source of UV light (Kowal et al. 2017). As a result, less photochemical energy is available indoors than outdoors and OH radical concentrations are generally low, largely generated by ozone/alkene reactions. Coupled with short indoor air residence times (on the order of hours) (Murray and Burmaster 1995), conditions are not conducive for gaseous reactions to be the primary chemical sink for most indoor contaminants. Ozone is an important low-light oxidant, but it is not generated *in situ* to a significant degree (Young et al. 2019). While secondary organic aerosol formation can occur in specific situations with high organic precursor and oxidant levels (Waring 2014), the relative contribution of indoor secondary aerosol formation is smaller than the importance of secondary aerosol formation to the total outdoor aerosol mass. Rather, a characteristic feature of indoor environments is that the major flux of photochemically generated secondary pollutants, such as O₃, NO₂, and organic- and sulfate-containing aerosol, is usually associated with introduction of outdoor air. As described above, tracking outdoor-to-indoor transport is a major focus of indoor chemistry and represents a key connection point to outdoor air quality.

With oxidant mixing ratios considerably lower than in outdoor environments, a common misconception is that little oxidation chemistry occurs indoors. In specific situations, gas-phase reactions of ozone with high mixing ratios of terpenes and photolysis of HONO in direct sunlight are important sources of indoor OH (Finlayson-Pitts and Pitts 2000; Gómez Alvarez et al. 2013). As well, ozone mixing ratios are low indoors because *so much* oxidation chemistry is occurring. Just as in outdoor environments, where ozone dry deposits onto reactive surfaces like vegetation, ozone experiences efficient deposition to indoor surfaces with high surface-area-to-volume ratios and which can be coated by reactive surface-sorbed molecules (Morrison 2008), such as unsaturated oils from humans or cooking (Zhou et al. 2019b), or products of incomplete combustion, such as polycyclic aromatic hydrocarbons (Zhou et al. 2019a). Whereas the approach of outdoor air pollution research is to focus on the exposure to airborne pollutants by inhalation, it is important to consider indoor exposures based also on human contact with contaminated surfaces,

like dermal uptake or ingestion. The broader spectrum of exposure routes relevant to indoor environments lends importance to understanding the nature of gas-surface multiphase processes.

In the gas phase, an exciting recent finding is the significance for organic molecules of auto-oxidation processes driven by rapid intramolecular isomerizations, giving rise to the formation of highly oxygenated organic molecules (HOMs) (Crounse et al. 2013). Although studied to understand rapid oxidation processes in outdoor environments, even low indoor OH radical and ozone concentrations have the potential to drive the formation of secondary organic aerosol (Kruza et al. 2020). As well, surface-sorbed molecules can react via OH-surface collisions, leading to gradual modification of surface composition over long periods (Alwarda et al. 2018; Morrison et al. 2019).

A distinct and important set of indoor chemical reactions occurs via the use of cleaning agents. The oxidizing capacity of the indoor environment can be amplified significantly in a manner not applicable to outdoor air. Cleaning agents like chlorine bleach and hydrogen peroxide, which are excellent nonspecific biological oxidizing agents, are used in large quantities, especially during the COVID-19 pandemic. HOCl, which exists in both the aqueous and gaseous phases during chlorine bleach use, reacts with a wide variety of organic functional groups, including amines, thiols, and carbon-carbon double bonds to form organochlorine products. In addition, HOCl can drive the formation of volatile chloramines and other reactive species when bleach washing is used (Wong et al. 2017; Mattila et al. 2020). H₂O₂ is also an effective biocide that can photochemically release gas-phase OH when used in large quantities and can also decompose to generate condensed-phase OH radicals on surfaces in the presence of iron.

A challenge to both indoor and outdoor communities is the study of reactions between closed-shell molecules without direct photochemical involvement. High molecular weight organic species form within aerosol particles via condensation reactions between oxygenated organic precursors (Jang et al. 2002). They are likely to also form in highly concentrated organic films like the sea-surface microlayer and are important on indoor surfaces where reaction times are long and reactant surface concentrations can be high. As well, it is known that the ester linkages in surface-bound phthalates can hydrolyze if the pH conditions of the substrates are appropriate (Bope et al. 2019). Such reactions are generally neglected outdoors, given that they are the fastest under alkaline conditions.

Partitioning

Determining whether a molecule resides in the gas phase or in an aerosol particle, or is part of a surface reservoir, is of central importance to assessments of human chemical exposure, both indoors and out. Gases can be inhaled but soluble species are scavenged from the breath high in the respiratory tract. Molecules residing in fine particulate matter can reach deep into the lungs before being deposited. Dermal

exposure can occur via touching contaminated surfaces or through interactions with contaminants that have partitioned to clothing.

In the outdoor environment, the recent focus on phase partitioning has centered around secondary organic aerosol: the oxidation of VOC precursors leads to the formation of semi-volatile species that can partition to aerosol particles. The HOMs that arise from auto-oxidation processes (see section “[Reactivity](#)”) are frequently of such low volatility that they either undergo one-way condensation to preexisting particles or to help nucleate new particles (Bianchi et al. 2019). On the other hand, some emissions from the tail pipe of an internal-combustion-engine car are initially part of the particulate exhaust from the car, but then evaporate as dilution occurs downwind of the emission source (Robinson et al. 2007). It is important to describe this highly dynamic environment, with molecules readily moving from the gas phase to aerosol particles and back again.

Recent indoor studies also attempt to capture that dynamic partitioning, illustrated nicely by the impact of third-hand tobacco smoke on indoor air quality. Semi-volatile smoking emissions deposited to indoor walls, furniture, and clothing re-volatilize from these surfaces long after, or far away, from the smoking event (DeCarlo et al. 2018). A striking example is the impact of tobacco smoking on the air quality in a nonsmoking movie theater, where high levels of smoke-derived VOCs are observed in the theater having been carried inside on the clothing of occupants who previously smoked outside (Sheu et al. 2020). These VOCs can partition to aerosol particles, changing their composition to partly reflect the composition of the third-hand smoke (Collins et al. 2018b).

Gas-surface partitioning behavior is also apparent in indoor spaces when they are ventilated, by opening windows for example. The mixing ratios of most gases, ozone and NO_x being notable exceptions in most cases, decline because the indoor air is diluted with cleaner air from outside. When the windows are closed, the mixing ratios reestablish steady state levels, reflecting the flux of molecules from indoor surface reservoirs to the gas phase (Collins et al. 2018a; Wang et al. 2020). On the other hand, when excess HONO is added to a house, for example, from a gas stove, it is readily taken up by the indoor surface reservoirs (Collins et al. 2018a). Valuable insights into chemical mechanisms can be readily conducted indoors by such perturbation experiments.

A perturbation also arises from the partitioning-dependence of acidic and basic molecules when acidic (i.e., vinegar) or basic (i.e., ammonia) cleaning solutions are used (Wang et al. 2020). Acidic gases that dissociate upon partitioning into polar indoor surface reservoirs are released to a room when vinegar washing proceeds, that is, the additional acidity shifts the equilibrium state in the surface toward the more volatile, non-dissociated form of the acid. Less water-soluble molecules do not behave in this manner, likely because they are either partitioned into a less polar, more organic-rich surface reservoir or because pH does not affect their volatility.

Outdoor, forced system perturbations are not possible, and we rely instead on the natural variability of the environment to provide such information. For example, the flux of ammonia to and from the Earth’s surface is dependent on the gas-phase ammonia mixing ratio, the pH of the water in the ground, and the pH of the aerosol in

the overlying atmosphere. Such bidirectional flux behavior is only now being incorporated into chemical transport models of the outdoor atmosphere (Whaley et al. 2018; Pleim et al. 2019).

Finally, partitioning to liquid water is a well-known phenomenon in outdoor environments, where water-soluble gases are readily scavenged to cloud water. This is one of the major atmospheric cleansing processes. These lessons are being applied indoors when considering the impact of air conditioning systems on the behavior of water-soluble molecules (Duncan et al. 2019; Wang et al. 2020). Liquid water condenses on the cold coils of the air conditioning unit, leading to partitioning of soluble gases. This process is manifest as oscillatory water-soluble gas mixing ratio behavior in the indoor space, as the air conditioning unit that recycles the air turns off and on. There is a direct analogy to clouds: when it rains, water-soluble gases are removed from the atmosphere, but cloud droplet evaporation leads to their release back to the gas phase. Likewise, with air conditioning, if sufficient water builds up on the cooling coils that it drains from the unit, then the air inside the house is cleaned somewhat of those species. If the water evaporates instead, those species are returned to the gas phase. In addition to impacts on gas-phase composition, control of indoor environmental conditions also affects aerosol phase state and water content (Cummings et al. 2020).

Impact of Dynamics on Chemistry

Simultaneous production, consumption, phase partitioning, and transport of chemicals in the environment necessitates a broad and multifaceted approach to realizing an understanding of the system as a whole. Advances in atmospheric chemistry often come through the interplay of field measurements, laboratory studies, and modeling due to the complex nature of atmospheric chemical processes and their interplay with environmental conditions and the dynamics and structure of the atmosphere (Burkholder et al. 2017).

The atmosphere, while a seemingly continuous fluid medium, has a variety of structural features that control chemistry. Atmospheric boundaries, like zonal boundaries in a building, limit mixing between two parcels of air but are penetrable on relatively long timescales. Certain chemical processes that may be rapid in one region of the atmosphere, such as catalytic ozone destruction in the stratosphere, are unimportant in other regions. The so-called ozone hole in Earth's stratosphere is a seasonal feature that only becomes apparent when cloud particles are abundant during polar sunrise (Molina et al. 1987; Tolbert et al. 1987) and when a distinct fluid dynamical zone, the polar vortex, restricts mixing with air at lower latitudes (Schoeberl and Hartmann 1991). Still, the halocarbon compounds that lead to catalytic ozone depletion (Molina and Rowland 1974) are emitted at Earth's surface and are only capable of reaching the stratosphere because they have atmospheric lifetimes that are much longer than the characteristic mixing time across the tropopause (the boundary that separates the troposphere from the overlying stratosphere). This classic atmospheric chemistry example illustrates

the importance of characterizing the chemical environments of different indoor zones by carefully taking into account the sources, chemistry, transport, and the importance of different phases to a given phenomenon.

Recent studies using real-time measurements of trace gases have illustrated the level of control that transport dynamics and the boundary structure within buildings have on the composition of indoor air. Space- and time-resolved measurements of inhabited buildings (e.g., residences, schools, and offices) require sophisticated instrumentation, broad access to the building for scientists, and careful collection of metadata but can yield important results and information about the impact of indoor activities and building structure on indoor air quality. A notable study using a residence across multiple seasons employed a chemical tracer approach to understand and quantify transport between zones (Liu et al. 2018). The *route* of air exchange between the indoors and outdoors may be important to consider and may include a variety of parallel paths including transit through other zones of the building. Such behavior may have important implications for the chemicals that can be lost from, or entrained within, the air as it moves from outdoors to indoors; physical and chemical aspects of the building itself may have important and non-intuitive impacts on the chemistry that drives indoor air quality.

Modeling the interplay of chemistry and dynamics in the outdoor atmosphere is often performed on a variety of spatial scales: from full global simulations down detailed regional models, and then even further down to simulate the detailed physics of single clouds, for instance. The level of detail in a large-scale model is necessarily coarse and becomes generally more sophisticated as the model scale becomes smaller. Gas phase chemistry can be simulated in roughly any pixel or grid cell size with the assumption that the grid cell is homogeneously mixed. Using this “well mixed” assumption, box modeling has proven useful for a variety of indoor chemistry scenarios for the last few decades. Exciting results from computational fluid dynamics (CFD) models that include chemical mechanisms are beginning to show interesting and important chemical gradients within a single building zone (Won et al. 2019, 2020). Spatially resolved chemical measurements of air within a room could be designed to couple with CFD modeling. Process-level chemical models may be nested within the CFD simulations or could be parameterized to reduce computational expense. Efforts to reduce computational cost have enabled major advancements in atmospheric and chemical modeling. Collaboration between computational scientists (Shiraiwa et al. 2019) will help to translate indoor measurements and process-level studies into actionable outcomes and should strive to produce new computational tools to advance the practice of producing and maintaining healthy environments within buildings.

Working Toward Solutions

Collaboration among experts in diverse fields of engineering, chemistry, biology, public policy, building science, public health, and others will be required to grasp the breadth of interactions that influence indoor air quality and to devise methods for

optimizing the living and working environment where many people spend the majority of their lives. Outdoor atmospheric chemistry issues that represent degraded environmental conditions (e.g., acid rain, stratospheric ozone depletion, urban pollution) have been addressed through broad public policy actions such as the international Montreal Protocol on Substances that Deplete the Ozone Layer or the Clean Air Act in the United States. Indoor air quality, however, is subject to weaker government regulation and has been mostly addressed by concerned homeowners or private institutions. A commercial indoor air quality industry has thus emerged to enable private mitigation actions to take place. Outdoor air quality issues include important aspects of environmental justice, as poor air quality disproportionately affects impoverished and non-white communities (Mikati et al. 2018). Health risks due to ambient airborne particulate matter pollution exposure are decreasing in wealthier regions and increasing in poorer regions worldwide (Murray et al. 2020). Since people spend a dominant fraction of their time indoors (Klepeis et al. 2001), a large portion of unhealthy outdoor air is actually breathed while inside the home. Housing quality has also been shown to have a relationship with rates of asthma and other chronic diseases, specifically among urban public housing inhabitants (Digenis-Bury et al. 2008; Northridge et al. 2010), where poor indoor environmental quality can compound negative effects of outdoor air quality. The comparatively weak ability of poorer groups living in nations with highly developed economies, along with large swaths of people in nations with still developing economies, to implement adaptations to our changing climate will exacerbate inequalities in housing and indoor air quality (Islam and Winkel 2017). The commercialization and private-responsibility that has been built into improving indoor air quality has the potential to multiply existing environmental inequalities as groups of people with low access to financial resources may not have the means or the opportunity to implement engineering solutions or retrofits that mitigate degraded indoor air quality (Northridge et al. 2010). As experts and practitioners of air quality studies and solutions, we must acknowledge and work against structural inequality from our own perspectives and positions of power.

Abstract

There are many similarities between indoor and outdoor air chemistry, not least the richness of the oxidation chemistry. Indoors, oxidation is driven to a large extent by ozone and the hydroxyl radical, with nitrate and chlorine radicals also making a contribution depending on the conditions. These reactions can lead to a variety of products, many of which are multifunctional and relatively long-lived. Some of them can then take part in further reactions indoors. This chapter summarizes the main gas-phase reactions indoors and also highlights the interconnectedness between some of the oxidation reactions, particularly between ozone and the hydroxyl radical. Oxidation of common indoor species such as monoterpenes by ozone leads to the formation of hydroxyl and peroxy radicals. There is then a range of radical-radical reactions possible that further transform the gas-phase composition indoors. Oxidation of terpenes and other volatile organic compounds by the hydroxyl radical can also produce ozone if there is

sufficient light indoors, so that these two oxidants are likely to coexist for many conditions typically experienced in buildings.

Introduction

Sources of air pollution are diverse indoors, with pollutants generated through activities such as cooking (particulate matter (PM), carbon monoxide (CO), nitrogen oxides (NO_x)), cleaning (mainly volatile organic compounds (VOCs) such as monoterpene, but also chlorinated compounds), and smoking (CO, PM, NO_x , and VOCs). Air pollutants can also be emitted from furnishing and building materials, home decoration products, and personal care products (Nazaroff and Weschler 2004). Consequently, many air pollutants are ubiquitous in typical buildings, and indoor VOC concentrations are often higher than those observed outdoors (Sarwar et al. 2002; Saarela et al. 2003), particularly during activities such as cleaning (Singer et al. 2006).

What is perhaps more surprising is that despite the low light levels indoors compared to outdoors, there is a vast array of gas-phase chemistry that can happen under typical indoor conditions, with many of these reactions familiar to those readers who have studied the chemistry of the ambient atmosphere. Of course, differences between conditions indoors and outdoors mean that indoor reactions can be more or less important than their outdoor counterparts. However, just like outdoors, much of the indoor gas-phase chemistry is driven by oxidation reactions, particularly with ozone (O_3) and hydroxyl radicals (OH) and to a lesser extent by nitrate radicals (NO_3^-) and chlorine (Cl) radicals.

The key requirement for a gas-phase reaction to be important indoors is that it can occur on a competitive time scale with ventilation (Weschler and Shields 2000). What does this mean in practice? Typical air exchange rates with outdoors can range from perhaps 0.2 h^{-1} for an airtight house to 2.0 h^{-1} for a leakier construction (Weschler 2000). So taking the value of 0.2 h^{-1} , for a gas-phase reaction to compete with removal via ventilation, its loss rate would need to exceed 0.2 h^{-1} . If we take the example of ozone, the loss rate ($\text{molecule cm}^{-3} \text{ s}^{-1}$) due to ventilation can be expressed simply as:

$$\text{Loss rate of ozone due to ventilation} = 0.2 / 3600 \times [\text{ozone}]$$

Note that the square brackets denote concentration (molecule cm^{-3}), and the ventilation rate has been converted to units of per second. Now, if we consider gas-phase loss of ozone, such as through reaction with limonene, then:

$$\text{Loss rate of ozone due to reaction with limonene} = k \times [\text{ozone}] \times [\text{limonene}]$$

where k is the rate coefficient for the reaction of ozone with limonene ($2.2 \times 10^{-16} \text{ cm}^{-3} \text{ molecule}^{-1} \text{ s}^{-1}$ Table 2). So we can now compare the losses. The ozone concentration can be ignored as it would be the same for each loss:

$$0.2/3600 = 2.2 \times 10^{-12} * [\text{Limonene}]$$

By rearranging this equation, we find that gas-phase loss will dominate ventilation loss when the limonene concentration exceeds $\sim 2.5 \times 10^{11} \text{ molecule cm}^{-3}$ (approximately 10 ppb), a situation that is frequently encountered indoors such as during cleaning (Singer et al. 2006). A similar calculation for the hydroxyl and nitrate radicals using the rate coefficients in Table 2 shows that limonene concentrations need to exceed less than 1 ppt for gas-phase loss to dominate removal of these species by ventilation. For limonene at least, oxidation by these species competes with, or significantly exceeds, removal by dilution from air exchange.

This chapter provides a summary of the key gas-phase reactions that occur indoors, the main reaction pathways for these reactions, and the species that can be formed through the resulting indoor air chemistry.

Gas-Phase Chemistry

Reactions of Ozone

Ozone (O_3) is a powerful oxidizing agent and will readily attack any molecule that contains a carbon-carbon double bond, such as alkenes and monoterpenes (Atkinson and Arey 2003). Unlike outdoors, where the hydroxyl radical (OH) tends to dominate oxidation of VOCs, the lower light levels indoors mean that the photochemical reactions that lead to OH production are less favored, and VOC oxidation by ozone becomes relatively more important. Ozone concentrations indoors are much lower than outdoors, as it rapidly deposits on indoor surfaces and also reacts with nitric oxide (NO). Consequently, indoor ozone concentrations tend to be 0.2–0.7 of those outdoors (Weschler 2000).

One group of indoor reactions that has received significant attention to date has been ozone-monoterpene reactions (Weschler and Carslaw 2018). These reactions have been studied in detail for several reasons: (i) monoterpenes are ubiquitous indoors given they are used in large quantities in personal care and cleaning products (Nazaroff and Weschler 2004); (ii) ozone is also ubiquitous indoors, gaining access from outdoors via windows, doors, and cracks in the building envelope as well as from indoor sources such as photocopiers and laser printers where they exist (Weschler 2000); and (iii) ozone-monoterpene reactions are fast enough to compete with typical air exchange rates indoors (Weschler and Carslaw 2018) and can produce a range of short-lived (e.g., radicals) and longer-lived complex multi-functional species in both the gas and condensed phases (Walser et al. 2007).

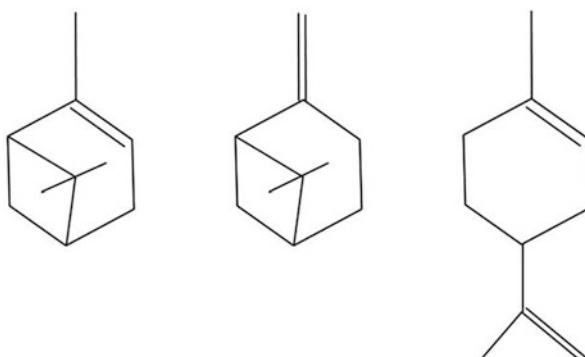

These reactions have also been widely studied by the atmospheric chemistry community, as monoterpenes are emitted in vast quantities from vegetation and their high reactivity and propensity to form secondary organic aerosol have implications for chemistry and climate (Steiner 2020).

Just like outdoors, there are seasonal and latitudinal implications for the importance of ozone concentrations and hence ozone chemistry indoors (Weschler 2000). High NO_x concentrations reduce those of ozone and tend to peak in the winter months outdoors when NO_x emissions are higher. Outdoor ozone concentrations therefore tend to peak in spring/summer, coinciding with the time of year when windows are typically open more often. Given the major contribution of outdoor ozone to indoor ozone concentrations, the location, time of year, and air exchange rate with outdoors are all vitally important in determining the indoor ozone concentration.

The monoterpenes are a group of species that have the formula C₁₀H₁₆ and are derived from two isoprene (C₅H₈) units. Figure 1 shows the structures of three common monoterpenes: α -pinene, β -pinene, and limonene. The presence of monoterpenes in numerous products and materials used indoors gives them an easy route into indoor environments (Nazarioff and Weschler 2004; Singer et al. 2006). Despite a common chemical formula, different monoterpenes have very different distributions of atoms within their complex ring structures, and the location of their one or two double bonds can be external and/or internal. The position of this double bond can have an impact on the resulting reactivity of these species, as well as the products that are formed when they are oxidized (Youssefi and Waring 2015).

The first step in the reactions between ozone and double-bonded species, such as monoterpenes, involves the addition of ozone across the double bond to form an ozonide. As ozonide species are energy-rich and very unstable, they quickly disintegrate to form stable carbonyl products, hydroxyl radicals, and Criegee Intermediate (CI) radical species (Aschmann et al. 2002). Figure 2 shows the first few steps of limonene ozonolysis as an example. Note that the ozonide is not shown here given it rapidly disintegrates, so the two products shown after the preliminary oxidation step of limonene by ozone in Fig. 2 are the CI radical species.

Fig. 1 The structures of three monoterpenes, common in indoor products such as cleaning products and fragrances: from the left are shown α -pinene, β -pinene, and δ -limonene

There are several implications of these reactions for indoor air chemistry. The formation of the hydroxyl radical (Fig. 2) allows the potential for even more oxidation chemistry (see next section). Hydroxyl radicals participate in similar reactions indoors to those they are involved in outdoors, including oxidizing numerous VOCs. Second, it is important to note that as well as forming OH radicals, ozone-monoterpene/alkene reactions also produce peroxy radicals (Fig. 2). This radical production then opens up the possibility of even more reactions indoors.

Given that ozone-monoterpene reactions produce OH radicals (Fig. 2) and that OH radicals can also react with monoterpenes (see next section), this raises the question about whether the monoterpenes act as a source or sink of OH. That depends on the rates of reaction of the individual monoterpene with OH and ozone, as well as the yield of OH formation from the ozone-monoterpene reaction (i.e., how many OH radicals are formed each time ozone reacts with a monoterpene). Table 1 illustrates this point for a selection of common monoterpenes.

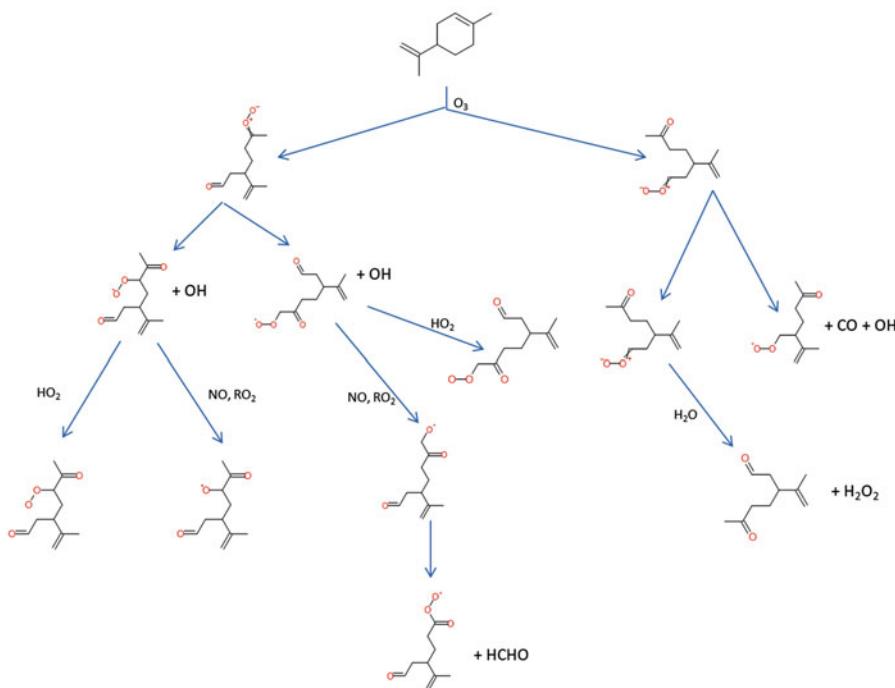

Fig. 2 The first three oxidation steps of limonene by ozone according to the master chemical mechanism, MCM (MCM n.d.). The blue arrows denote the dominant reaction pathways during cleaning with a limonene-based cleaner (based on results from Carslaw 2013) with the reactant that drives each reaction alongside the arrow. Absence of a reactant alongside an arrow means that the molecule decomposes/is collisionally stabilized to form the new species (e.g., the subsequent reactions of the CI radicals formed in the first step). Also shown are places where an OH radical is formed

Table 1 The OH yield following reaction between various monoterpenes and ozone, the rate coefficients for the reaction of each monoterpene with ozone and OH ($\text{cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$) (Atkinson et al. 2004; IUPAC Task Group n.d.) and the ozone concentration in ppb (O_3 switch) at which the VOC switches from being an OH sink to an OH source, assuming a background OH concentration of $3.4 \times 10^5 \text{ molecule cm}^{-3}$ (~0.01 ppt) (Carslaw 2007)

	OH yield	$k(\text{O}_3)$	$k(\text{OH})$	O_3 switch /ppb
Limonene	0.66	2.20×10^{-16}	1.65×10^{-10}	15
α -Pinene	0.8	9.60×10^{-17}	5.30×10^{-11}	9
β -Pinene	0.3	1.90×10^{-17}	7.60×10^{-11}	181
α -Terpinene	0.38	1.90×10^{-14}	3.50×10^{-10}	0.7
α -Terpinolene	0.7	1.60×10^{-15}	2.20×10^{-10}	3

The first point to notice from Table 1 is that the rate coefficients for reaction of monoterpenes with ozone are much slower than for OH. However, the indoor ozone concentration is often 5 to 6 orders of magnitude larger than that of OH indoors, which compensates somewhat. Table 1 also shows that there is a large variation in the OH yields for the different monoterpenes. Again, these variations relate to the structural differences as discussed earlier. The final column in Table 1 shows the ozone concentration at which a monoterpene will switch from being an OH sink to an OH source, assuming a background OH concentration of $3.4 \times 10^5 \text{ molecule cm}^{-3}$ (~0.01 ppt) as estimated in a modeling study by Carslaw (2007). It is likely that most of these monoterpenes act as net radical sources given typical indoor ozone concentrations (Weschler 2000), though β -pinene will always be an OH sink indoors. Note also that given ozonolysis of monoterpenes produces peroxy radicals and that these can be recycled to OH (see next section), these ozone concentrations are likely to be an upper limit for where monoterpenes become OH sources indoors.

Reactions of the Hydroxyl Radical

Once the hydroxyl radical is formed indoors such as through the ozonolysis reactions discussed in the previous section (Fig. 2), or indeed via indoor photolysis, it can initiate oxidation reactions just as for the outdoor environment, leading to more oxidative chemistry indoors than might otherwise have been expected. Reaction rates for the hydroxyl radical with VOCs are much faster than both its deposition onto indoor surfaces and exchange with outdoor air, which are negligible for OH indoors (Weschler and Shields 1996). Modeling studies since the 1990s typically predicted concentrations of the order of $1\text{--}4 \times 10^5 \text{ molecule cm}^{-3}$ (Weschler and Shields 1996; Sarwar et al. 2002; Carslaw 2007) and that the most important source of OH indoors was through the reaction of ozone with monoterpenes (Sarwar et al. 2002; Carslaw 2007; Mendez et al. 2017). These predicted indoor OH concentrations are about a factor of 5–10 less than outdoors in summer and comparable to outdoor concentrations at nighttime (Faloona et al. 2001) and during the daytime in winter (Heard et al. 2004).

These predicted background concentrations have been confirmed through recent measurement studies, which have also demonstrated that concentrations of OH can be substantially higher indoors. Gomez-Alvarez et al. (Gomez Alvarez et al. 2013) found that OH concentrations were elevated (1.8×10^6 molecule cm^{-3}) near windows owing to the photolysis of HONO (nitrous acid). Carslaw et al. (2017) measured elevated concentrations of OH radicals (4×10^6 molecule cm^{-3}) during surface cleaning with a limonene-based cleaner in a University PC classroom. In the same study, they operated an air-cleaning device which elevated OH concentrations even more, peaking at 2×10^7 molecule cm^{-3} . Background OH concentrations in this study were determined to be 6.5×10^5 molecule cm^{-3} . The enhanced indoor OH concentrations during cleaning are similar to, or even greater than ambient concentrations. Clearly then, OH formation and subsequent OH-driven oxidation is possible for a range of indoor conditions and could be particularly important depending on the activities that are taking place within a building.

Just like outdoors, OH is a powerful oxidant and very reactive indoors, able to react with NO_2 and NO, as well as a range of VOCs. It is less selective than ozone and reacts with single-bonded VOC species too, though the fastest reactions tend to be with the species that ozone preferentially reacts with, such as alkenes and monoterpenes (Atkinson et al. 2004). When OH reacts with VOCs, it can abstract an H atom to form an alkyl and then a peroxy radical. As an example, the initial net step for oxidation of ethane to form ethyl peroxy radicals is shown in R1:

Note that reaction R1 really encapsulates two steps (R1a and R1b):

However, given the ethyl alkyl radical formed in reaction R1a is so reactive, and that the quantity of oxygen in the atmosphere is so high, it is reasonable to write these two as one step (R1) and this convention will be adopted throughout the rest of this chapter. OH reactions with other VOCs follow the same general mechanism as in R1.

For alkenes (and other double-bonded species), OH can initially add to the double bond to form a peroxy radical, as shown for ethene in R2:

Oxidation by the OH radical is much more complicated for aromatic species. Toluene is a relatively common indoor VOC (Wang et al. 2017), and following reaction with OH can produce a number of different products with various yields (Jenkin et al. 2003; Bloss et al. 2005). The main oxidation pathway (~65%) leads to the production of a rather complex peroxy radical that involves breaking the original aromatic ring. The reaction also produces a second peroxy radical that maintains the

aromatic ring structure but at a lower yield (7%), as well as cresol (18%) and 2, 3-epoxy-6-oxo-4-heptenal (10%).

Once the peroxy radicals are formed, they either react with nitric oxide, NO (R3), or with other peroxy radicals (R4 and R5):

RO_2 is used here to denote peroxy radicals in general (where R denotes an alkyl group). The importance of the different pathways in R5 depends on the parent hydrocarbon. Indeed, whether a peroxy radical reacts with NO or another peroxy radical is determined by the particular conditions. If there is a source of NO_x indoors (e.g., a gas cooker), reactions such as R3 would be the most likely fate of the peroxy radicals. However, in the absence of NO_x sources indoors, or any from outdoors (e.g., if the building in question is not next to a busy road where pollutants are able to ingress), radical propagation reactions such as those represented by R4 and R5 would be more important. Note that R3b shows the minor (<1%) pathway for R3, to form ethyl nitrate. For the equivalent peroxy radical for dodecane (12 carbon atoms), the organic nitrate pathway is 44% of the total (Jenkin et al. 1997). The minor route represented by R3b becomes more important as the hydrocarbon gets bigger.

The $\text{C}_2\text{H}_5\text{O}$ radical produced in R3a can react further as shown in R6, in this case, to form acetaldehyde and the hydroperoxy radical (HO_2):

Depending on the indoor conditions, the hydroperoxy radical can then be rapidly recycled to OH as shown in R7, or react with other peroxy radicals, such as through reactions like R4:

Reactions R5 and R6 also produce aldehyde species, with the generic structure RCHO (where R can be H or an alkyl group). Once formed, aldehydes can react with OH, or to be photolyzed as shown in R8 and R9 respectively for formaldehyde (HCHO):

although deposition to surfaces and ventilation are likely to be more important removal mechanisms (Mendez et al. 2015). Reactions R7 and R8 are examples of propagation reactions between OH and HO₂ radicals. Just like outdoors, where one exists, so does the other, and so rapid regeneration of OH becomes possible through these cycles, opening up the possibility of further VOC oxidation reactions.

As well as aldehydes, these reactions lead to the production of other oxygenated VOCs such as peroxides (R4) and alcohols (R5b, R5c). The main fate of peroxides indoors is likely to be deposition onto surfaces and air exchange with outdoors (Fan et al. 2005), though partitioning to form secondary organic aerosol (SOA) is also likely to be significant for the larger peroxides (Carslaw 2013). This means that reactions such as R4 represent a radical termination reaction, effectively removing radicals from the system. The alcohols will likely react with OH to form HO₂ and an aldehyde, such as shown for ethanol in R10 to form acetaldehyde, another example of propagation of OH to HO₂ radicals:

It is worth noting that aldehydes from C₂ (acetaldehyde) and bigger can react with the OH radical to form acetyl peroxy radicals (RCO₃, where R is an alkyl group), which themselves react with NO₂ to form PAN (peroxyacetyl nitrate)-type species, as shown in reactions R11 and R12 for acetaldehyde:

There have been very few studies of PAN-type species indoors. One such study showed that the simplest PAN-type species as shown in R12 was formed indoors through chemistry rather than transported from outdoors and that concentrations were enhanced when the ozone concentration was higher (Fischer et al. 2014). PAN species are thermally labile, and so the indoor temperature will also determine where the equilibrium lies in R12.

Another interesting aspect of this indoor chemistry is the ability of peroxy radicals to convert NO to NO₂ (nitrogen dioxide), as shown in reactions R3a and R7. This opens up the possibility of forming ozone indoors through photolysis, as shown in reactions R13, R14:

where “M” represents a molecule (typically nitrogen or oxygen molecules in air) that acquires excess energy from the reaction without affecting the chemistry. Clearly, reaction R13 happens much more slowly indoors compared to outdoors, but it is still possible under some indoor conditions, particularly next to a window or with strong indoor lighting such as compact fluorescent lights (Kowal et al. 2017).

The last two sections have shown that the chemistry of ozone and the hydroxyl radical indoors are intimately linked. VOC oxidation by ozone can make OH (and other radicals), but OH oxidation of VOCs can produce ozone indoors if there is sufficient lighting to drive R13. Therefore, if you have one of these oxidants indoors, you are likely to have the other. These connections are summarized in Fig. 3. Many of these reactions look similar to those observed outdoors. Apart from the photolysis rates, many of the rates of reaction indoors are comparable to outdoors and some can even exceed those typically observed outdoors, such as the reactions of ozone and the hydroxyl radical with monoterpenes (Carslaw 2007).

Finally, in the presence of NO_x , the major termination route for OH radicals is with NO_2 as shown in R15 to form nitric acid vapor (HNO_3):

As well as representing a loss of radicals from the system, this reaction also removes NO_x from indoor air. The major fate of HNO_3 indoors depends on the conditions. Deposition onto indoor surfaces and exchange with outdoors are likely to be important (Weschler et al. 1992), although partitioning to the aerosol phase to form ammonium nitrate could be important if ammonia concentrations are high indoors (Ampollini et al. 2019).

Reactions of the Nitrate Radical

The nitrate (NO_3) radical is another important oxidant outdoors, participating in various oxidation reactions. Outdoors, it only becomes important at night-time as it is photolyzed rapidly during the day (lifetime of ~ 5 s), and can also react rapidly with NO (Carslaw et al. 1997). Given the lower light levels indoors, it might be assumed that the nitrate radical could reach appreciable concentrations within buildings.

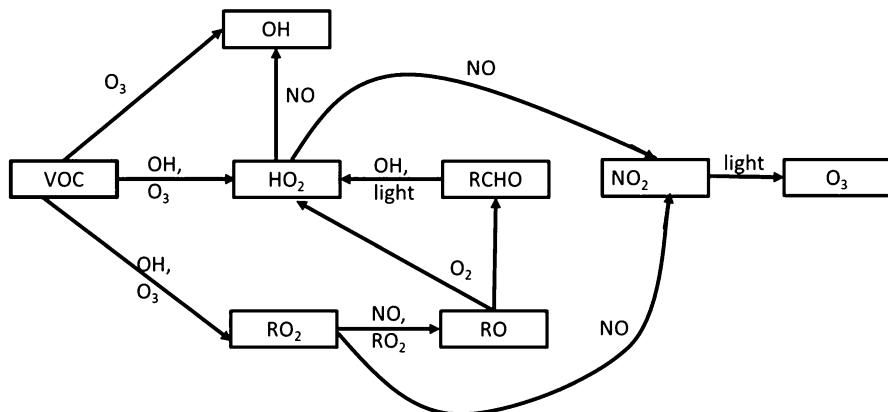

Fig. 3 Summary of the main connections between hydroxyl radical and ozone reactions indoors

Nitrate radicals are formed from the reaction of NO₂ with ozone, as shown in R16:

Once formed, the NO₃ radical can react rapidly with NO to reform NO₂ (R17):

So, you would only expect to find NO₃ indoors in the absence of indoor sources of NO (e.g., no combustion sources present). Indeed, high NO concentrations would also remove indoor ozone through R18, making it unlikely that the conditions would be favorable for NO₃ formation in the first place:

The nitrate radical can also react with NO₂ to form dinitrogen pentoxide (N₂O₅), with which it exists in equilibrium as shown in R19:

Outdoors, the accommodation coefficients of both NO₃ and N₂O₅ suggest that they may undergo deposition to moist particle surfaces (Carslaw et al. 1997). Such reactions would effectively remove NO₃ (and NO₂) from the system, but this chemistry has not been investigated indoors to date.

The NO₃ radical can undergo a series of oxidation reactions, more rapidly with species with a double bond. For instance, the reaction with ethene is shown in R20, which forms a nitrated peroxy radical:

The peroxy radicals so formed can then partake in reactions such as those described in the previous section. The difference with the peroxy radicals formed through NO₃ oxidation is that at some point, NO₂ is likely to be formed, or a nitrated product that is analogous to the hydroxyl radical route equivalent. For instance, for the nitrated peroxy radical formed in R20, it will most likely react with NO or RO₂ to form the respective alkoxy radical, NO₃CH₂CH₂O. This radical in turn can then go through one of two pathways as shown by reactions R21 and R22:

With the rate of R22 being approximately seven times faster than R21 at 293 K (Jenkin et al. 1997). Reaction R22 can be considered to be analogous to R6 for OH: both reactions produce an aldehyde and HO₂ as products, but the aldehyde produced in R22 contains a nitrate rather than a hydroxyl group.

The nitrate radical can also react with some species to form HNO_3 , such as the reaction with 1,3,5-trimethylbenzene, as shown in reaction R23:

And similarly for the reaction with aldehydes, as shown in R24 for formaldehyde:

The NO_3 radical had not been directly measured indoors until a recent study confirmed its presence for the first time with an experiment that manipulated indoor concentrations (Arata et al. 2018). A portable butane stove was used to provide NO_x emissions in a residential kitchen which removed indoor ozone and consequently, no NO_3 was observed. However, when an ozone generator was used to enhance the indoor ozone concentration to ~40 ppb, there was sufficient NO_2 formed through reaction R18 to produce NO_3 at mixing ratios of ~3–4 ppt. Although these concentrations are low, they can still have significant impacts on indoor chemical processing. For instance, for a simulated UK residence under typical conditions, the indoor NO_3 concentration was predicted to never exceed 0.03 ppt, but NO_3 -monoterpene reactions were still responsible for ~17% of the RO_2 formation through initiation reactions under these conditions (Carslaw 2007). Further research is needed to more fully understand the impact of the nitrate radical on indoor gas-phase chemistry.

Reactions of the Chlorine Radical

Reactions of the chlorine (Cl) radical are analogous with those of the OH radical. They are generally faster than with OH, and there is also the potential to make chlorinated products through oxidation reactions. The reactions of the chlorine radical with ethane and ethene are shown in R25 and R26 and are analogous to R1 and R2 respectively for the equivalent hydroxyl radical reactions:

It can be seen from reaction R25 that the same peroxy radical is made as for oxidation by OH in R1, but HCl is made instead of H_2O as a byproduct.

Chlorine radical formation indoors is possible following cleaning activities that liberate various chlorine compounds. For instance, significant concentrations of both chlorine molecules and hypochlorous acid (HOCl) were shown to be formed in the 10s–100s of ppb range following floor mopping with a bleach cleaner (Wong et al. 2017). Both of these species can be photolyzed to liberate chlorine radicals as shown in R27 and R28 for chlorine and hypochlorous acid, respectively, the latter reaction also producing OH radicals:

The level of light indoors is therefore critical in determining the importance of these sources of chlorine radicals. For instance, predicted indoor concentrations of chlorine radicals varied from near zero in the dark to approximately 3×10^5 molecule cm⁻³ if it was assumed that 3% of outdoor UV light and 10% of outdoor visible light were able to penetrate indoors (Wong et al. 2017).

As well as undergoing reactions with VOCs, chlorine radicals can react with HO₂ (R29), NO₃ (R30), and ozone (R31):

Out of these four reactions, the reaction with ozone (R31) dominates for typical indoor conditions. Although the rate coefficient for R31 (1.2×10^{-11} cm³ molecule⁻¹ s⁻¹) is a factor of 2 lower than that for R30 (2.4×10^{-11} cm³ molecule⁻¹ s⁻¹) and three times lower than R29b (3.5×10^{-11} cm³ molecule⁻¹ s⁻¹) at 293 K (Xue et al. 2015), the ozone concentration indoors is typically 1000 times higher than the concentrations of HO₂ and NO₃. The rate coefficient for R29a (9.0×10^{-12} cm³ molecule⁻¹ s⁻¹) is actually lower than that for R31 at 293 K.

The chlorine monoxide (ClO) formed in reactions R29a, R30, and R31 can then react with HO₂ (R32), OH (R33), NO (R34), and NO₂ (R35):

Given typical indoor conditions, reaction with NO and NO₂ is to be the most likely fate of chlorine monoxide. The rate coefficient for the reaction with NO₂ (R35) is approximately four times faster than that for NO (R34). Therefore, the ratio of NO to NO₂ will determine which of these two reactions controls the removal of chlorine monoxide. The fate of ClONO₂ is to undergo photolysis through one of two routes shown in R36 and R37, with R37 approximately ten times faster for typical indoor conditions (e.g., with halogen or incandescent lighting):

The chlorine and ClO chlorine monoxide radicals so produced can then cycle back through the reactions already described.

Comparing Indoor Oxidants

This chapter has demonstrated that there is a range of oxidants that can exist indoors, all contributing to the chemistry in the gas-phase and competing, in particular, to oxidize VOCs. Although hydroxyl, chlorine, and nitrate radical reactions tend to be faster than those of ozone, the latter typically exists at much higher concentrations than the radical species. Table 2 compares the rate coefficients of the four oxidative species with limonene, a ubiquitous VOC indoors. It then shows what the comparable radical concentrations would need to be to compete with oxidation for different concentrations of ozone.

Table 2 shows that even for higher indoor concentrations of ozone, the concentrations of NO_3 and OH that are required to oxidize equivalent limonene have been observed under some conditions as described in previous sections (Gómez Alvarez et al., 2013; Carslaw et al. 2017; Arata et al. 2018). Although chlorine radicals have not been measured directly indoors to date, their indoor concentration has been simulated using a model, to be in the range of values shown in Table 2, particularly with sufficient indoor light (Wong et al. 2017). Also, as discussed throughout this chapter, cycling between these oxidants means that once one of them is formed, there is potential for all of them to be produced and to take part in further indoor air chemistry.

Role of Gas-Phase Chemistry in Particle Formation

This chapter has focused on gas-phase reactions, but it is important to note that such reactions can also produce products which are sufficiently involatile to promote

Table 2 Rate coefficients for reaction of different oxidants with limonene ($\text{cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$) at 293 K. Values for NO_3 , ozone, and OH from Atkinson et al. (2004) and the IUPAC Task Group (n.d.) and those for Cl from Dash and Rajakumar (2014). Also included are the concentrations of NO_3 , OH and, Cl that are needed to oxidize an equivalent amount of limonene as the stated mixing ratio of ozone

	NO_3	O_3	OH	Cl
Rate coefficient	1.22×10^{-11}	2.2×10^{-16}	1.65×10^{-10}	9.12×10^{-10}
Equivalent concentration of oxidant (molecule cm^{-3}) for different ozone mixing ratios				
5 ppb	2.1×10^6		1.7×10^5	2.8×10^4
10 ppb	4.1×10^6		3.3×10^5	5.6×10^4
20 ppb	8.3×10^6		6.7×10^5	1.1×10^5
40 ppb	1.7×10^7		1.3×10^6	2.2×10^5

particle formation and growth, often referred to as secondary organic aerosol (SOA). The monoterpenes are an important group of SOA-forming VOCs, given the ubiquity of their sources indoors (Nazaroff and Weschler 2004). Following oxidation, they can produce a wide range of multifunctional species, including alcohol, aldehyde, ketone, and carboxylic acid groups: such groups tend to have lower vapor pressures than their parent terpene and can condense to form SOA (Walser et al. 2007).

The composition of particles formed in this way changes depending on indoor conditions. For instance, Carslaw et al. (2012) found from a modeling study that for typical background conditions in a UK residence, the simulated concentration of SOA was around $1 \mu\text{g}/\text{m}^3$ out of a total indoor particle concentration of $10.7 \mu\text{g}/\text{m}^3$, with the composition mainly comprised (85%) of organic nitrates and PAN-type species, with a smaller contribution from peroxide species (12%). However, during cleaning, the SOA concentration increased to $20 \mu\text{g}/\text{m}^3$ for a total indoor particle concentration of $30 \mu\text{g}/\text{m}^3$, with the composition now dominated by peroxide species (73%) and a much smaller contribution from nitrated organic species (21%). Clearly then, it is possible for gas-phase chemistry to lead to particles indoors, with the composition of these particles being dependent on indoor conditions. This in turn will have an impact on the volatility of the indoor air mixture.

Conclusion

This chapter has shown that there can be a wealth of gas-phase chemistry indoors, with the dominant reactions determined by the indoor conditions, such as light levels, oxidant, and NO_x concentrations, building location, occupant activities, and ventilation rates. The numerous controlling factors mean that two identical buildings could have very different indoor pollutant concentrations. So, a building next to a busy road where vehicle-emitted pollutants were able to infiltrate could have very different indoor air concentrations to one in a rural setting with higher outdoor ozone concentrations. Even the same building could have very different indoor air pollutant concentrations depending on the time of year, as ozone concentration and window opening frequency vary with season. Indoor VOC concentrations have also been shown to vary enormously in identical houses in the same street, depending on the behavior of the occupants (Wang et al. 2017).

Nevertheless, the gas-phase chemistry of indoor air is typically driven by ozone reactions with terpenes, which are reactions that can produce radical species, stable species such as carbonyl compounds, and also fine particles in the sub-micron range. An important product of such reactions is the OH radical, which can proceed to initiate further oxidation processes in an analogous manner to outdoors. This chapter has also shown that peroxy radicals are likely to be present wherever the OH radical exists, and there are also interactions between these radicals and chlorine radicals if there is a source of the latter indoors.

It is likely that indoor chemical processing indoors has become more important in recent years through a combination of increased outdoor ozone concentrations,

greater use indoors of terpenes in cleaning products and fragrances, and decreased ventilation rates (Weschler et al. 2006). The international lockdowns accompanying the 2020 COVID-19 pandemic have also allowed a glimpse of how indoor air chemistry might change in the future. The decreased NO_x emissions in urban areas that accompanied various lockdowns could be viewed as a proxy for future improvements in vehicle technologies that aim to decrease NO_x emissions outdoors. For instance, in the UK, the main lockdown in spring 2020 led to decreases in ambient NO_x concentrations of about 30–40% and a corresponding ozone increase of about the same amount (AQEG 2020). Model simulations showed that this increase in outdoor ozone led to an increase in indoor ozone concentrations of around 50% for typical residential conditions, with an accompanying 30% increase in HCHO caused by additional chemical reactions indoors. Further, the expected improvements in future vehicle emissions technologies also means that VOCs from use of personal care products indoors are likely to be responsible for an increasing proportion of fossil fuel VOC emissions in industrial areas outdoors, with a recent study estimating this proportion approached half of the total (McDonald et al. 2018). Coupled with climate change impacts that are likely to lead to more heatwaves and associated higher outdoor pollutant (e.g., ozone, PM) concentrations that can impact indoors (Terry et al. 2014), the gas-phase reactions described in this chapter are only likely to increase in importance.

Abstract

Photochemistry is a rapidly growing research area in the field of indoor chemistry. Advances in measurement techniques and predictive models have altered our understanding of the effects of light on the composition of indoor atmospheres. Large knowledge gaps remain, however, including the question, “does photochemistry matter indoors?”. This chapter introduces readers to basic principles of photochemistry; provides context to indoor photochemistry using examples from better-understood outdoor atmospheric photochemical reactions; discusses our current understanding of the processes that control indoor photochemical reactions; outlines experimental and theoretical techniques commonly used to study indoor photochemistry; and provides some thoughts for the future.

Keywords

Photolysis · Kinetics · Radicals · Photon flux · Light source · Indoor photolabile species

Introduction to Photochemistry

Photochemistry describes chemical reactions initiated by the absorption of a photon. Photochemical reactions can be classified as “direct” or “indirect.” Direct photochemical reactions occur when the compound of interest (the “analyte”) absorbs a photon and reacts. A common form of direct photochemical reaction in the atmosphere is photolysis (the breaking of bonds following absorption of a photon). Direct photolysis can also involve other molecules. For example, the analyte can absorb a photon and then react with O₃ or another species in the air (or other reaction matrix, such as water). Indirect photochemistry occurs when a molecule other than the analyte absorbs a photon, and then causes the analyte to undergo a chemical transformation. In the gas phase, indirect photochemistry almost always refers to radical reactions. Radicals such as hydroxyl radicals (OH) and chlorine atoms (Cl) are formed from photolysis of (among other things) O₃ and Cl₂. These radicals go on to react with a wide range of atmospheric species. The reaction of radicals with atmospheric gases is often referred to as “photolysis,” despite the fact that only the radical was formed photochemically (i.e., the reaction between the radical and the analyte does not involve the absorption of photons). These types of reactions are more appropriately termed indirect photochemistry.

To understand indoor photochemistry, and how it differs from outdoor photochemistry, we must understand what factors determine the speed (or rate) at which photochemical reactions occur (and whether they occur at all). Full discussions of the fundamentals of photochemical reactions are available in textbooks such as Turro et al. (2009), and introductions to photochemistry from an atmospheric science perspective are provided in textbooks such as Jacob (1999), Finlayson-Pitts and

Pitts (2000), and Seinfeld and Pandis (2016). Here we give a brief overview of the fundamentals of photochemistry that are most relevant to indoor chemistry.

Photochemical reaction rates are generally given by the rate law (Eq. 1):

$$\text{Rate} = J[\text{analyte}] \quad (1)$$

Where J is the photolysis rate constant and $[\text{analyte}]$ is the analyte concentration. For a given analyte concentration, the larger the rate constant, the faster the reaction. Photochemical rate constants (J) depend on three factors, as shown in Eq. 2:

$$J = \sigma\phi F \quad (2)$$

Where σ is the absorption cross section of the analyte (in units of $\text{cm}^2 \text{molecule}^{-1}$), Φ is the photolysis quantum yield (unitless), and F is the photon flux ($\text{photons cm}^{-2} \text{s}^{-1}$). We discuss each of these variables in detail below. Note that Eq. 2 is for a single wavelength of light. In atmospheric chemistry (including indoor chemistry) light sources often span a broad range of wavelengths, and the appropriate equation becomes:

$$J = \int_{\lambda_i}^{\lambda_f} \sigma(\lambda)\phi(\lambda)F_\lambda d\lambda \quad (3)$$

In this equation, photolysis rate constants are integrated across the range of wavelengths of interest ($\lambda_i - \lambda_f$). The notation of $\sigma(\lambda)$ and $\Phi(\lambda)$ indicate that absorption cross sections and photolysis quantum yields are wavelength dependent. F_λ denotes the photon flux at a specific wavelength, and $d\lambda$ is the interval between wavelengths used in the calculation. The magnitude of the rate constant, and therefore on the reaction rate (as given by Eq. 1) depends on the magnitudes of σ , Φ , and λ . If one or more variable is zero or extremely low, reaction will not occur, regardless of the magnitude of other variables.

Absorption Cross Section and Photolysis Quantum Yield

While photon flux (F) depends on the light source, absorption cross section (σ) and photolysis quantum yield (Φ) are characteristic of individual analytes. Their magnitudes can depend on external factors such as temperature, pressure, and “solvent” (in either the gas or condensed phase). Since indoor chemistry generally occurs within a fairly narrow range of temperatures and pressures, we will not discuss these variables here. For now, we will focus on a solvent of air (i.e., gas phase reactions).

Several requirements must be met in order for photolysis to occur. First, the energy of the absorbed photon must be high enough to promote an electron into a higher electronic energy level. Such transitions are generally only achieved with ultraviolet (UV) (and occasionally visible) light. This is illustrated by Process (a) in Fig. 1. Once an electron is promoted to a higher electronic energy level, photolysis

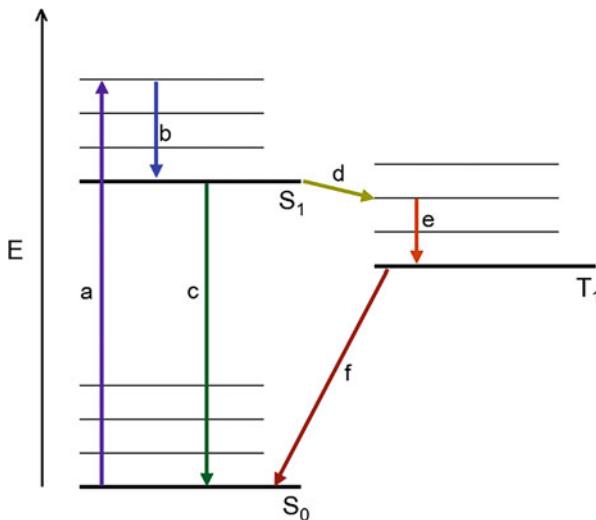

Fig. 1 Simplified Jablonski diagram showing energies (not to scale) of potential electronic and vibrational transitions following absorption of a photon. S_0 represents the ground state of the analyte, S_1 represents the first electronically excited singlet state, and T_1 represents the first excited triplet state. Thin horizontal lines denote vibrationally excited states of each electronic state (S_0 , S_1 , T_1). Arrows denote some possible processes: (a) electronic excitation from S_0 to a vibrationally excited level of S_1 ; (b) vibrational relaxation to S_1 ; (c) transition from S_1 to S_0 ; (d) intersystem crossing from S_1 to a vibrationally excited level of T_1 ; (e) vibrational relaxation to T_1 ; (f) transition from T_1 to S_0 . This schematic is an incomplete representation of possible processes, and does not include chemical reactions

will only occur if (1) the energy is sufficient to initiate a reaction (e.g., by breaking a bond), and (2) the reaction occurs rapidly enough to compete with other processes.

The photolysis quantum yield (Φ) describes the probability that the absorption of a photon will lead to a photochemical reaction. It is generally a fraction between 0 and 1. After absorbing a photon, molecules can release excess energy in various ways. Chemical reaction is one possibility, but nonchemical (i.e., physical) methods include vibrational relaxation, intersystem crossing, physical quenching, and radiative and non-radiative decay (represented by Processes (c), (d), and (f) in Fig. 1). The magnitude of Φ depends on the kinetics of photolysis relative to other competing processes.

$$\Phi = \frac{k_{react}}{\sum k_i} \quad (4)$$

Where k_{react} is the rate constant for chemical reaction and $\sum k_i$ is the sum of rate constants for all possible pathways of the excited species. If k_{react} is much larger than all other terms, the equation will simplify to

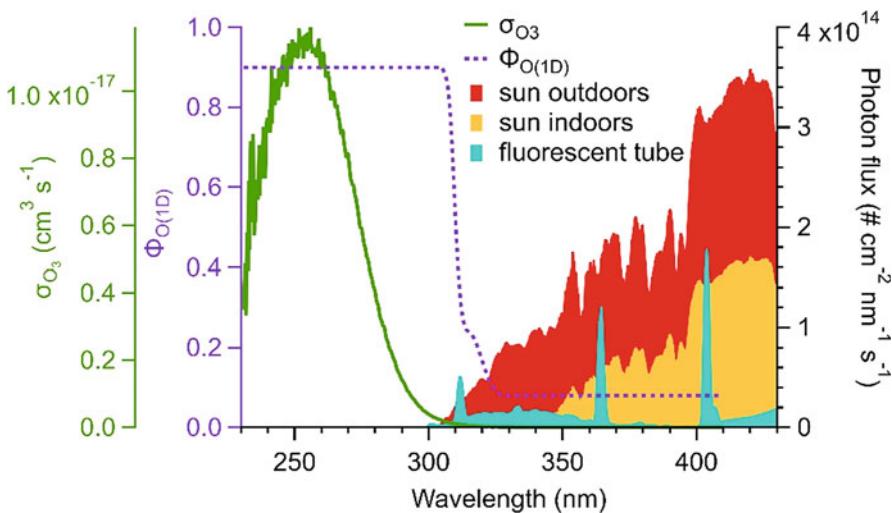

Fig. 2 Wavelength-resolved absorption cross sections and photolysis quantum yields for photochemical OH production from O_3 photolysis (left y axes), and wavelength-resolved photon fluxes from sunlight outdoors and indoors at a house in Austin, Texas around 11 am, June 23, 2018 and from a bare fluorescent tube at 2 mm from the tube center (right y axis; from data used in Zhou et al. (2020a))

$$\Phi = \frac{k_{react}}{k_{react}} \quad (5)$$

and the quantum yield will be 1, meaning that all absorbed photons lead to photochemistry. On the other hand, if k_{react} is very small compared to other processes, Φ will be very small. The product of σ and Φ determines the speed with which a reactant will undergo photolysis when irradiated with light at a given wavelength. As shown in Fig. 2, the photolysis quantum yield for $O(^1D)$ from O_3 photolysis drops to near-zero at wavelengths longer than ~ 320 nm. Thus, OH formation is generally negligible under irradiation at longer wavelengths.

Photon Flux

Photon flux describes the intensity of light available to analytes. In atmospheric chemistry, this includes direct light (from the sun or a lightbulb) as well as scattered and reflected light. A related term is “irradiance,” which describes the rate at which photons cross a unit area of a plane (from a hemisphere of directions). This is what many instruments measure; very few instruments capture photons from a full 360° . Measurement of irradiance and photon flux is discussed in section “[Photon Flux Measurements and Predictions](#).” Irradiance and photon flux differ only by the factor $\cos(\theta)$, where θ is the deviation of the direction of incoming photons from the

vertical to the plane of detection (i.e., light impinging directly on the real or imaginary plane will have $\theta = 0^\circ$, while light that travels parallel to the plane will have $\theta = 90^\circ$). When $\theta = 0^\circ$, $\cos(\theta) = 1$, and irradiance and photon flux are equal. This occurs when light is unidirectional, such as collimated outdoor sunlight on a clear day. Indoors, the contribution of light from different directions to total photon flux is poorly constrained, although research in this area is evolving rapidly. This is discussed in section “[Photon Flux Measurements and Predictions](#).”

Different Considerations for Condensed Phase and Heterogeneous Photochemistry

The above discussion focused on gas-phase photochemistry. Photochemical reactions also occur in condensed phases (such as aqueous solutions) and at atmospheric surfaces. The same principles apply, and the photochemical rate constant is still given by J . In liquids, σ is generally replaced by molar absorptivity (ε). The only difference between σ and ε is the units. Absorption cross sections ($\text{cm}^2 \text{molecule}^{-1}$) work well with common units for gas phase concentrations of molecule cm^{-3} , while $\varepsilon (\text{L mol}^{-1} \text{cm}^{-1})$ works well with molar concentrations commonly used in condensed phases (mol L^{-1}). The resulting photolysis rate constant is still in units of s^{-1} , and reaction rates are often in units of $\text{mol L}^{-1} \text{s}^{-1}$, since condensed-phase concentrations are generally given in terms of molarity rather than number density. For heterogeneous reactions, J is calculated as for gas phase reactions, but reaction rates have units of $\text{molecule cm}^{-2} \text{s}^{-1}$, since we use surface coverages (or surface densities) that represent a 2D coverage, rather than 3D concentration terms.

Analyte absorbance spectra are often different in the gas phase, condensed phase, and at surfaces. In condensed phases, interactions with solvent molecules lead to band broadening, so spectra are generally “smeared” across a range of wavelengths, whereas gas-phase absorbance spectra of small molecules often feature sharp, discrete peaks. Absorbance spectra on surfaces can be different from both the gas phase and the liquid phase. Spectra may be shifted to higher energies (“blue shifts”) or lower energies (“red shifts”) in liquids or at surfaces compared to in the gas phase due to interactions with surrounding molecules, and the magnitude of σ and Φ at a given wavelength may change.

The speciation of analytes may also be different in the different phases. For example, nitric acid (HNO_3) is in its molecular form in the gas phase, but in its ionic form (NO_3^-) in aqueous solution. These are distinct chemical species with different wavelength-resolved absorption spectra. At surfaces, nitric acid may exist in a mixture of ionic and molecular forms, depending on the availability of water molecules (Moussa et al. 2013; Riikonen et al. 2013; Marcotte et al. 2013; Morenz and Donaldson 2017). Photon fluxes at surfaces may also be very different than those in the nearby air. For example, light scattering within aqueous aerosols and ice granules has been reported to increase the effective photon flux by ~50–70% compared to in bulk aqueous solution (Nissenson et al. 2006; McFall and Anastasio 2016; Malley et al. 2017). Reflective surfaces can also increase effective photon fluxes. Little is currently known about surface and condensed phase photochemistry

indoors; we will summarize what is known in section “[Condensed Phase and Heterogeneous Indoor Photochemistry](#).”

Concentration and Steady-State Concentration

The above sections discuss what goes into a photochemical rate constant. We are often interested in photochemical *rates*, which depend on both the photochemical rate constant and the concentration of the reactant. A reaction rate describes the amount of change that occurs in some set time period, and has units of amount/time. The rate for a photochemical reaction is given by Eq. 1. Photochemical reaction rates depend linearly on reactant concentration. So even if a reaction has a large photolysis rate constant, the reaction will be slow if reactant concentration is very low. Conversely, high reactant concentrations can offset small rate constants, leading to nonnegligible reaction rates despite small J (see, for example, Wang et al. (2020) with respect to indoor ozone photochemistry).

Much of the chemistry of interest indoors is indirect photochemistry. Specifically, we often want to know how quickly species such as volatile organic compounds (VOCs) react with photochemically formed oxidants such as OH or Cl. The rate of reaction in this situation will be given by:

$$\text{Rate} = k[\text{analyte}][\text{oxidant}] \quad (6)$$

Where k is the second-order rate constant for the reaction between the analyte and the oxidant. Oxidant concentrations will be determined by their formation and loss rates (note: there may be multiple formation and loss mechanisms for a single oxidant).

$$\frac{d[\text{oxidant}]}{dt} = \sum \text{Rate}_f - \sum \text{Rate}_l \quad (7)$$

where $d[\text{oxidant}]/dt$ is the rate of change of the oxidant concentration with time and $\sum \text{Rate}_f$ and $\sum \text{Rate}_l$ are the total formation rates and total loss rates, respectively. When the total loss rate is much larger than the total formation rate, the oxidant will be consumed more rapidly than it is formed, and will be present at a constant low concentration referred to as a steady-state concentration, denoted by $[\text{oxidant}]_{ss}$. Under these conditions, we can assume that the rate of change of the oxidant is approximately zero (“the steady-state assumption”), which allows us to replace $d[\text{oxidant}]/dt$ in Eq. 7 with 0 and solve for oxidant concentration:

$$[\text{oxidant}]_{ss} = \frac{\sum \text{Rate}_f}{\sum k'_l} \quad (8)$$

where k'_l is the first-order or pseudo-first-order rate constant for a loss process. This is given by the rate constant for the reaction multiplied by the concentrations of any reactants involved in the process *other than* the oxidant. The steady-state concentration calculated from Eq. 8 can be substituted into Eq. 6 to calculate the analyte

oxidation rate. The steady-state approximation is an important tool for calculating kinetics in atmospheric chemistry, both outdoors and indoors. We discuss steady-state approximations for various radicals in detail in section “[Indoor Reactant Concentrations and Oxidant Steady-State Concentrations](#).”

Outdoor Photochemistry

To provide context to our discussion of indoor photochemistry, we will provide a brief overview of key concepts in outdoor photochemistry. Photolysis reactions in the outdoor environment occur in the gas and condensed phases. Here we will focus primarily on gas-phase chemistry, but will discuss condensed phase and heterogeneous indoor chemistry in section “[Condensed Phase and Heterogeneous Indoor Photochemistry](#).” The dominant source of light outdoors is the sun, although limited photolysis can be initiated by artificial lights at night (Stark et al. 2011). The intensity and energy of sunlight are affected by two major factors: (i) the location of the sun, and (ii) the amount of light absorbing or scattering materials between the point of interest and the sun. The first factor, the location of the sun, is measured using the solar zenith angle (SZA), which is the angle between the position of the sun and a vertical line from the point of interest. Thus, an SZA of zero occurs when the sun is directly overhead. Several factors affect the SZA, including time of day, latitude, and time of year. For example, an SZA of zero occurs at the equator around noon on the solar equinoxes. Solar irradiance is inversely proportional to SZA, such that a higher angle results in less light reaching the surface. This occurs because at higher SZAs, light from the sun travels a longer distance through the atmosphere. Gas molecules that make up our atmosphere absorb and scatter light emitted from the sun, changing the light that reaches the surface of the Earth. This effect is more prevalent at shorter wavelengths, so fewer high-energy photons reach the surface of the Earth at high SZAs. The second factor, the presence of absorbing/scattering materials, is determined primarily by altitude, which determines how much of the atmosphere is between the point of interest and the sun. At the Earth’s surface, the second factor is determined mainly by the presence or absence of clouds, which reduce the light reaching the surface. The abundance of suspended aerosols that can absorb and scatter light also plays a role. On cloud-free days with little aerosol pollution, the shortest wavelengths that reach the surface of the Earth are approximately 290 nm. The intensity of this high-energy light reaching the surface is highly dependent on SZA (Fig. 3). Higher quantities of lower-energy (longer wavelength) photons reach the surface of the Earth, with less dependence on SZA.

As an example of gas-phase photolysis outdoors, we will examine three molecules: Cl₂ (Burkholder et al. 2015), HONO (Stutz et al. 2000), and O₃ (Burkholder et al. 2015):

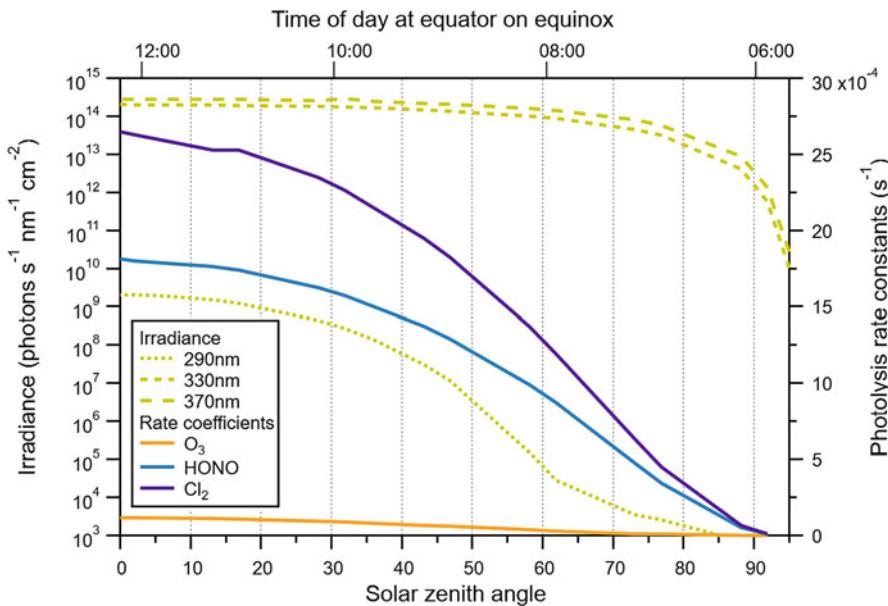

Fig. 3 Irradiance at 290, 330, and 370 nm shown with photolysis rate constants for O_3 , HONO, and Cl_2 as a function of solar zenith angle (SZA). Irradiance and rate constants were calculated using Tropospheric UV model for clear-sky conditions at sea level (Madronich and Flocke 1999)

While Cl_2 and HONO photolyze with visible light, O_3 photolysis requires UV light. Figure 3 shows that Cl_2 and HONO photolysis rate constants are much larger than O_3 photolysis rate constants at all times of the day. Despite this, ozone photolysis remains the dominant radical source over most daylight hours because of its high concentrations. At low SZAs, however, Cl_2 and HONO photolysis rates can exceed O_3 photolysis rates, and photolysis of HONO has been observed to be a much more important radical source than O_3 early in the morning (Young et al. 2012), as well as in the wintertime (Kim et al. 2014). Indoor environments have low UV light availability and are expected to have conditions similar to low-light outdoor conditions.

Overview of Indoor Photochemistry

While photochemistry drives atmospheric composition outdoors, its role indoors is less clear. The high energy photons ($\lambda < 320 \text{ nm}$) responsible for OH production from O_3 photolysis are attenuated by walls, roofs, and windows indoors. This shuts

down the primary source of atmospheric radicals outdoors, and leads to a chemical environment that may be similar to outdoor low-light conditions (with no light, such as at night, or with low light levels, especially at short wavelengths, such as at dawn and dusk). This means that radical levels will generally be lower indoors than outdoors, and that indoor photochemistry will be dominated by species that photolyze at longer wavelengths (>330 nm). While the possibility of indoor photochemistry has been suggested for decades (e.g., Nazaroff and Cass 1986; Carslaw 2007; Gligorovski and Weschler 2013), the first direct evidence of its importance was published in 2013, when measurements in a sunlit classroom demonstrated the formation of OH due to HONO photolysis (Gomez Alvarez et al. 2013), with measured OH concentrations reaching levels on the order of 10^6 molec cm^{-3} , similar to those outdoors. Since then, several studies have confirmed the importance of this reaction, and have identified other photochemical reactions as possible sources of indoor radicals (e.g., Young et al. 2019 and references therein; Carslaw et al. 2017; Farmer et al. 2019; Wang et al. 2020; Zhou et al. 2020b).

Although we know that photochemical reactions can occur indoors, we do not yet have enough information to reliably predict photochemical reaction rates under common indoor conditions, and to constrain the effects of photochemistry on indoor air composition. Knowledge from outdoor photochemical reactions, which have been widely studied, is very helpful to our understanding of indoor photochemistry, but indoor environments differ from outdoor environments in terms of photon fluxes and concentrations of photolabile analytes. Happily, research on indoor photochemistry is progressing rapidly on several fronts. Here we provide an overview of the current state of indoor photochemistry.

Important Gas Phase Photochemical Reactions Indoors

The photolysis of HONO to form OH (Eq. 10) is currently believed to be the most important photochemical source of indoor oxidants (Gligorovski and Weschler 2013; Gligorovski 2016; Gligorovski and Abbatt 2018; Young et al. 2019; Abbatt and Wang 2020). Nitrous acid has large absorption cross sections at wavelengths as long as 400 nm, and its photolysis quantum yield is 1 at all relevant wavelengths. This means that photons at wavelengths commonly present indoors (> 330 nm) can induce photolysis. This is similar to low-light environments outdoors (e.g., early morning and late evening) where HONO replaces O₃ as the dominant OH source, as discussed in section “[Outdoor Photochemistry](#).“ Hydroxyl radicals have been experimentally detected in sunlit rooms containing HONO (Gomez Alvarez et al. 2013), and OH has been predicted to form from HONO photolysis under a variety of light sources indoors including sunlight and indoor electric lights (Gandolfo et al. 2016; Kowal et al. 2017; Zhou et al. 2018, 2020a, 2020b). Particulate matter formation has been reported from HONO photolysis induced by fluorescent tubes (Wang et al. 2019). Other species such as formaldehyde (HCHO) and acetaldehyde (CH₃CHO) have been predicted to photolyze to form HO₂ under illumination from fluorescent tubes due to emission at ~ 318 nm, although this has not been experimentally verified

(Kowal et al. 2017). Nitrogen dioxide (NO_2) photolysis has been predicted to increase indoor O_3 levels under sunlit conditions (Kowal et al. 2017; Farmer et al. 2019). Photolysis has been suggested to be an important sink for nitrate radicals (NO_3), but calculations and experiments suggest that under common conditions in residential buildings, NO_3 steady-state concentrations will be negligible (Zhou et al. 2018; Arata et al. 2018; Young et al. 2019). Nitrate levels may be higher – and photochemistry an important sink – in non-residential buildings (Nøjgaard 2010). Nitrate steady-state concentrations are discussed in section “[Indoor Reactant Concentrations and Oxidant Steady-State Concentrations](#).”

While HONO, HCHO, and CH_3CHO are generally present indoors at fairly constant levels, some photolabile species have large temporal variability. The major class of compounds for which this is an issue is cleaning products. The use of chlorine bleach (NaOCl) can release photolabile species such as HOCl and Cl_2 into the air, which photolyze to produce OH and Cl radicals. Gas-phase products formed from the reaction of Cl_2 and HOCl with limonene, a common indoor VOC, formed high loadings of particulate matter under illumination by sunlight or a fluorescent tube (Wang et al. 2019). A combined measurement-model study reported high OH and HO_2 levels in a classroom following surface cleaning with a lemon-scented (i.e., limonene-containing) cleaner, and predicted that HO_2 was primarily formed by photolysis of volatile precursors emitted from the cleaning solution (Carslaw et al. 2017). Hydrogen peroxide (H_2O_2) emitted by H_2O_2 -based household cleaners has been predicted to photolyze under indoor sunlit conditions to form OH, although photolysis of ambient HONO is predicted to remain the major indoor OH source even during the use of H_2O_2 cleaners (Zhou et al. 2020b).

Cleaning in households and most commercial buildings is limited to the physical application of cleaning solutions to surfaces (e.g., mopping, spraying). In buildings where surface disinfection is extremely important, such as hospitals and food-processing plants, “no-touch devices” (NTDs) are increasingly used to decontaminate surfaces. These devices emit high concentrations of gas-phase disinfectants (or in some cases aerosolized disinfectant) into a sealed room or chamber. After emission, the disinfectant molecules settle on surfaces where they efficiently deactivate viruses and bacteria (e.g., ASHRAE; Davies et al. 2011). After some period of time (often ranging from 1 to 12 h), emission ceases and ventilation is resumed. People are allowed to enter the room after disinfectant levels have reached safe levels. Several disinfectants commonly used in NTDs (e.g., chlorine dioxide (OCIO), H_2O_2 , O_3) are photolabile. A modeling study predicted that the presence of photons from either room lights or sunlight during NTD use may greatly increase indoor oxidant levels (Wang et al. 2020). During OCIO fumigation, Cl radicals were predicted to reach peak levels greater than 2×10^8 molec cm^{-3} , and modeled O_3 (formed by reactions of photo-produced O atoms with O_2) reached peak levels of ~1500 ppm. This is 3 orders of magnitude larger than background O_3 levels, and 2 orders of magnitude larger than O_3 levels commonly used for fumigation. Under some conditions, predicted oxidant levels remained elevated after modeled fumigant levels decreased to safe levels. In the case of OCIO fumigation, Cl levels remained above 10^6 molec cm^{-3} after OCIO decreased to background levels (Wang et al.

2020). This means that people entering the room could be exposed to very high oxidant levels, as well as to oxidation products of species such as VOCs.

Ultraviolet light is sometimes used to disinfect indoor air and surfaces (e.g., ASHRAE). Germicidal UV disinfection often uses mercury lamps with emission centered at 254 nm. In some heating, ventilation, and air conditioning (HVAC) systems, UV-C lights are used to disinfect surfaces such as cooling coils and well pans, or to disinfect air as it passes by. Upper room or near-ceiling UV-C disinfection involves placing UV-C lamps facing the ceiling. UV-C portable room decontamination involves a bank of UV-C lights on wheels that is programmed to roll around an enclosed space. These are often used to disinfect surfaces in hospital rooms (e.g., ASHRAE). Additional uses of UV-C light such as handheld lights designed to disinfect small surfaces (e.g., door handles) and as components of portable air purifiers have gained popularity recently. Light at \sim 254 nm is very effective at deactivating bacteria and viruses. However, it can also photolyze a wide range of atmospheric species such as VOCs and small inorganic molecules, and exposure to UV-C light may cause skin and eye damage. The use of UV-C for HVAC and upper room disinfection is well-established and has clear benefits. As long as lightbulbs are purchased from reputable manufacturers (to ensure that only a narrow range of wavelengths is emitted) and installed properly (for example, with proper airflow), UV-C is a useful tool to improve IAQ and decontaminate surfaces, and unintended photochemical reactions should not affect the composition of indoor air apart from very near the light source. UV-C portable room decontamination is effective at decontaminating surfaces, and these units are not used when occupants are present, so air quality issues should be minimal (ASHRAE). On the other hand, UV-C in handheld units and in air purifiers is not necessarily effective at decontaminating air or surfaces, and the lack of regulation and standardization of these devices may lead to the formation of O₃ or other pollutants indoors (EPA 2018).

Factors Controlling Gas Phase Indoor Photochemistry

Photochemical reaction rates indoors can differ greatly from those outdoors due to differences in variables such as photon fluxes, analyte concentrations, and competing analyte sinks. Analyte concentrations and sinks are discussed in detail in other chapters. Here we will focus on photon fluxes. Indoor photon fluxes depend on the type of light source(s) present indoors, as wavelength-resolved emission profiles vary greatly between light sources. Common indoor light sources include sunlight entering buildings through windows and electric lights including light emitting diodes (LEDs), incandescents, halogens, compact fluorescent lights (CFL), and fluorescent tubes. While LED bulbs emit only within the visible spectrum, filtered indoor sunlight, incandescent light bulbs, and halogens all have substantial continuous emissions at wavelengths shorter than 400 nm (Kowal et al. 2017). Fluorescent lamps, including CFLs and fluorescent tubes, additionally feature strong discrete line emissions in the UV (Kowal et al. 2017;

Zhou et al. 2020a). Thus, the type of reactions – and their rates – that occur indoors will depend on the illumination source.

Solar Photon Flux

During the day, the dominant source of light indoors is sunlight entering the room through glass windows and/or doors. However, window glass acts as a filter, so the intensity and energy profile of sunlight indoors is altered from that outdoors. The optical properties of windows (due to factors such as composition, thickness, and coatings) and the presence of insect screens determine the transmission profile of sunlight (Hong Soo Lim and Kim 2010; Blocquet et al. 2018; Zhou et al. 2020a). Wavelength-resolved transmission varies greatly between individual windows; a recent comparison of UV transmittance of 77 windows and window glass samples suggested that J_{HONO} (and therefore OH_{ss}) could vary by up to a factor of 50 between individual windows (Zhou et al. 2020a). Despite the large variability between individual windows, transmittance profiles appear to be generally similar for windows in residential and nonresidential buildings (Zhou et al. 2020a), with the exception of windows coated with UV-reflecting films used in some energy-saving (“green”) buildings (Blocquet et al. 2018; Zhou et al. 2020a). Figure 4 shows average wavelength-resolved light transmittance, the distribution of total transmittance between 330 nm and 400 nm, and the distribution of cutoff wavelengths for windows and window glass samples reported by Zhou et al. (2020a). In general, most windows completely attenuate light at wavelengths shorter than 320 nm. Considering the overlap between the absorption band of photolabile molecules and window transmittance spectra, this suggests that O_3 will not photolyze from indoor sunlight, and that photolysis of HCHO will be very weak. If present at sufficiently high concentrations, other gas species such as H_2O_2 , NO_2 , NO_3 , HONO , Cl_2 , and HOCl could photolyze indoors under solar illumination and contribute to indoor oxidation chemistry in most buildings, regardless of window type.

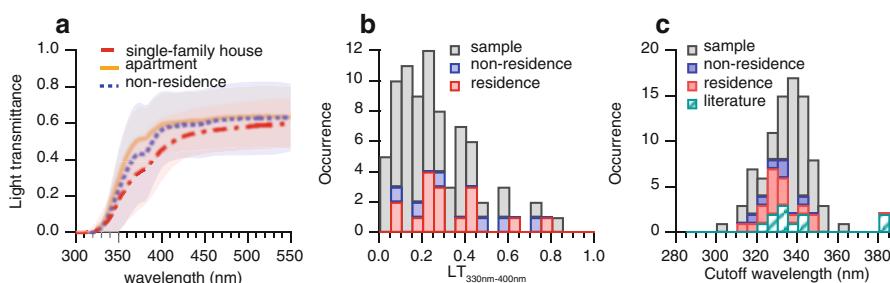

Fig. 4 (a) Average light transmittance spectra for windows in three types of buildings in the USA. Shaded bounds the standard deviations. (b) Histogram of average light transmittance (LT) between 330 nm and 400 nm for 77 windows or window glass samples. (c) Histogram of the cutoff wavelength of 88 windows or window glass samples. Window transmittance is a key factor in controlling indoor photon fluxes from sunlight, but a number of other variables are also important.

Direct vs. diffuse sunlight When a window is fully illuminated by direct sunlight, sunlight indoors will be direct within the volume described by the window shape and the angle of the incoming sunlight relative to the window, while all other light in the room will be diffuse. Conversely, when the window is not oriented toward the sun or it is overcast outdoors, light entering the building will be diffuse. Indoor diffuse sunlight has a similar spectral profile as indoor direct sunlight, but its intensity in the UV range is substantially lower and irradiances are less than 10 % of direct sunlight indoors (Gandolfo et al. 2016; Blocquet et al. 2018; Zhou et al. 2020a).

Distance from window Indoor UV solar fluxes from direct sunlight decrease linearly with increasing distance from the window (Hong Soo Lim and Kim 2010; Kowal et al. 2017; Blocquet et al. 2018; Zhou et al. 2020a). The rate of decrease depends primarily on SZA, with a weak distance dependences reported at low SZA (near noon), and strong dependences at high SZA (e.g., near sunrise and sunset) (Zhou et al. 2020a). Indoor diffuse solar UV irradiance decreases more rapidly with distance, with an exponential distance dependence (Zhou et al. 2020a).

Incident angle of sunlight on windows Most transmittance information about windows assumes an incident angle of 0° (i.e., a light path perpendicular to the plane of the window). However, sunlight rarely enters buildings at an incident angle of 0°. Model simulations and laboratory measurements have shown that window transmittance of UV light remains generally unchanged at incident angles lower than 20°–50°, but decreases rapidly at larger incident angles; at an incident angle of 80°, UV transmittance decreases to 13%–60% of the transmittance at normal incidence (Karlsson et al. 2001; Blocquet et al. 2018; Zhou et al. 2020a). The effect of solar incident angle on window transmittance could vary with individual windows, depending on many factors such as glass thickness, number of panes, infilling gas type, and composition.

Temporal variations Indoor UV fluxes can vary greatly over the course of the day, driven largely by the diurnal profile of outdoor solar irradiance and the orientation of the window relative to the sun (Zhou and Kahan 2021). Changes in outdoor cloud cover and the presence of objects blocking the sun outdoors or indoors can cause abrupt changes in indoor solar intensity. As a result, maximum indoor photon flux, and therefore indoor photolysis rates, will often occur at different times from that outdoors, and individual rooms within a building will have maximum photochemical reactivity at different times of the day (Zhou and Kahan 2021).

Photon Flux from Light Bulbs

Multiple factors affect the ability of electric light bulbs to initiate photochemistry indoors. As mentioned earlier, LEDs will not photolyze most indoor gas species, as

they do not emit at wavelengths shorter than 400 nm. Incandescent, halogen, and CFL bulbs emit UV radiation. As a result, these light sources could initiate photochemistry of many indoor species and may create elevated local oxidant and radical concentrations in the vicinity of the light source. However, emissions from these light sources depend strongly on the distance from the lamp. It has been estimated that they will generally only initiate photochemistry indoors within ~30 cm from the source (Kowal et al. 2017). Fluorescent tubes emit at wavelengths as short as 300 nm. Because they do not act as point sources, their intensity depends less strongly on distance than that of compact light bulbs. Photon fluxes from fluorescent tubes remain above 10% of original intensity within a distance of ~1.3 m from the source, which is sufficient intensity in the UV to initiate photochemistry (Kowal et al. 2017). In the absence of direct sunlight, fluorescent tubes may be important sources of photochemically generated radicals. They may also drive photolysis of analytes that only photolyze at wavelengths shorter than ~340 nm, such as formaldehyde (Kowal et al. 2017; Young et al. 2019). The effect of distance on photolysis is illustrated in Table 1, which provides a summary of the illumination conditions under which several indoor gas-phase species might be important photochemical radical precursors. While most light sources will initiate photochemistry near the source, only direct indoor sunlight and fluorescent tubes are expected to initiate radical production 1 m from the source.

Table 1 Common indoor light sources with their shortest emission wavelengths (λ_{\min}) and photolabile molecules that may be important radical precursors indoors under different lighting conditions as indicated by shaded cells

		λ_{\min} (nm)						
		Direct sunlight	Diffuse sunlight	Fluorescent tube	Halogen	Incandescent	CFL	LED
		325 – 350	325 – 350	300	300	300	360	400
O ₃	Near source							
HONO								
HCHO								
H ₂ O ₂ ^a								
NO ₂								
HOCl ^a								
Cl ₂ ^a								
ClNO ₂ ^a								
O ₃	1 m							
HONO								
HCHO								
H ₂ O ₂ ^a								
NO ₂								
HOCl ^a								
Cl ₂ ^a								
ClNO ₂ ^a								

^aPhotolysis of these analytes is too slow to generate significant radical levels at background concentrations. They are only expected to be important radical precursors when present at high concentrations, such as following the use of bleach (for HOCl, Cl₂, and ClNO₂) or H₂O₂-based (for H₂O₂) cleaners

Besides emission profiles, one of the largest factors affecting UV irradiance from electric lights is the presence of shades. Plastic shades covering fluorescent tubes were reported to attenuate UV light almost completely, effectively shutting off all indoor photolysis (Kowal et al. 2017). It is likely that different types of covers attenuate UV emission to different degrees, but this has not been investigated.

UV intensity increases with radiant power for halogens and CFLs (Kowal et al. 2017), and likely for other lamp types as well. Color temperature of light bulbs also affects UV emission intensities. Warmer color temperature has been shown to be associated with lower UV emissions for fluorescent tubes and CFLs; photochemical HO₂ production rates from HCHO photolysis is predicted to be 12 times greater under illumination from a warm white fluorescent tube (3000 K) than under illumination from a daylight tube (6500 K) (Zhou et al. 2020a).

Indoor Reactant Concentrations and Oxidant Steady-State Concentrations

Concentrations of gas-phase species are often very different indoors compared to outdoors. While many photolabile gas reactants have lower concentrations indoors, some – such as HONO – have much higher concentrations. Sources and sinks of reactants and photochemical products are also different indoors compared to outdoors. A major consideration is the air change rate (ACR). For a chemical reaction (photochemical or otherwise) to be important to the fate of a molecule, it must be rapid enough to compete with removal to the outdoors. Since ACRs can vary greatly, the contribution of indoor photochemistry to analyte fate and radical production will also vary. Measured indoor concentrations of a number of photochemical oxidant precursors are summarized in Young et al. (2019).

A major goal of constraining indoor photolysis rate constants is to better quantify indoor oxidant concentrations. Most indoor oxidants have large loss terms, so their concentrations are determined by the steady-state approximation (section “Concentration and Steady-State Concentration”). Equations 12 and 13 present simplified expressions for steady-state concentrations of OH ($[OH]_{ss}$) and NO₃ ($[NO_3]_{ss}$).

$$[OH]_{ss} = \frac{J_{HONO}[HONO] + k_{O3-alkene}[O_3][alkene]}{ACR + k_{OH-NO}[NO] + k_{OH-NO2}[NO_2]} \quad (12)$$

$$[NO_3]_{ss} = \frac{k_{O3-NO2}[O_3][NO_2]}{ACR + J_{NO3} + k_{NO3-VOC}[VOC] + k_{NO3-NO}[NO]} \quad (13)$$

J_{HONO} is the HONO photolysis rate constant. $k_{O3-alkene}$ is the second order rate constant for OH formation from ozone-alkene reactions. This calculation generally includes several alkene species thought to be important indoors. See for example Weschler and Shields (1996). k_{OH-NO} and k_{OH-NO2} are the second order rate constants of OH with NO and NO₂, respectively, k_{O3-NO2} is the second order rate constant for

O_3 with NO_2 , J_{NO_3} is the NO_3 photolysis rate constant, and k_{NO_3-VOC} and k_{NO_3-NO} are the second order rate constants for NO_3 with VOCs and NO. Other sources and sinks of OH and NO_3 exist indoors; Eqs. 12 and 13 include only the processes expected to dominate steady-state concentrations under common indoor conditions. These equations can be modified to include additional processes.

The primary known indoor OH sources are HONO photolysis and ozone-alkene reactions. In the dark, the ozone-alkene reaction becomes the only source term. Steady-state OH levels in the dark have been estimated to be on the order of 10^5 molecule cm^{-3} in the presence of 20 ppb O_3 and ~ 11 ppb alkenes (Weschler and Shields 1996). These O_3 levels are consistent with measurements in nonresidential buildings, but in residential buildings much lower O_3 levels (often less than 5 ppb) are commonly reported (Young et al. 2019). Steady-state OH levels in residences in the dark are therefore likely closer to 5×10^4 molecule cm^{-3} . Under direct sunlight, indoor $[OH]_{ss}$ can exceed 10^6 molecule cm^{-3} , making HONO photolysis the dominant OH source. We note that this applies primarily to areas illuminated by direct sunlight. Steady-state OH levels from HONO photolysis in volumes of air illuminated by diffuse sunlight have been predicted to range from $\sim 10^5$ – 10^6 molecule cm^{-3} within 1 m of an illuminated window (Zhou et al. 2020a). Illumination by fluorescent tubes can photolyze HONO, leading to predicted $[OH]_{ss}$ of $\sim 3 \times 10^6$ molecule cm^{-3} directly adjacent to the bulb, but this decreases by a factor of 10 at a distance of 1 m. Depending on the color temperature of the fluorescent tube and the presence of a shade, OH levels may be much lower (Zhou et al. 2020a).

Nitrate radical levels will likely be negligible in residences due to low source concentrations (especially O_3) and high sink concentrations (especially NO) (e.g., Young et al. 2019). Nitrate radical levels of up to ~ 20 pptv were reported in a conference room (Nøjgaard 2010); NO_3 levels may generally be higher in non-residential buildings, since larger ACR leads to higher O_3 concentrations and lower NO concentrations. Nitrate photolysis may therefore be important in some indoor locations.

Condensed Phase and Heterogeneous Indoor Photochemistry

One of the unique aspects of indoor environments is the high surface area to volume ratio (S/V). Many reactions can occur on these surfaces, as discussed in detail in Chap. VII.6. Here, we briefly discuss photochemical reactions on indoor surfaces and within condensed phases.

Few studies have directly investigated heterogeneous and condensed phase photochemical reactions indoors. These have primarily focused on two topics: photochemical formation of oxidants on painted surfaces, and photochemical transformations of pollutants associated with flame retardants in dust. These will be discussed below. Other photochemical processes may be important indoors, but there is a lack of literature on this. We discuss some potentially important areas of study in section “Future Directions.”

With respect to common indoor surfaces, photon fluxes within 1 cm of walls, floors, and metal counters were reported to be ~10% greater than those 1 m away due to reflections (Zhou et al. 2020a). While this enhancement will not significantly affect volume-averaged photon fluxes, it could increase heterogeneous photolysis rates as well as reaction rates very near the surfaces. If water or surface films are present, they may also alter the local photon flux through light scattering or competitive absorption (absorption of light by species other than the reactant of interest, also referred to as the inner filter effect).

Photochemical Formation of Oxidants on Painted Surfaces

Titanium dioxide (TiO_2) is a well-known catalyst both in manufactured materials and in the atmosphere (as a component of mineral dust). It has been incorporated into outdoor surfaces (e.g., buildings, roads) to reduce local NO_x and VOC levels, and to coatings applied to windows and high-touch surfaces to make the surfaces “self-cleaning.” Indoor paints containing TiO_2 nanoparticles are marketed as photocatalytic paints that remove NO_x and VOCs from the air; these have been shown to improve occupants’ assessment of indoor air quality under illuminated conditions (Kolarik and Toftum 2012). Indoor photocatalytic paints have been shown to reduce NO_2 levels under illumination at wavelengths relevant to indoors (e.g., Saltherammer and Fuhrmann 2007; Gandolfo et al. 2015, 2017), but gas-phase NO and HONO have been detected following NO_2 photocatalysis (Gandolfo et al. 2015, 2017). It has been suggested that HONO formed via NO_2 photocatalysis could double local OH levels (due to subsequent HONO photolysis) (Gandolfo et al. 2017), and high levels of gas-phase formaldehyde and acetaldehyde have been reported, likely caused by reactions of photocatalytically formed OH with components of the paint binder (Gandolfo et al. 2018).

Paint that is not designed with photocatalysis in mind may still contain TiO_2 as a brightener. Photocatalytic uptake of NO_2 to white interior paint resulting in gas-phase HONO formation has been reported (Bartolomei et al. 2014), and irradiation of nitrate-doped white house paint by artificial bulbs resulted in the production of gas-phase NO (Schwartz-Narbonne et al. 2019). The uptake of NO to surfaces coated with white, red, and green interior paints has also been investigated (Jones et al. 2020). Uptake was observed in the dark, and re-release of NO to the gas phase was observed under illumination by artificial bulbs. This behavior was attributed to physical uptake in the dark, including adsorption and diffusion through the paint, followed by photooxidation of NO to HONO, which photolyzes rapidly to produce NO as the primary gas-phase product (Jones et al. 2020). Interestingly, this result is different from observations when TiO_2 powder was the substrate, rather than paint containing TiO_2 . Under the same experimental conditions, the authors observed photo-enhanced NO uptake to TiO_2 resulting in the formation of gas-phase $\text{NO}_2 + \text{HONO}$ (NO_2 and HONO were not speciated in this study) (Jones et al. 2020).

Photochemistry in Dust and on Indoor Surface Films

Dust presents a complex indoor matrix. Its role in indoor chemistry (photochemical or otherwise) is poorly understood, but there is some evidence that photochemical reactions in dust could affect indoor exposure risks. An area of research that has received some interest in recent years is photochemical transformations of brominated flame retardants such as PBDEs (polybrominated diphenyl ethers). Several studies have reported that brominated flame retardants in dust collected from houses and vehicles undergo chemical transformation when exposed to outdoor sunlight or simulated sunlight (Stapleton and Dodder 2008; Lagalante et al. 2011). Smaller brominated species appear to be common products; photodegradation may therefore increase human exposure to smaller brominated congeners (Stapleton and Dodder 2008). We note that the studies performed to date have used illumination conditions relevant to outdoor environments; the kinetics and products of brominated flame retardants in dust irradiated at wavelengths relevant to indoor environments have not been reported.

Species other than brominated flame retardants may also undergo photochemical reactions in house dust. A number of aromatic pollutants such as polycyclic aromatic hydrocarbons (PAHs) have been detected in house dust (e.g., Salthammer 2020 and references therein). Many of these species absorb light at wavelengths relevant to indoor conditions, and photodegradation products can pose greater exposure risk than parent compounds. Azo dyes, which absorb visible light, have been identified as the dominant brominated species in house dust (Peng et al. 2016), and photosensitizers including benzophenones have been detected in house dust (Liu et al. 2016; Liu and Mabury 2019). Photodegradation of these photosensitizers has been reported in laboratory studies (Liu and Mabury 2019), although as with brominated flame retardants, these studies used illumination sources representative of outdoor sunlight.

Another complex matrix that may be important to indoor photochemistry is indoor surface films (Weschler and Nazaroff 2017; Lim and Abbatt 2020; Ault et al. 2020; Liu et al. 2020). Increased photo-enhanced conversion of NO₂ to HONO on glass was reported when surface films were present (Liu et al. 2020). At NO₂ levels of 50 ppb (relevant to levels reported during the use of gas stoves (Zhou et al. 2018; Liu et al. 2019b)), HONO levels in a 30 m³ kitchen were predicted to increase by ~4 ppb under illuminated conditions compared to in the dark. While photochemistry on indoor surface films remains largely unexplored, existing knowledge of photochemistry on outdoor surface films, or “urban grime,” may provide insight. Surface films can alter analyte partitioning coefficients; outdoors, surface films have been reported to enhance surface partitioning of a range of pollutants (e.g., Diamond et al. 2000; Wu et al. 2008). Surface films can also alter the chemical environment experienced by adsorbed analytes. For example, an indoor surface film coating an interior painted wall might shield analytes from TiO₂ in the paint and suppress photocatalytic reactions. Indoor surface films may alter local photon fluxes. Outdoor and indoor surface films have been reported to consist at least partially of particulate matter (as opposed to homogeneous films) (Grant et al. 2019; Kroptavich et al. 2020; Liu et al. 2020). This heterogeneous morphology could increase local photon fluxes via scattering (Kroptavich et al. 2020; Liu et al. 2020). Both indoor

and outdoor surface films have also recently been reported to absorb photons as long as 400 nm (Kroptavich et al. 2020; Liu et al. 2020). This overlaps with photons available indoors ($>\sim 330$ nm) and could reduce the number of photons available to analytes (competitive photon absorption). Absorbance of photons by surface films could also enable them to participate in photochemistry, for example, by forming reactive species or acting as photosensitizers (Kroptavich et al. 2020; Liu et al. 2020). In addition to the photo-enhanced NO₂ uptake reported on indoor surface films (Liu et al. 2020), photo-enhanced NO₂ uptake and nitric acid photolysis have been reported to occur more rapidly on outdoor surface films than on glass (Baergen and Donaldson 2016; Liu et al. 2019a). These enhancements have not been directly linked to absorptive properties of the surface films; further study is recommended.

Photochemistry in Indoor Aqueous Phases

Aqueous phase chemistry is not generally associated with indoor environments, but water is present indoors. Even at a relative humidity (RH) of 20%, which is on the low end of common indoor RHs, a thin film of water is present on most surfaces (Sumner et al. 2004). This water film appears to increase uptake of water-soluble organic compounds (WSOC) to indoor surfaces such as walls (Duncan et al. 2018). The effects of surficial water on heterogeneous indoor reactions have not been studied, but they may be important. For example, many atmospheric (outdoor) heterogeneous reactions show RH dependencies, and the uptake and reemission of NO to painted surfaces is different at 0 and 50% RH (Jones et al. 2020). Effects of water at surfaces could include competition for reactive surface sites, participation in photochemistry (e.g., photochemical heterogeneous transformation of NO₂ to HONO), or by affecting the speciation of analytes. As noted in section “[Different Considerations for Condensed Phase and Heterogeneous Photochemistry](#),” ionic species such as HNO₃ on indoor surfaces may be present in either the molecular form or the ionic form (NO₃⁻), or as a combination of both. Uptake of water vapor to indoor surface films has been reported to be substantially larger than to films of silicone vacuum grease used as a control at RHs relevant to indoor environments (Schwartz-Narbonne and Donaldson 2019). Those authors suggested that this uptake may be spatially heterogeneous; “pools” of water may exist at indoor surfaces.

Liquid water is present on “hidden” indoor surfaces such as condensate on cooling coils in HVAC systems. The composition of this water may be very different than that on visible indoor surfaces, and a wide range of photochemical reactions could occur when UV disinfection is used in HVAC systems.

Current Research

Measurements of Photochemically Generated Species

Photochemically generated species are often radicals. These are extremely difficult to detect and quantify. Photochemically produced OH and HO₂ indoors have been detected using laser-induced fluorescence – fluorescence assay through gas

expansion (LIF-FAGE) (Gomez Alvarez et al. 2013; Carslaw et al. 2017). While most researchers will not be able to detect radicals indoors, secondary products that are more easily detected may help to constrain the role of indoor photochemistry under different illumination conditions. For example, the formation of particulate matter was observed in an atmospheric chamber containing HONO when fluorescent lights were on, but not in the dark (Wang et al. 2019). This particle formation was attributed to secondary and tertiary reactions involving photochemically generated OH.

A number of field observations have reported results that may point to the influence of photochemistry. It is becoming increasingly common for studies to incorporate calculations of photolysis rate constants in manuscripts to provide some context about the possible role of photochemistry. These rate constants can be taken from the literature or calculated using photon fluxes that are either measured during the field campaign or reported in the literature, as discussed below.

Photon Flux Measurements and Predictions

Wavelength-resolved photon fluxes are key to predicting photochemical reaction kinetics, and, therefore, indoor air composition under illuminated conditions. Despite increasing attention to this area, there are no generalizable models of indoor UV photon fluxes. As discussed above, this is nontrivial, since photon fluxes depend strongly on location (both geographically and even within a single room) and time (both over the course of day and seasonally).

A range of techniques have been used to measure indoor photon fluxes. The gold standard for measuring outdoor photon fluxes is spectroradiometers that capture photons from 180 degrees. Some models combine two such instruments to capture a full 360°, and therefore true spherically integrated photon fluxes. Such radiometers have been used occasionally indoors (Gomez Alvarez et al. 2013; Gandolfo et al. 2016; Blocquet et al. 2018), but they are cost-prohibitive for most researchers and require significant training and calibration, so they are unlikely to be widely used for indoor measurements. Hand-held spectrometers are an attractive alternative, as they are easy to use and cost less than 10% of spectroradiometers that capture 180 or 360°. Their portability is another advantage; they can be rapidly moved throughout an indoor space to investigate the spatial distribution of photon fluxes, as demonstrated in Kowal et al. (2017), Blocquet et al. (2018), Zhou et al. (2020a), and Zhou et al. (2021). The main drawback of these instruments is that they collect photons from a limited range of angles. As discussed in section “[Different Considerations for Condensed Phase and Heterogeneous Photochemistry](#),” irradiance is related to photon flux by $\cos(\theta)$. So if all incoming light is unidirectional (e.g., collimated sunlight) and impinges directly on the detector surface, the irradiance measured by a handheld spectrometer should be roughly equal to total photon flux. However, if photons do not directly impinge on the detector surface, irradiance will need to be converted to photon flux. A more complicated scenario is when light is not unidirectional (e.g., a combination of direct, diffuse, and reflected light). In this case, photons that do not impinge directly on the surface will be undercounted. The

magnitude of the uncertainty in photon fluxes and predicted photolysis kinetics due to this undercounting has not been quantified, though some studies suggest that diffuse and scattered sunlight indoors will not significantly contribute to HONO photolysis (Gandolfo et al. 2016; Zhou et al. 2020a). If this observation is generalizable, accounting for the angle of incoming direct sunlight may be sufficient to quantify indoor UV photon fluxes using handheld spectrometers, but further characterization and validation of these devices for indoor use is suggested.

Another inexpensive option for indoor light measurements is photosynthetically active radiation (PAR) sensors, which provide total irradiance over a wavelength range (commonly 400–700 nm, although extended wavelength ranges of 340–1040 nm are available). These have been used to investigate spatial distributions of indoor photon fluxes (Blocquet et al. 2018). These are useful in conjunction with wavelength-resolved sensors, but are not well-suited for quantifying UV photon fluxes. The lack of wavelength resolution can also be an issue since analyte absorption cross sections and photolysis quantum yields can have strong wavelength dependences. Even with photon flux measurements that extend into the UV, the spectral dependence to that light can be extremely important. For analytes such as HONO, which absorb strongly throughout the UV, this is not an issue, but for analytes such as O₃, H₂O₂, and HCHO, which have strong wavelength dependences to either σ or Φ , knowing the wavelength dependence of F is crucial for predicting photolysis rate constants. Recent studies have provided comparisons of visible and UV light intensity indoors (Blocquet et al. 2018; Zhou et al. 2020a). If generalizable equations relating measured visible photon fluxes to UV photon fluxes indoors can be established, PAR sensors may become powerful tools for indoor photon flux measurements due to their portability and low cost. The issue of wavelength dependence mentioned above will still be a factor, however, so measurements with PAR sensors should be complemented by wavelength-resolved measurements whenever possible.

Models

Predictive models applied to indoor chemistry are discussed in detail in Chap. VII.10. Here, we focus on the way different models address indoor photochemical reactions. Box models use rate constants for sources and sinks to predict temporal evolutions of analyte concentrations under a range of atmospheric conditions. Commonly used for the study of reactions outdoors, box models designed specifically to study indoor chemistry have been developed. The INDCM (INdoor Detailed Chemistry Model) (Carslaw 2007) includes explicit chemical reactions for approximately 5000 chemical species. Photochemical rate constants are calculated using Eq. 3. Generally, a total, wavelength-independent photon flux of 2.3×10^{13} photons cm⁻² s⁻¹ is assumed between 300 and 400 nm. The INDCM can be modified to account for wavelength-resolved photon fluxes for specific

species by inputting values of J for each analyte. This feature has been used to calculate indoor radical levels under different lighting conditions (e.g., sunlight, fluorescent tubes) (Wang et al. 2020; Zhou et al. 2020b). The INteraction with Chemistry and Aerosols (INCA)-Indoor model (Mendez et al. 2015) serves a similar purpose as the INDCM. This model includes 1400 reactions and 640 VOCs, with some simplifications to reduce computation time. These simplifications make it a “semi-explicit” model, compared to the INDCM, which is an “explicit” model. Detailed comparisons of the two models are provided by the developers of the INCA-Indoor model (Mendez et al. 2015). Photolysis rate constants are calculated using literature values of σ and Φ , and photon fluxes are computed using the Total UltraViolet (TUV) model ((Madronich and Flocke 1999), described below) and attenuation factors for indoor light from Nazaroff and Cass (1986). INCA-Indoor has been used to investigate the importance of photon fluxes, ventilation rates, and cooking on indoor OH levels in the presence and absence of HONO (Mendez et al. 2015).

Box models are powerful predictive tools for indoor chemistry. A limitation of existing models is that they assume spatial homogeneity in terms of gas-phase composition. Sources and sinks of analytes can be spatially heterogeneous (e.g., due to emission from point source such as a gas stove). As discussed in section “[Factors Controlling Gas Phase Indoor Photochemistry](#),” indoor photon fluxes are often very spatially variable, so radical levels may differ by orders of magnitude in two locations within the same room, simply due to different lighting conditions. Computational flow dynamics (CFD) models have long been used to predict spatial distributions of analytes in various environments. A CFD model has recently been used to investigate the spatial distribution of radicals in a room due to photolysis of HONO generated from a gas stove (Won et al. 2019). This work reported that increased radical levels (compared to indoor background levels) were confined to directly sunlit volumes of air, but that oxidation products were distributed throughout the room. Figure 5 shows the predicted spatially resolved indoor OH levels in a room illuminated by sunlight entering the window from different angles, and Fig. 6 shows OH concentrations under illumination by various artificial light sources. This type of model is an important complement to indoor box models such as the INDCM and INCA-Indoor.

Finally, the TUV model bears mentioning, despite the fact that it is not designed for indoor chemistry (Madronich and Flocke 1999). This freely available and user-friendly model allows the calculation of irradiance and J values for more than one hundred common atmospheric gases under a variety of user-specified conditions (e.g., SZA, altitude, cloud, and aerosol prevalence). The TUV is widely used to calculate J values in models that describe outdoor chemistry (e.g., Gressent et al. 2016). It is already used in at least one indoor chemistry model (INCA-Indoor) (Mendez et al. 2015), and as further information about the relationship between outdoor and indoor solar photon fluxes emerges from studies such as those described in section “[Photon Flux Measurements and Predictions](#),” it will likely become an even more powerful tool for indoor chemistry research.

Conclusions and Future Directions

The study of indoor photochemistry has made rapid bounds in recent years, but it remains an area ripe for discovery. The most pressing issue is constraining the role of photochemistry on the composition of the air indoors. We know that photochemistry

can occur indoors, and that it can greatly increase local radical levels. But under what conditions will it influence average radical levels throughout an indoor space? Can local regions of increased radical levels affect air quality? And what role does photochemistry on indoor surfaces play in determining indoor air composition? Given the rapid progress in indoor photochemistry research in recent years, we may have at least partial answers to these questions before long.

Indoor photochemistry can cause large spatial variability in indoor air composition within a single room due to the spatial heterogeneity of indoor photon fluxes, as illustrated in Figs. 5 and 6 (Won et al. 2019). The geometry of illuminated areas can change dramatically over the course of a day. This spatial and temporal variability makes it difficult to constrain the effects of photochemistry on indoor air composition. Box models, CFD models, and even architectural models that predict the spatial distribution of visible light intensity within a building will be powerful tools to predict the impact of photochemistry in indoor spaces. These models could be used for sensitivity tests on air composition under different lighting conditions, and to visualize the spatial distribution of analytes throughout an indoor environment over time. Existing box models could be modified to include multiple compartments with different photon fluxes, such as directly illuminated air volumes, diffusely illuminated air volumes, dark air volumes, and near-surface volumes. This practice is employed in many (outdoor) atmospheric models to account for different regions of the atmosphere that have different conditions (e.g., emissions, light availability, etc.). For example, GEOS-Chem, one of the most widely used chemical transport models, includes numerous air compartments to represent conditions in different surface locations and altitudes (Bey et al. 2001). The Multimedia Urban Model (MUM) is a box model that includes compartments for air, water, soil, and urban surfaces coated with urban grime (Diamond et al. 2001). The creators of MUM recently developed the Activity-Based Indoor Chemical Assessment Model (ABICAM) to investigate human exposure to semi-volatile pollutants such as phthalates (Kvasnicka et al. 2020). This model includes nine compartments relevant to indoor environments, including air, human skin lipids, various types of flooring, and indoor surface films, but does not include explicit chemical reactions. Employing these types of approaches to explicit and semi-explicit indoor box models could improve our ability to predict and understand photochemistry indoors.

Characterizing the temporal and spatial variations of indoor UV photon fluxes will also further our understanding of indoor photochemistry. Existing knowledge of indoor light intensity, including spatial and temporal variations, is almost entirely based on visible light. As discussed above, UV photon fluxes often do not scale linearly with visible photon fluxes indoors. Further measurements will lead to more robust relationships between UV photon fluxes and variables that are more widely measured such as visible photon fluxes indoors and outdoors. This information can be used to estimate the impact of photochemistry on measured indoor air composition and can provide models with useful input and parameterization information.

With improved characterization of inexpensive sensors such as handheld spectrometers and PARS, widespread indoor photon flux measurements may become possible. Measuring photon fluxes concurrently with photolabile species will be especially important to constraining the role of photochemistry on indoor air

composition. This has been done in a few experiments (e.g., Gomez Alvarez et al. 2013; Bartolomei et al. 2014; Blocquet et al. 2018; Zhou et al. 2018; Farmer et al. 2019; Liu et al. 2019b; Schwartz-Narbonne et al. 2019; Gandolfo et al. 2020; Mattila et al. 2020), but it is not currently standard practice.

Surface chemistry is likely very important indoors, but indoor surface photochemistry remains largely unexplored. Early results suggest that various surfaces such as painted walls (with and without photocatalytic coatings) and indoor surface films may contribute to NO_x cycling via photocatalyzed NO and NO₂ uptake (e.g., Bartolomei et al. 2014; Gandolfo et al. 2015; Schwartz-Narbonne et al. 2019; Jones et al. 2020; Liu et al. 2020), and photodegradation in dust may affect the exposure risks posed by aromatic pollutants (e.g., Stapleton and Dodder 2008; Lagalante et al. 2011; Liu and Mabury 2019). The field of indoor surface photochemistry is currently wide open.

Photochemistry initiated by UV disinfection may become increasingly important as this technology becomes more widely used. Unwanted photochemical reactions of UV-C disinfection are minimal when properly installed and operated. However, “off-label” uses of UV disinfection may adversely affect indoor air quality via photochemistry. The magnitude of these effects has not been widely studied. Further, UV disinfection in HVAC systems could also affect air composition, but photochemistry within HVAC systems remains unexplored.

Indoor photochemistry is a relatively new research field. The importance of indoor photochemistry to indoor air composition and air quality remains unclear, and will certainly depend greatly on local illumination conditions. Although many large questions remain, research in this area is progressing rapidly, and great strides toward answering key questions will likely be made in coming years.

Abstract

Indoor surfaces support a wide variety of chemical transformations that can both reduce and increase the concentrations of indoor air pollutants. Building materials, furnishings, and occupants contribute to the large amount and very wide variety of exposed surfaces. Chemistry can take place directly at the interface between surface and air or in films that coat these surfaces. Important transformations include ozone reactions with surface oils like triglycerides and squalene; these lower indoor air concentrations of ozone but consequently increase the air concentrations of aldehydes, acids, and particles. Nitrogen oxides can react at surfaces to generate nitrous acid which then participates in the conversion of amines to potentially carcinogenic nitrosamines. Hydrolysis of phthalate plasticizers increases levels of odorous chemicals and acid-base chemistry controls the rate of some reactions while serving to store vast amounts of otherwise volatile molecules in surface reservoirs. To better understand and control indoor

chemistry, research is now seeking a more fundamental understanding of the composition and morphology of surfaces as well as the mechanisms and rates of surface chemistry that degrade our indoor air quality.

Keywords

Surfaces · Furnishings · Condensed phase · Oxidation · Chemistry

Introduction

To alter the concentration of airborne pollutants in buildings, sources and sinks must be present and active. As a generalization, sources increase concentrations, while sinks reduce concentrations. Indoor surfaces act as both source and sink. Primary emissions of volatile organic compounds are a well-known source. But chemical transformations taking place on surfaces also play an important role. These transformations can consume some chemicals like ozone. This is why indoor ozone concentrations are so much lower than outdoor concentrations in most buildings. Reactions also generate products. If sufficiently volatile, these products can be released from surfaces, thereby making that surface a source of newly generated chemicals that increases their concentrations in indoor air. Indoor surfaces are particularly important because so much surface area is accessible to indoor air. These surfaces, including building surfaces, furnishings, and people, have an outsized impact on the composition of indoor air relative to chemistry taking place in air alone.

Until very recently, research into indoor surface chemistry has been sporadic, empirical, and often occurring as a secondary outcome of other research. Now more focused, fundamental, and theoretical studies are underway that are revealing in much greater detail the processes taking place on indoor surfaces. This chapter surveys the past several decades of indoor surface chemistry studies with a focus on several specific chemicals and phenomena. This chapter begins with a description of indoor surfaces and important characteristics of those surfaces that influence the chemistry. Then specific chemical species, classes, or phenomena are discussed including the chemistry of ozone, nitrogen oxides, chlorine, as well as acid-base chemistry and hydrolysis.

Surfaces and Chemical Transformations

Indoor Surfaces

The materials that make up our indoor environments include structural components, furnishings, decorations, and other functional elements. For this chapter, surfaces are broadly defined as the areas of materials or their coatings that are exposed to indoor air. This includes the two-dimensional interface between air and the solid/condensed

material and perhaps some three-dimensional thickness of material beneath that interface. It is at these surfaces where deposition, emission, and much indoor chemistry take place, thereby altering indoor air quality. The surface area available in buildings is quite large relative to the volume, providing ample area for chemical processes to occur. The geometrically projected (i.e., ignoring surface roughness and porosity) surface area to volume ratio has been estimated to range from $<2\text{ m}^2/\text{m}^3$ for empty rooms to $>5\text{ m}^2/\text{m}^3$ for small rooms with furnishings (Hodgson et al. 2005; Manuja et al. 2019). Surface area increases considerably when roughness and porosity are considered (Gall et al. 2015). For reactive gases depositing on surfaces at transport limited rates, removal rates can be greater than $20/\text{h}$ which is much higher than the rate of air change ($\sim 1/\text{h}$) in most buildings.

Indoor surfaces can influence chemistry from molecular scales to whole building scales (Shiraiwa et al. 2019). Indoor surfaces are neither clean nor smooth. For example, paint may look uniform and smooth to eye but is rough and porous under microscopy. Each building surface can be characterized by the substrate composition (e.g., polyvinylchloride of some flooring materials), the morphology (including surface area and porosity), and soiling (e.g., accumulation of particles and low-volatility chemicals).

The underlying compositions of building materials and furnishings (aka substrates) can be complex and wide-ranging. However, they can be generalized to two broad categories: organic and inorganic substances. Organic substances are often polymers such as cellulose (wood and paper), polyvinyl chloride (PVC flooring), latex (paint), and polyethylene terephthalate and nylon (carpet fibers). Low-volatility non-polymeric organic compounds that comprise building materials include plasticizers such as phthalates. Mineral-based inorganic substances include gypsum wallboard, concrete, and glass. Most building materials are composites of these categories. For example, drywall is usually composed of gypsum mixed with organic binders and faced with paper adhered by an organic adhesive. Ault et al. (2020) developed a list of building surfaces that include most of these substrate materials for laboratory studies of molecular scale indoor chemistry.

It has become well established that all indoor surfaces (absent recent cleaning) are coated with a film of “grime” that develops over time (Liu et al. 2003; Wallace et al. 2004, 2017; Weschler and Nazaroff 2017; Eichler et al. 2019; Or et al. 2020; Lim and Abbatt 2020). The coating is composed of deposited particles as well as organic and inorganic compounds including water. This film is thought to be responsible for much of observations of surface-related chemical phenomena including chemical partitioning and reactive deposition. Surface cleaning removes or alters the coating, changing surface characteristics (such as pH) and reducing exposure to accumulated chemicals.

Water present on surfaces can alter surface properties such as polarity, act as necessary reactants for some chemical transformations, or provide an aqueous environment for absorption and acid-based chemistry. Nazaroff and Weschler (2020) assign water indoors to three overlapping domains: bulk (such as present in a glass of water), sorbed, and surface films. For indoor chemistry, sorbed water and surface films of water are of most interest as they are more accessible (lower

transport barriers) and spread across large areas, including the internal pores of materials. For a typical residence, Nazaroff and Weschler predict sorbed or condensed water to be present on the order of tens of liters, thereby providing ample volume for sorption of polar molecules. At 50% RH, water covers most surfaces with the equivalent of approximately a monolayer, ensuring that chemistry can proceed if that reaction requires the presence of a water molecule.

Relative to indoor air, surfaces can enhance chemistry in buildings by increasing the time that the chemicals are retained indoors or altering the chemical environment. Processes such as adsorption and absorption allow chemicals to accumulate on surfaces and increase their average time spent indoors before being removed by ventilation or surface cleaning (Weschler and Nazaroff 2008). Even slow reactions may become relevant if this time increases from the timescale of air exchange (~ 1 h) to months or years (Morrison 2008). Surfaces may also alter the rates and mechanisms of reactions relative to the gas phase; for example, acid-catalyzed reactions may be slow or negligible in the gas phase but proceed at meaningful rates in an acidic surface film.

Ozone Initiated Chemistry

Indoor ozone concentrations are usually much lower than outdoor concentrations when no indoor ozone sources are present (Weschler 2000). This is because ozone that enters the building by ventilation or infiltration is consumed by reactions taking place in the gas phase and on surfaces. Early studies quantified this removal in buildings by reporting an ozone decay rate coefficient (a.k.a. loss-rate coefficient), k_{loss} (1/h), or a deposition velocity, v_d (m/h). The decay rate coefficient accounts for all losses, excluding outdoor-to-indoor air exchange, without ascribing the removal to a particular mechanism or sink. For a well-mixed building volume at steady state with no indoor ozone source,

$$k_{loss} = \lambda \left(\frac{C_{out}}{C_{in}} - 1 \right) \quad (1)$$

where λ is the air exchange rate (defined as the outdoor air flow rate entering the volume, Q , divided by the volume, V), C_{out} is the outdoor concentration of ozone, and C_{in} is the indoor concentration of ozone. The deposition velocity, on the other hand, is defined by assuming that ozone is lost primarily by deposition and conversion to other products on indoor surfaces. The deposition area is usually defined as the geometrically projected area, A . For a well-mixed building volume at steady state with no indoor ozone source or appreciable gas phase reactive loss of ozone,

$$v_d = \lambda \left(\frac{V}{A} \right) \left(\frac{C_{out}}{C_{in}} - 1 \right) \quad (2)$$

Both parameters can be influenced by air mixing. Higher air velocities and more intense turbulence both reduce the fluid-mechanical resistance for transport of gases from bulk room air to surfaces. Loss rate coefficients and deposition velocities have been reported for buildings and specific materials and reviewed in several sources (Nazaroff et al. 1993; Grontoft and Raychaudhuri 2004; Lamble et al. 2011). In general, clean smooth glassy or polymer-coated surfaces tend to have lower ozone deposition velocities. Surfaces that are rough and have a higher surface area, are porous and/or fleecy (e.g., textiles), are soiled or coated with reactive oils (e.g., skin), and masonry surfaces tend to have high ozone deposition velocities. These observations are consistent with ozone converting to other products on surface sites. When surface reactivity and uptake is relatively low, the conversion rate and therefore the deposition velocity increase with increasing surface area (both geometrically projected and internal) and a greater density of reactive sites (Morrison and Nazaroff 2002a; Gall et al. 2015). For a higher reactivity surface, the deposition velocity approaches an asymptote that is more influenced by air mixing (Cano-Ruiz et al. 1993). At the building level, the deposition velocities (and ozone decay rates) fall within a much narrower range than observed for individual materials; Nazaroff et al. (1993) speculated that this may be due to a net “averaging” of indoor surface reactivity and uniform soiling of accessible indoor surfaces.

In the absence of strong emissions of volatile alkenes, the primary loss mechanism for ozone on indoor surfaces is its reaction with carbon-carbon double bonds present in organic compounds present on the surfaces. There are many sources of double-bonded chemicals that replenish surfaces including natural fats, skin lipids, and terpenes (Deming and Ziemann 2020). A generalized reaction scheme is shown in Fig. 1.

Ozone reacts at a double-bond, forming a primary ozonide (not shown). This then can form a number of higher and lower volatility products. Carbonyl compounds are the most volatile, followed by acids, then other species such as secondary ozonides, peroxy species, and oligomer. Evidence for this chemistry became apparent in early studies that observed an increase in the air concentrations of aldehydes when indoor materials were exposed to ozone (Weschler et al. 1992b; Reiss et al. 1995; Morrison and Nazaroff 2002b). From building materials and indoor surfaces, nonanal and other aldehydes are dominant products of this reaction (Wisthaler et al. 2005; Wang and Morrison 2006, 2010; Nicolas et al. 2007; Weschler et al. 2007; Coleman et al. 2008; Lamble et al. 2011; Abbass et al. 2017). This points to the presence of one or more forms of an oleate and other unsaturated fatty acids or esters which are common in natural oils, but are also present in manufactured products.

The reactions of ozone with occupants, their clothing, and their skin lipids have been shown to be an important loss mechanism for ozone and contributor to products in indoor air (Wisthaler et al. 2005; Weschler et al. 2007; Coleman et al. 2008; Pandrangi and Morrison 2008; Wisthaler and Weschler 2010). The chemistry behind these observations has now been well documented (Thornberry and Abbatt 2003; Wisthaler and Weschler 2010; Zhou et al. 2016a, b). Squalene comprises about 12–15% (Nicolaides 1974) of skin oil but is responsible for approximately half of the

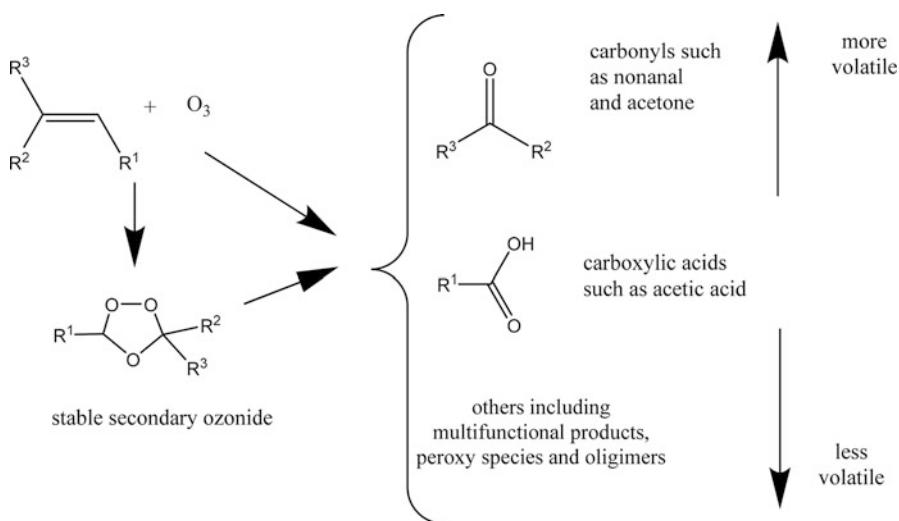

Fig. 1 Ozone reacts with a double bond present in a generalized chemical present on an indoor surface. This reaction results in multiple products that may remain on the surface or volatilize, increasing the air concentration

double bonds present (Pandangi and Morrison 2008). The other double bonds are distributed mostly among unsaturated fatty acids, their esters, ceramides, and cholesterol. Major unique products of ozone reactions with fresh skin lipids include 6-methyl-2-heptenone and geranyl acetone; these can volatilize and further participate in gas-phase chemistry. These ozone-human signature chemicals have been observed in occupied aircraft studies (Wisthaler et al. 2005; Weschler et al. 2007), classrooms and offices (Wisthaler and Weschler 2010; Liu et al. 2016; Tang et al. 2016), museums (Pagonis et al. 2019), a football stadium (Veres et al. 2013), a theater (Stönnér et al. 2018), and in controlled chamber experiments with people and or their clothing (Coleman et al. 2008; Rai et al. 2014; Salvador et al. 2019). Yields of products from skin lipid ozonolysis (the yield is defined as the molar generation rate of a product divided by the molar consumption rate of ozone) vary among individuals and may be influenced by the presence of exogenous fats (Morrison et al. 2020). The rates of product emissions from surfaces can be influenced by the intermediate formation of ozonides that store volatile products until the ozone decomposes (Zhou et al. 2019). Humidity can in turn influence the stability of ozonides and the proportion of products generated (Zhou et al. 2016a, 2019; Arata et al. 2019).

Consumer products contain fragrance compounds, terpenes, and terpene alcohols that contain double bonds that react with ozone. Most research has focused on the gas-phase chemistry of these species; despite their volatility, however, they do react with ozone when sorbed onto surfaces. Singer et al. (2006) observed enhanced ozone uptake at surfaces after they had been exposed to the gas-phase emissions of a fragranced air freshener. Ham and Wells (2011) observed products consistent with

oxidation of terpineol in pine-oil scented cleaners that had been applied to vinyl flooring and exposed to ozone. Adsorbed dihydromyrcenol, α -pinene, limonene, and terpineol have been observed to increase ozone uptake to model (glass/PVC) and real (paint) surfaces (Ham and Wells 2008; Springs and Morrison 2008; Shu and Morrison 2011, 2012).

Airborne particles can also be generated when ozone reacts with indoor surfaces and their coatings. Production of particles has been observed upon ozone exposure of building materials, filters, and terpenes adsorbed to solid substrates (Aoki and Tanabe 2007; Beko et al. 2007; Rai et al. 2013; Waring and Siegel 2013; Wang and Waring 2014; Avery et al. 2019).

Ozone reaction kinetics, and possibly mechanisms, may be enhanced relative to gas-phase reactions. For example, reactions of ozone with condensed compounds can occur much faster than that in the gas phase (e.g., benzo[a]pyrene (Kwamena et al. 2004)). Several terpene compounds have been shown to react with ozone at much higher rates when sorbed to glass, polyvinylchloride, and painted surfaces (Springs and Morrison 2008; Shu and Morrison 2011, 2012). In some cases, the surface rate of ozone with adsorbed terpenes exceeds that in air, due to the high indoor surface area and enhanced reaction rates. Ham and Wells (2008, 2011) observed that yields of ozone-terpene reaction products are altered on surfaces, relative to gas-phase reactions. Stable secondary ozonides may also form in condensed materials and their stability influenced by the presence of water (Zhou et al. 2019). Humidity also influences the products formed when ozone reacts with squalene (Zhou et al. 2016a; Arata et al. 2019).

Nitrogen Oxides

Nitrogen oxides (NO , NO_2 , NO_3 , HNO_3 , HONO , N_2O_5) present in buildings are derived from outdoor air, indoor chemistry, or indoor combustion sources. With the exception of NO , most nitrogen oxides measurably partition, deposit, or react at indoor surfaces. The spatially averaged deposition velocity of NO_2 to indoor surfaces has been estimated to range between 0.007 and 0.4 m/h (Nazaroff et al. 1993), which is smaller than for ozone. Wainman et al. (2001) measured an NO_2 deposition velocity of ~1.2 m/h for carpet. There are few field measurements of gas phase NO_3 (Nøjgaard 2010), but as yet no field deposition measurements. Given the similarity to ozone (chemical rates and mechanisms), it is anticipated that NO_3 would deposit at rates similar to ozone. Deposition of HONO and HNO_3 is thought to be driven by gas-surface partitioning and acid-base chemistry (Weschler et al. 1992a; Wainman et al. 2001; Wang et al. 2020).

Important to the indoor chemistry of nitrogen oxides is the formation of nitrous acid (HONO) on indoor surfaces. Pitts et al. (1985) showed that NO_2 will deposit on indoor surfaces and form volatile HONO . With an indoor source of NO_2 (gas burners), the resulting concentration of HONO in indoor air can exceed outdoor concentrations (Pitts et al. 1989; Febo and Perrino 1991; Spicer et al. 1993). As long as some water is available, most surfaces can support this chemistry. For surfaces

that have been conditioned, that is, accumulated a thin layer of organic and inorganic “grime,” the chemistry is insensitive to the composition of the underlying surface, including Teflon and glass (Pitts et al. 1984). The reaction is first order in water and NO₂ (Finlayson-Pitts et al. 2003). The primary mechanism appears to be reactive dissolution into adsorbed water (Spicer et al. 1993), which also produces HNO₃ and other species (Finlayson-Pitts et al. 2003).

Light can also influence the surface chemistry of nitrogen oxides. Several studies have shown enhanced HONO production upon exposing indoor-relevant surfaces to light including paint, lacquer, glass-coated with cleaners, etc. Gómez Alvarez et al. (2014) suggested that coatings of organic compounds on indoor surfaces may act as photo-sensitizers, similar to photo-induced production of HONO on humic acid (Stemmler et al. 2007). Illuminated by some light sources, NO₂ uptake and release of HONO can be enhanced on white paint (Bartolomei et al. 2014) and on photo-catalytic paint (Gandolfo et al. 2015, 2017). Painted surfaces, coated with a nitrate salt, released NO, NO₂, and HONO when exposed to some light sources (Schwartz-Narbonne et al. 2019).

Surfaces and surface films may act as long-lasting reservoirs for HONO. Febo and Perrino (1991) and Spicer et al. (1993) observed that HONO concentrations will rebound quickly after airing out the building. This suggested that indoor surfaces have stored a substantial amount of HONO that can be released over an extended period of time. Wainman et al. (2001) observed similar behavior in a laboratory reactor and showed that this storage effect was enhanced at higher humidity and for materials with higher surface areas. They proposed that HONO will reversibly dissociate to the nitrite ion (NO₂⁻) in surface water (see also section “[Acid Base Chemistry](#)”); the accumulated NO₂⁻ acts as a future HONO source. For a pH above the pK_a of HONO (3.3), NO₂⁻ can dominate, and over time, a large nitrite reservoir can develop. This behavior has been observed in the HOMECHM experiments (Farmer et al. 2019; Wang et al. 2020) and successfully modeled (Collins et al. 2018a). During HOMECHM, bleaching surfaces resulted in a lowering of indoor HONO concentrations which was ascribed to an increase in surface film pH (shifting aqueous equilibrium from HONO to NO₂⁻) and formation of ClONO.

Nitrogen oxides also participate in organic chemistry on surfaces. Upon observing HONO formation indoors, Pitts suggested that this could lead to the *in vivo* formation of carcinogenic nitrosamines. *Ex vivo* formation was later observed by Sleiman et al. in their “third-hand smoke” studies (Sleiman et al. 2010, 2011). They observed conversion of nicotine (sorbed to a cellulose substrate) to multiple nitrosamines in a flow reactor. They also measured nicotine-specific nitrosamines on surfaces of a household, a vehicle, and skin, all of which were frequently exposed to cigarette smoke. Upon application of chlorine bleach, ClNO₂ is observed and ascribed to the chemistry of hypochlorous acid with NO₂⁻ (Wong et al. 2017; Mattila et al. 2020a, b).

Chlorine Chemistry

Chlorine-based chemical oxidants have been used for cleaning and disinfection indoors for over a century but have only recently been the subject of indoor chemistry investigations. To investigate the impact of gaseous oxidants, used for biological decontamination in buildings, Corsi and associates exposed a variety of surface materials to a high concentration of chlorine dioxide (ClO_2); they observed substantial uptake of ClO_2 to wallboard, carpet, paper, textiles, and dust with initial deposition velocities similar to ozone (Hubbard et al. 2009). The uptake rate decayed relatively rapidly, but the exposure concentrations were very high, hinting at chemistry that oxidized reactive sites on these materials. They also observed persistent emissions of carbonyl compounds as well as chlorinated by-products, long after exposure (Corsi et al. 2006).

Chlorine bleach can also contribute to chemical transformations on surfaces; several groups have observed increased emissions of nitrogen and chlorine containing compounds (Wong et al. 2017; Mattila et al. 2020a, b). Mattila et al. (2020a) proposed that amide absorption into the aqueous bleach film resulted in their observed emissions of isocyanates. The reaction of HOCl with amino acids was thought to be responsible for observed production of cyanogen chloride. Other compounds generated, presumably by reactions taking place in this aqueous surface film, included isocyanic acid, chloramines, trichloromethane, and tetrachloroethylene. In a modeling analysis of HOMEChem data, they ascribed observed emissions of chloramines and nitrilechloride to reactions of HOCl with ammonia and the nitrite ion (Mattila et al. 2020b). In a study of bleach cleaning of athletic gym equipment, Finewax et al. (2020) observed formation of chloraldimines, presumably from the reaction of HOCl with amino acids.

Acid-Base Chemistry

Many indoor chemicals have acid-base functionality such that reaction kinetics, mechanisms, and their affinity for a surface or a condensed phase may be influenced by the effective acidity of that phase. Examples include ammonia, organic bases (e.g., nicotine), inorganic acids (CO_2 , HNO_3 , HONO , HOCl), and organic acids (formic acid, acetic acid). What follows is a brief overview that draws greatly on the critical review of this chemistry by Nazaroff and Weschler (2020), which focused on chemicals that have a tendency to donate or accept protons (Brønsted-Lowry acids and bases).

Some gaseous acids and bases such as CO_2 , formic acid, acetic acid, NH_3 , and nicotine can be present at concentrations that meaningfully influence the pH of condensed water. Nazaroff and Weschler (2020) estimate that, in the absence of other ions, condensed water will be at a near-neutral pH (7) when in equilibrium with typical indoor concentrations of CO_2 and NH_3 . When considering other acids and bases, they tentatively conclude that condensed water indoors will be slightly acidic ($\text{pH} < 7$).

Where an aqueous phase is present and accessible, volatile acids and bases will partition to that phase. At equilibrium, the concentration of an acid in the aqueous phase is given by Henry's law:

$$[\text{HA}] = k_H P_{\text{HA}} \quad (3)$$

where, k_H is the Henry's law constant and P_{HA} is the partial pressure of the acid in air. The acid can dissociate

and the equilibrium constant for dissociation is given by

$$K_a = \frac{[\text{H}^+][\text{A}^-]}{[\text{HA}]} \quad (5)$$

By Eq. (3), at a given gas phase partial pressure, $[\text{HA}]$ is a constant and uninfluenced by pH. However, by Eq. (5), the concentration of the conjugate base, $[\text{A}^-]$, is strongly influenced by pH. Where $\text{pH} > \text{pK}_a$, $[\text{A}^-] > [\text{HA}]$; conversely, where $\text{pH} < \text{pK}_a$, $[\text{A}^-] < [\text{HA}]$. Similar expressions can be developed for bases that accept protons. The total molar concentration of the acid and its conjugate base ($[\text{HA}] + [\text{A}^-]$) is therefore dependent on both gas-aqueous partitioning and pH. A high pH will drive more of the acid to $[\text{A}^-]$, thereby increasing the total of "A" in solution.

Since $[\text{H}^+]$ can vary over many orders of magnitude, exposed condensed water can act as a large aqueous reservoir of volatile acids and bases. During real-time measurements of airborne organics in a residence, Duncan et al. (2019) observed that the concentrations of formic and acetic acids decreased dramatically when the central air conditioner (AC) was running, then increased when it was turned off. This behavior suggested that the acids absorbed into water that condensed on the AC coils. During an intensive investigation of chemistry in a test house (a.k.a. HOMEChem), Wang et al. (2020) observed a drop in the gas phase concentration of acids (including HONO, formic acid, and butyric acid) when windows were opened, but then a rapid rise upon window closure. They ascribe some of this behavior to the presence of partitioning to, and subsequent acid dissociation within, surface water reservoirs.

In more acidic solutions, the dominant form of amines can be the protonated conjugate acid (i.e., (amine) H^+); therefore one would also expect condensed water to act as an important reservoir. For example, the pK_a of the conjugate acid of nicotine is 7.9. In an aqueous solution with a pH lower than 7.9, the protonated form of nicotine will be dominant. The capacity of the surface water reservoir will increase by approximately a factor of 10 for each unit decrease in pH; therefore at a neutral pH, the aqueous concentration of protonated nicotine is expected to be ~10 times that of the neutral form. Other amines such as aniline have much lower pK_a values for their conjugate acid, suggesting that surface reservoirs will be less influential. Reservoir behavior for amines has been observed for particles (DeCarlo et al. 2018;

Collins et al. 2018b), building surfaces (Ongwandee et al. 2005; Ongwandee and Morrison 2008), people, skin, and textiles (Morrison et al. 2015; Sheu et al. 2020). A review of amines, amino acids, and other nitrogen-containing compounds found indoors can be found in Nazaroff and Weschler (2020).

The form of the species can also influence reaction mechanisms and kinetics. For example, the form of nitrite determines how rapidly it will become oxidized by ozone. HONO that has partitioned to an aqueous phase will dissociate,

Ozone can also partition to the solution. Ozone reacts rapidly with NO_2^- to form NO_3^- but much more slowly with HONO (Liu et al. 2001). Therefore, little reaction will take place if HONO dominates in the solution (when the $\text{pH} < \text{p}k_a$). Since the $\text{p}k_a$ for HONO is 3.16, NO_2^- will dominate in a neutral solution and the conversion to nitrate will proceed readily in the presence of ozone. Similarly, most of the chlorine chemistry discussed in the previous section is initiated by HOCl and less so by the conjugate base OCl^- . The neutral form of nicotine is known to react on surfaces with ozone (Destaillass et al. 2006; Petrick et al. 2010). However, Nazaroff and Weschler (2020) note that, “Given that pH plays a significant role in nicotine’s sorption to surfaces, related issue for future study is how the reactivity of non-ionized nicotine compares to that of monoprotonated nicotine.”

Acids are also responsible for material corrosion. This is particularly of concern for cultural artifacts. For example, acetic acid aggressively corrodes artifacts made of lead, nitric acid corrodes copper, and so forth. In efforts to slow the degradation of artwork and other artifacts, museums often focus on acid controls.

Hydrolysis

Hydrolysis, literally to “split apart with water,” cleaves parent molecules to form smaller, possibly more volatile and polar products. As the name implies, hydrolysis is influenced by the presence of water, but also by pH and temperature. In general, hydrolysis is slow under typical indoor conditions and neutral pH. However, given the large amount of building materials, and therefore large total mass of esters present, volatile reaction product emissions can be significant. Emissions resulting from hydrolysis do not decay over time in the same way as emissions of residual volatile species present in newly manufactured materials. Because the esters are degraded slowly but relatively continuously, meaningful emissions of degradation products can occur during the entire useful life of the product.

Esters that are prone to hydrolysis in indoor environments include some plasticizers and flame retardants. Protonated water can catalyze the hydrolysis of esters to form a carboxylic acid and an alcohol. Under basic conditions, the hydroxyl ion acts as a reactant that cleaves the ester to from a carboxylate salt and an alcohol.

For example, odor nuisance products such as 2-ethyl hexanol and 2-butanol are observed where plasticized materials are present, including polyvinylchloride (PVC)

flooring (Uhde and Salthammer 2007). Hydrolysis products of organophosphate esters have also been observed (Salthammer et al. 2003). Tri(chloropropyl)phosphate (TCP) hydrolyzes to odorous 2-chloro-1-propanol and tri(dichloropropyl)phosphate (TCCP) hydrolyzes to 1,3-dichloro-2-propanol, a suspected carcinogen. Urea-formaldehyde resins, which have been used as adhesives and as insulation foam, hydrolyze forming volatile formaldehyde.

Conclusion

There are many reactions taking place on indoor surfaces. These reactions alter surfaces, remove some chemicals from indoor air while generating volatile products that increase indoor concentrations of mainly oxidized compounds like aldehydes, alcohols, and acids. Our current understanding of this chemistry has improved substantially in the last decade but remains somewhat fragmentary. Key questions still to be addressed include

- What is the composition of real surface films?
- How are surface films organized? Are they homogenous or are they characterized by semi-separate aqueous and organic phases, as is sometimes observed in aerosols.
- What is the water content of indoor surfaces, where is it, and how much of the water can support aqueous solution chemistry?
- What is the pH of water on indoor surfaces, and how should this be defined?
- How important are substrate characteristics in controlling surface chemistry?
- What are the morphologies of indoor surfaces? Which surfaces and how much of that surface area is relevant to indoor chemistry and air quality.

These questions and more are the subject of contemporary indoor chemistry research; expect to see actionable answers soon.

Abstract

Humans are a major source of indoor chemicals. Breath and skin Occupant-Related Chemical Transformations in emissions meaningfully contribute to the chemical composition of indoor air. Volatile organic compounds emitted by humans originate from endogenous sources (metabolic processes), and from exogenous sources (environmental exposure, diet, and personal care products). They can result from microbial activity and can lead to odor nuisance and decreased perceived air quality. The emitted compounds can undergo chemical transformations, such as ozone-initiated reactions, which produce a range of new compounds. The reactions of ozone with squalene and other constituents of skin oils have been shown to significantly alter the composition of indoor air and alter its OH reactivity. Dermal emissions may impact perceived air quality more than emissions via breath. The understanding of the effects of various environmental and personal factors (e.g., temperature, humidity, personal hygiene, diet, clothing, personal care products, age, sex, emotional state) on human emissions, their chemical transformations, and their consequences for indoor air quality, comfort, and health is limited. This chapter presents an overview of occupant emissions and the indoor air chemistry associated with them. Personal and environmental factors that may influence human emissions are discussed. Emerging research on the potential impacts of occupant emissions on perceived indoor air quality and human health is presented, and key research questions to advance our understanding of occupant-related indoor air chemistry are highlighted.

Human emissions · Breath · Skin · Chemical transformations · Organic compounds

Introduction

In the past, building materials and furnishing were considered the dominant sources of indoor air pollution. As emissions from building products were gradually reduced, the role of human emissions in indoor air quality began to be increasingly recognized. The presence of people indoors leads to chemical changes occurring both in the gas phase and on indoor surfaces. It has been reported that the compounds associated with the presence of humans contribute up to 40% of the measured daytime volatile organic compounds (VOC) concentration in indoor spaces (Liu et al. 2016). In another study, human-emitted VOCs were the dominant source during occupied periods in a well-ventilated classroom (57%) together with ventilation supply air, which was the second most important source of pollution (35%) (Tang et al. 2016). Indoor non-occupant emissions constituted 8% of the pollutant

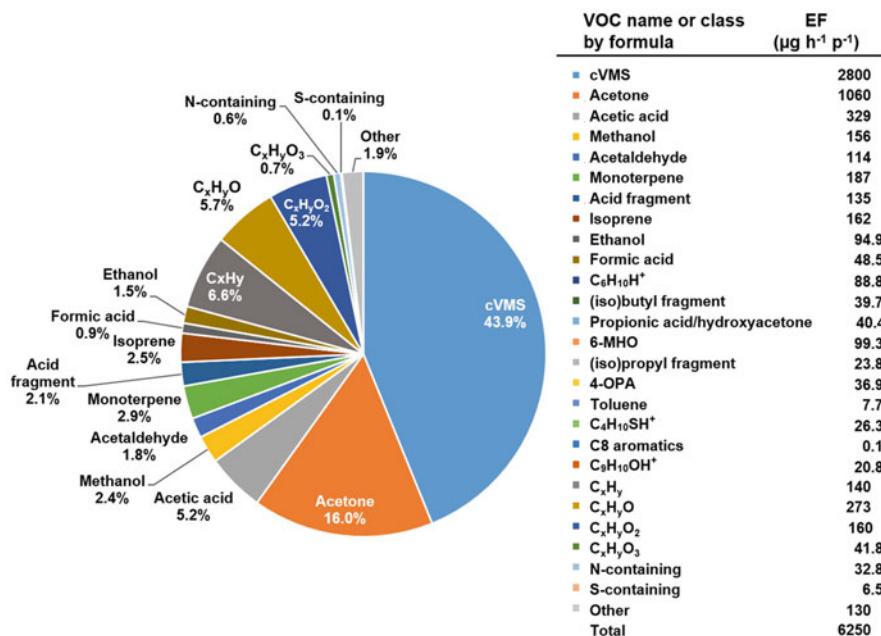

Fig. 1 Human occupant emission factors (EF, $\mu\text{g p}^{-1} \text{ h}^{-1}$) for chemical species shown as relative contributions to the total. (Reprinted with permission from “Tang et al. (2016) Volatile organic compound emissions from humans indoors. Environ Sci Technol 50:12686–12694,” Copyright (2016) American Chemical Society)

mass. The total occupant-associated VOC emission factor was 6.3 mg h^{-1} per person (Fig. 1).

Hundreds of VOCs are released from the human body via the breath, skin, and intestinal gases. These compounds are derived from endogenous metabolic processes in and on the human body and from exogenous sources such as airborne VOCs from environmental or occupational exposures, foods, and personal care products (Kwak and Preti 2011). They can influence indoor air chemistry and indoor air quality. Odorous compounds released in breath have been linked to oral microbial populations (Phillips et al. 1999). Body odor is also associated with decomposition of sweat and sebum by microbial activity (Barzantny et al. 2012; James et al. 2013).

The sebaceous glands across the body secrete oils to lubricate the skin. Many of the constituents of skin oils contain unsaturated carbon bonds that can undergo chemical transformations in the presence of ozone to produce a suite of new compounds in indoor air. These primary and secondary reactions can occur in the presence of humans and in previously occupied environments where skin oils are transferred to surfaces via touching and shedding of skin flakes. Ozonolysis of skin lipids is a sink for ozone present in indoor air, and an important source of indoor VOCs (Weschler et al. 2007; Wisthaler and Weschler 2010).

Changes in environmental conditions can influence the composition and rate of occupant emissions and their chemical transformations. Temperature affects occupant metabolic rates, sebum secretion and volatilization, and the rate of oxidation reactions. Higher temperatures have been shown to lead to higher emission rates of ammonia (Li et al. 2020). Humidity can affect emission of chemicals, their sorption to surfaces as well as chemical reactions occurring in indoor air. Ventilation can act as a source of reactive species such as ozone, reduce the concentration of reaction products, and reduce the time available for gas-phase reactions. Increasing ventilation rates will reduce the impact of occupants on indoor chemistry. Human occupancy itself can also reduce the air concentrations of some volatile and semi-volatile organic compounds (Weschler 2016).

Human skin and breath emissions vary over the course of day, as the influencing environmental and personal factors change. For example, emissions of siloxanes from personal care products depend on the time of their application. The factors that have been shown to influence breath and skin emissions include personal hygiene, diet, clothing, personal care products, but also health status (Shirasu and Touhara 2011), age and sex (Lechner et al. 2006; Sun et al. 2017), genetics (Preti and Leyden 2010), ethnicity (Prokop-Prigge et al. 2016), menstrual cycle (Sukul et al. 2018), and emotional state (Stönner et al. 2018; Williams et al. 2016).

Recent studies have highlighted the potential for human emissions to affect cognitive performance and cause neurobehavioral symptoms in people (Maddalena et al. 2015; Zhang et al. 2017a). Some ozonolysis products are suspected respiratory irritants (Jarvis et al. 2005; Anderson et al. 2007) or have previously been shown to cause skin irritation (Chiba et al. 2000). This chapter describes in greater detail the sources and underlying factors of human emissions as well as their chemical transformations and potential effects.

Table 1 Summary of major organic pollutants associated with various human body parts (Tsushima et al. 2018a, b)

Body part	Organic pollutant
Whole-body	acetic acid, acetone, butanol, butyric acid, ethanol, isoprene, lactic acid, methanol, pyruvic acid, toluene
Exhaled	acetone, dimethyl sulfide, ethanol, hydrogen sulfide, isoprene, methanol, methyl mercaptan
Dermally emitted:	
• Skin except head	• decanal, geranyl acetone, heptanal, nonanal, octanal, 6-MHO
• Axillae	• androstanol, androstenone, isovaleric acid, 3-hydroxy-3-methylhexanoic acid, 3-methyl-2-hexenoic acid
• Scalp	• γ -decalactone
• Hand, forearm	• decanal, dimethyl hexanedioate, geranyl acetone, lilia, nonanal, octanoic acid, pentadecane, phenol, 2-furancarboxaldehyde, 2-furanmethanol, 6-MHO
• Feet	• hydrogen sulfide, isovaleric acid, methanethiol
Intestines	ammonia, hydrogen sulfide

Primary Emissions from Humans

Humans emit many different organic compounds originating from breath, skin (sweat and sebaceous secretions), and intestinal gases (flatulence). Some studies measured whole-body bioeffluents, others analyzed bioeffluents emitted through breathing (exhaled bioeffluents) and skin (dermally emitted bioeffluents), or bioeffluents from a particular part of the body, for example, the oral cavity, axillae, scalp, hand, feet, and intestines (Table 1).

Compounds identified in breath and skin emissions mainly include hydrocarbons, acids, esters, alcohols, alkanes, aldehydes, ketones, furans, ethers, sulfur, nitrogen and halogen-containing compounds, and chlorinated biphenyls (de Lacy Costello et al. 2014; Filipiak et al. 2012). Five major compounds that represent 99% of bowel gas are nitrogen, oxygen, carbon dioxide (CO_2), hydrogen, and methane, though these do not necessarily lead to odor nuisance. However, intestinal gas contains a wide variety of gases in low concentrations, such as ammonia, hydrogen sulfide, volatile amino acids, short chain fatty acids, as well as other sulfur and nitrogen-containing compounds, organic acids, aldehydes, and ketones (Sato et al. 2001; Garner et al. 2007). Some of these compounds have a low odor threshold.

Breath Emissions

Human breath is a significant source of pollutants emitted indoors. Exhaled breath is largely composed of nitrogen, oxygen, carbon dioxide, water, and inert gases, in addition to trace components (VOCs). Breath VOCs are typically present at ppb (or lower) concentrations and include compounds that are generated in the body and taken up from the environment. Endogenous VOCs are primarily blood-borne compounds released via the lungs. Exogenous VOCs include compounds inhaled from the external environment or absorbed through the skin, in addition to compounds produced following oral ingestion of food, and those derived from smoking cigarettes (Shirasu and Touhara 2011).

Typical exhaled gases (e.g., CO_2 , nitrogen) are found in percent concentrations. Concentrations of exhaled CO_2 are used as an indicator of occupancy/human bioeffluents and ventilation in buildings. Constituents present at ppb concentrations or less include VOCs associated with normal metabolism (e.g., ethanol, isoprene, propanone, methanethiol, and nitric oxide (NO)), products of oxidative stress (e.g., propanedial, pentane) and compounds associated with food and environmental or occupational exposure (e.g., trichloromethane, benzene) (Wallace 1987). Breath analysis can be applied to examine exposure to environmental agents, from those in the typical home to domestic exposures influenced by nearby businesses and exposures outside the home (Vereb et al. 2011).

The chemical composition of human breath differs from person to person. Phillips et al. (1999) examined the breath VOCs of 50 humans and identified about 3500 compounds. About half of these had a positive alveolar gradient (abundance in breath minus abundance in air; positive when *in vivo* synthesis is greater than

clearance). However, the total number of breath VOCs did not vary between individuals widely within a fairly narrow range (a breath sample contained on average about 200 VOCs). Despite the large total number of different VOCs observed, there was a small group of 27 VOCs present in all subjects. These were suggested to be products of common metabolic processes.

Human breath contains the following compounds attributable to metabolic processes and observed at levels averaging 10 ppb or above: acetaldehyde, acetone, butanone, 1-butene, dimethyl sulfide, ethanol, ethyl acetate, ethylene, furan, hexanal, isoprene, isopropanol, methanol, methyl ethyl ketone, pentane, 1-pentene, and n-propanol. Compounds present from 1 to 10 ppb in breath include 1,1,1-trichloroethane, butane, cis- and trans-2-butene, 2-hexene, n-butyl alcohol, isobutyl alcohol, capryl alcohol, methyl isobutyl ketone, butyl acetate, ethyl benzene, indene, pentanal, and propanal (Fenske and Paulson 1999).

Sun et al. (2017) measured higher concentrations of endogenous VOCs than of exogenous VOCs in exhaled breath. However, the composition of exhaled breath can be considerably influenced by exposure to pollution, indoor-air contaminants, and particularly by smoking (Filipiak et al. 2012). Compounds that can be found in indoor and outdoor air as well as in exhaled breath include benzene, toluene, ethylbenzene, xylene (o-xylene, p-xylene), aldehydes (building materials and furnishing), benzaldehyde (combustion), acrolein, methacrolein, oleic acid and linoleic acids, propanal, and alcohols such as isomers of propanol (solvents, disinfectants). Constituents of consumer products such as siloxanes, d-limonene, camphor, plasticizers, Texanol, and its related compounds are also among the environmental volatiles possibly present in breath. Branched-chain alkanes in breath have been attributed to exposure in industrial and/or automotive emissions (Kwak and Preti 2011). In the study by Filipiak et al. (2012), most aldehydes had higher concentrations in indoor air than breath, indicating exogenous origin. More than 80 organic compounds were found to be significantly related to smoking, the largest group comprising unsaturated hydrocarbons (29 dienes, 27 alkenes, and 3 alkynes). VOCs with high concentrations in expired air were also often found in indoor air samples. Table 2 summarizes the major compounds reported in exhaled breath and compared to levels in indoor air.

Skin Emissions

Skin emissions are primarily derived from skin gland secretions and the resident microflora. Gland distribution at the skin surface varies across the body, and this is partially reflected in the regional diversity of emissions from the skin. The eccrine glands are distributed across the body and secrete water and electrolytes. The apocrine glands are localized in a few regions of the skin, and they secrete sweat (a fluid containing water, lipids, proteins, and odor precursors). Apocrine glands contribute greatly to VOC emissions produced from the underarm (axillary) regions. Malodor generation on axillary skin has been associated with biotransformation of

Table 2 Summary of major compounds measured in exhaled breath and indoor air by Filipiak et al. (2012)

Species	Compounds	Notes (corresponding to compounds)
Ketones	• 2-butanone, 2-pentanone	• both higher in breath than indoor air
Aldehydes	• acetaldehyde, propanal, acrolein, crotonaldehyde	• higher in exhaled breath of smokers • all aldehydes mostly significantly lower in breath than in indoor air; correlation found for few aldehydes
	• butanal, formaldehyde	
Alcohols	• methanol	• same in exhaled breath as indoor air
	• ethanol	• 3 times higher in breath than indoor air
Acids and esters	• acetic acid, propionic acid	• higher in breath than indoor air; higher in active smokers
	• methyl acetate	• found in nearly all breath samples, not in all indoor air samples (endogenous), higher level in expired than inspired air
Furans	• furfural	• lower in breath of smokers
	• furan; 2-methylfuran; 3-methylfuran; 2,4-dimethylfuran; 2,5-dimethylfuran; 2-ethyl-5-methylfuran; 2,3,5-trimethylfuran	• significant differences between smoker and non-smoker groups • all except 3-methylfuran and 2-ethyl-5-methylfuran found at nearly the same level in exhaled breath and indoor air samples for non-smokers • over fivefold higher level in breath of smokers compared to non-smokers
Aromatics	• toluene, benzene, ethyl benzene, phenol, styrene, o-xylene, p-xylene	• mostly higher in smokers; apart from toluene, all measured aromatics show lower levels in exhaled breath than indoor air for non-smokers
Saturated hydrocarbons	• propane, n-butane, n-pentane, n-hexane, n-decane, n-undecane, n-octane, n-nonane, n-heptane	• n-butane higher in inspired air than expired (in non-smokers) • n-heptane in breath only when also in inspired air; n-decane similar in air and breath • no straight-chained saturated hydrocarbons significantly related to smoking habit • methylated saturated hydrocarbons: significant difference between smokers and non-smokers
Unsaturated hydrocarbons	• alkenes: propene, 3-octene	• in breath similar to indoor air; higher in smokers
	• dienes	• almost never found in non-smokers (except pentadiene and hexadiene)
	• alkynes: propyne, 2-butyne, 1-butene-3-yne	• all especially in smokers, only propyne measured in non-smokers

(continued)

Table 2 (continued)

Species	Compounds	Notes (corresponding to compounds)
Sulfur compounds	• methanethiol	• same in breath and inspired air
	• dimethyl sulfide (DMS), methyl propyl sulfide, allyl methyl sulfide, 3-methylthiophene, 1-(methylthio)-1-propene	• elevated in breath compared to air; allyl methyl sulfide: only in breath, not air
	• ethyl methyl sulfide	• higher in smokers
Nitrogen-containing compounds	• acetonitrile; N,N-dimethylformamide; N,N-diethylformamide	• especially smokers' breath
	• 2-cyano-1-propene; N-methylpyrrole	• higher for smokers
	• (dimethylamino)-acetonitrile	• lower for smokers
	• 4-Propanenitrile	• lower for smokers, similar in breath as in indoor air

gland secretions into volatile odorous molecules by members of the skin microflora (James et al. 2013).

Emissions from the axillary region also contribute to poor indoor air quality. These compounds include androstenol, androstenone (ketone with a urine-like smell), and isovaleric acid (Bird and Gower 1981; Leyden et al. 1981). Axillary sweat contains marker compounds characteristic of individuals and sex. Among these, the following have been measured on skin: 2-phenylethanol, 1-tridecanol, undecanal, lilial, diphenyl ether (all characteristic of individual), pentadecanoic acid, hexadecanoic acid and heptadecanoic acid, methylhexadecanoic acid, and docosane (all characteristic of sex) (Bernier et al. 2000; Penn et al. 2007). C6 to C11 straight-chain, branched and unsaturated acids (3-methyl-2-hexenoic acid, 3-hydroxy-3-methylhexanoic acid) were the odorous compounds released in this region. Terminaly unsaturated acids, the 2-methyl-C6 to -C10 acids and the 4-ethyl-C5 to -C11 acids were also reported to be odor contributors (Zeng et al. 1996; Natsch et al. 2006). Short-chain fatty acid emissions from feet have been linked to foot odor (Marshall et al. 1988). VOCs emanating from palms include aromatics, amides, amines, halides, sulfides, and sulfonyls (Bernier et al. 1999, 2000). Alkenes and carboxylic acids have been shown to be emitted from the forearm (Ostrovskaya et al. 2001), 2-furancarboxaldehyde, 2-furanmethanol, decanal, dimethyl hexanedioate, nonanal, phenol, and carboxylic acid-methyl esters from hands (Curran et al. 2010; Prada et al. 2011). Tsushima et al. (2018b) contain a detailed summary of this literature.

The sebaceous glands secrete oils (sebum) to lubricate the skin. Sebum is composed of squalene, triglycerides, wax esters, and free fatty acids. The sebaceous glands are distributed across the body (except the palms of hands and soles of feet) and are found in the highest density on the face and scalp. Many of the constituents of skin oils contain unsaturated carbon bonds (C=C) which react readily with ozone. Humans are recognized as a sink for ozone in the environment and the reaction of

skin oil components with ozone produces a wide range of secondary products (further discussed in the “[Occupant-Related Chemical Transformations](#)” section below).

Skin oils contain pyroglutamic acid, a natural moisturizing substance present at 1% level in the human epidermis. Pyroglutamic acid does not react with gas-phase ozone, since it does not contain a carbon–carbon double bond. This chemical may be a convenient tracer of human skin oil contamination in indoor environments, given its relatively high abundance and low reactivity with the ozone (Zhou et al. 2016a). Liu et al. (2017) measured 12 carboxylic acids that correlated with CO₂ concentrations in a classroom. These have possible associations with human sources. A major component of human perspiration is lactic acid, although it is also used in commercial health-care products. Other human-related acids include saturated monoacids (octanoic, nonanoic, decanoic, undecanoic, and dodecanoic acid), unsaturated monoacids (hexenoic and nonenoic acid), and a carbonyl acid (pyruvic acid).

Emission rates of some VOC, for example, 1-butanol, acetic acid and 1,3-pentadiene, can be higher from skin than from breath. Aldehydes (e.g., 3-methyl-2-butenal, benzaldehyde, octanal, nonanal, and decanal) and ketones (e.g., 6-methyl-5-en-2-one) can be emitted through skin at volume fractions in the low parts per billion range (Ruzsanyi et al. 2012). 2-Ethylhexanol is often reported among skin emissions, but its endogenous nature is in fact not supported in the literature (Dormont et al. 2013). Ammonia is emitted from occupants’ skin as well as breath. Ammonia originates from the bacterial breakdown of proteins. It is transported by blood to the liver. Ammonia remaining in the blood can diffuse through the skin, in sweat, or breath. Li et al. (2020) summarized the limited research on ammonia emission rates from humans. Most research has focused on breath ammonia concentrations, despite the fact that dermal emissions tend to be substantially higher than breath emissions. Furukawa et al. (2017) measured dermal emissions from 13 locations on five males and five females. Higher ammonia emissions were measured on the feet, back, and lumbar region, and lower emissions were measured on upper arms, buttocks, thighs, and lower legs. This ranking roughly corresponds to the density of sweat glands at the different body locations. Li et al. (2020) isolated dermally emitted ammonia from exhaled ammonia in a climate chamber experiment, in which volunteers sat in one chamber with breathing masks covering their mouth and nose and exhaled into an adjacent twin chamber. Breath emission rates were estimated to be 15 to 50 times smaller than dermal emission rates. The difference between dermal-only and whole-body emission rates was relatively small, indicating the dominance of human ammonia emissions via the dermal route. Moreover, emission rates significantly increase with larger area of exposed (uncovered) skin area.

Occupant-Related Chemical Transformations

Human emissions can undergo chemical transformation and result in a suite of new compounds in indoor air. These reactions occur in the presence of humans and in previously occupied spaces, as skin oils are transferred to surfaces through touching,

and via skin flakes (squames) and their constituents shed by people in a process called desquamation contribute to the organic films on indoor surfaces. Squames contain skin surface lipids, and the squalene content of skin flakes is ~1% by weight (Clark and Shirley 1973). Settled dust in occupied settings also contains skin flakes and their associated skin oils, resulting in reactions between dust and ozone.

Approximately 80–90% (by weight) of skin oils contain long-chain acyl groups as free fatty acids, glycerides, wax esters, cholesterol esters, ceramides, and other species. Squalene is responsible for most of the remaining fraction (~10%) of skin surface lipids. The primary reaction is that between squalene and ozone. Reactions of unsaturated fatty acids are also meaningful. Squalene is responsible for about 50% of the unsaturated carbon bonds in skin surface lipids. Ozonolysis of skin lipids is an important source of indoor VOCs and a sink for indoor ozone. Acetone, geranyl acetone, 6-methyl-5-heptene-2-one (6-MHO; from squalene), aldehydes, especially decanal, undecanal, dodecanal, nonanal, hexanal, and octanal (from unsaturated fatty acids) are the major products (Weschler et al. 2007; Wisthaler and Weschler 2010; Fischer et al. 2013).

Other squalene-ozone reaction products include 4-oxopentanal, hydroxyacetone (also product of oxidation of isoprene), 1-hydroxy-6-methyl-5-hepten-1-one, as well as a number of secondary products, including, 5-hydroxy-4-oxopentanal (5-OH-4-OPA), 1,4-butanedial (succinic dialdehyde), 4-methyl-8-oxo-4-nonenal (4-MON), 4-methyl-4-octene-1,8-dial (4-MOD), 4-oxopentanoic acid, and 4-oxobutanoic acid. Additional less volatile products of ozonation of squalene include a number of long-chained polyunsaturated aldehydes and carboxylic acids, such as C27-pentaenal, C22-tetraenal, C17-trienal, C27-pentaenoic acid, C22-tetraenoic acid, and C17-trienoic acid, that remain bound to the surfaces as skin, hair, clothing, and particles. Ozone's reaction with squalene on these surfaces is fast and ozone removal is transport limited.

Some products (e.g., acetone, geranyl acetone, 6-MHO, and 4-oxopentanal (4-OPA)) are produced through secondary surface reactions between ozone and some of the primary squalene reaction products. For example, squalene and its ozonolysis product geranyl acetone are the major precursors for acetone and 6-MHO. 4-OPA is the major secondary reaction products as 6-MHO and geranyl acetone further react with ozone. Acetone can also be formed by 2-methyl-2-docosene (Yang et al. 2016). Salvador et al. (2019) applied a series of mass balance models to account for formation and removal of geranyl acetone, 6-MHO, and 4-OPA measured in a climate chamber with simulated occupancy using soiled t-shirts at two air change rates (1 h^{-1} and 3 h^{-1}) and two initial ozone mixing ratios (30 ppb and 60 ppb). Geranyl acetone was entirely produced in surface reactions on the t-shirts and removed almost equally by ventilation and further reaction with ozone. About 70% of gas-phase 6-MHO was produced in surface reactions on the t-shirts, the remainder in secondary gas-phase reactions of ozone with geranyl acetone. It was primarily removed by ventilation; reaction with ozone was responsible for about a third of its removal. 4-OPA was formed primarily on the surfaces of the shirts; gas-phase reactions of ozone with geranyl acetone and 6-MHO accounted

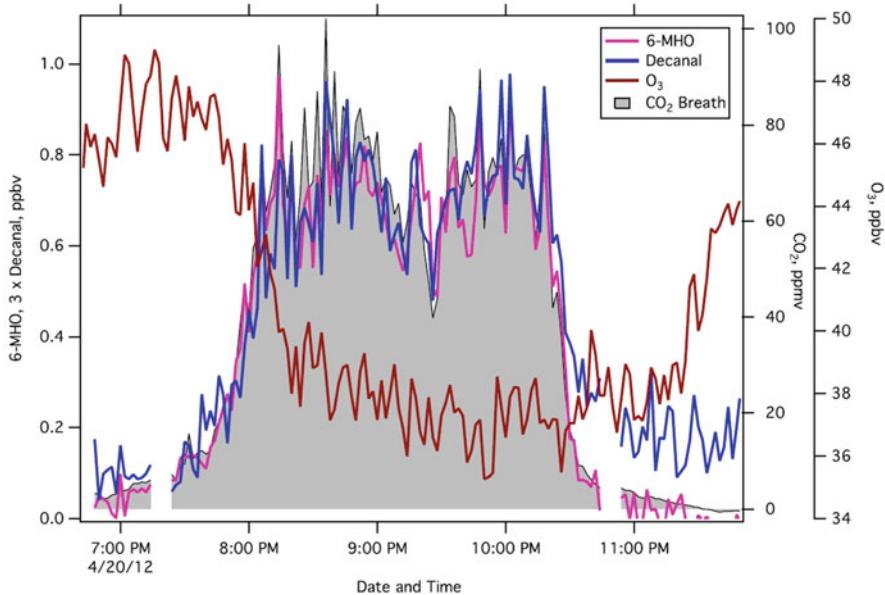

Fig. 2 Ozone (red), decanal (blue), and 6-MHO (green) measured in an occupied football stadium. The grey shading shows the CO₂ mixing ratios above background levels. (Reprinted from “Veres et al. (2013) Anthropogenic sources of VOC in a football stadium: Assessing human emissions in the atmosphere, Atmos Environ 77:1052–1059,” Copyright (2013), with permission from Elsevier)

for ~30% and ~10%, respectively. 4-OPA does not react with ozone and was therefore removed entirely by ventilation.

The removal of ozone and the production of ozonolysis reaction products such as 6-MHO and decanal has been observed upon the arrival of spectators in a football stadium (Fig. 2) (Veres et al. 2013). Ozonolysis reactions with VOCs and skin oils, combined with increased surface deposition during a match, were suggested to be responsible for titrating observed ozone by approximately 20%. A clear relationship between ozone and CO₂ was observed in occupied and unoccupied classrooms (Fischer et al. 2013). When students left the classroom, carbon dioxide levels decreased and ozone levels increased. When they returned, carbon dioxide levels increased and ozone levels decreased. First- and second-generation skin lipid ozonolysis products were found to correlate with CO₂ and anticorrelate with O₃ (Liu et al. 2016). These observations suggest a large impact that humans have on ozone levels in densely occupied rooms. Moreover, surface reactions of aged skin lipids (during unoccupied periods) transferred to indoor surfaces may be minor compared to the surface reactions on humans and on other indoor surfaces that contain freshly transferred skin oils during occupied periods.

Ozonolysis of skin lipids via the Criegee mechanism can produce hydrogen peroxide, organic peroxides, and short-lived highly reactive products including hydroxyl, hydroperoxyl, and alkyl peroxy radicals. The reactions of these radicals

with squalene and its reaction products, producing additional carbonyls, dicarbonyls, and hydroxycarbonyls. Some of the products of ozone/unsaturated fatty acid reactions include nonanoic acid, 9-oxononanoic acid, 9-oxooctadecanoic acid, and azelaic acid (from oleic acid), while in the case of linoleic acid, they include acrolein and α -acyloxyalkyl hydroperoxid (Weschler 2016). Dicarboxylic acids including adipic acid and suberic acid, arising from oxidation of the most common unsaturated acids, cis-hexadec-6-enoic acid and cis-octadec-8-enoic acid, respectively, were observed after exposing skin oil to ozone (Zhou et al. 2016a). Triolein, a high-MW compound present in skin oil, yields lower-MW ozonolysis products upon reaction with ozone, for example, nonanoic acid.

Levulinic acid, succinic acid, adipic acid, suberic acid, and 4-oxobutanoic acid are the major condensed phase products remaining on the skin, clothes, and other surfaces from heterogeneous ozonolysis of squalene (Zhou et al. 2016a, b). Some of these acids can partition into the gas phase. They were identified in the gas phase with their indoor concentration substantially higher than outdoors (Liu et al. 2017). 6-Oxohexanoic acid and levulinic acid were observed to correlate with CO₂ (Liu et al. 2017). Aromatic acids including benzoic and benzeneacetic acid (human skin secretions) have been reported by the authors but did not correlate with CO₂. Benzylsuccinic acid increased with increasing CO₂, but its human source has not been reported.

Some of the more important reactive species present in exhaled breath include isoprene, 1-ethene, 1-butene, 1-pentene, limonene, nitric oxide, and dimethyl sulfide. Exhaled isoprene reacts slowly with ozone, but reacts more quickly with hydroxyl and nitrate radicals (Weschler 2016). Tsushima et al. (2018b) measured the ozone-initiated transformation of organic compounds emitted from the human body in a unique stainless-steel twin-chamber that enabled the separation of dermal and exhaled emissions. Human subjects were sitting in a climate chamber wearing breathing masks. One-way valves ensured that they inhaled air from the chamber where they were sitting and exhaled into the adjacent chamber. Generally, larger concentration differences were observed between the two chambers when ozone was present. With ozone present, higher levels of reaction products were seen in the chamber with dermal bioeffluents. In a similar study performed in the same chambers, whole-body and dermal-only emissions removed around 75% of the ozone dosed into the chamber, while breath-only emission removed less than 10% (Bekö et al. 2020).

In addition to ozone, other major indoor oxidants include hydroxyl radicals (OH) and nitrate radicals (NO₃). The presence of occupants reduces oxidant concentrations and affects the formation of new products, including radicals (hydroxyl radicals (OH), hydroperoxy radicals (HO₂), and peroxy radicals (RO₂)) and nitrated organic compounds (Kruza and Carslaw 2019). Concentrations of OH and NO₃ are not meaningfully affected by reactions with squalene and unsaturated fatty acids on human surfaces. However, ozone/skin lipid chemistry produces species that affect the levels of free radical oxidants in the indoor environment. The reaction of ozone with 6-MHO produces hydroxyl radicals (OH), but 6-MHO rapidly consumes OH. It also reacts at a fast rate with nitrate radicals (produced by ozone reaction with NO₂). However, if humans are present in an indoor setting, ozone levels are lower, resulting in lower NO₃ levels. Geranyl acetone is expected to react rapidly with OH and NO₃,

producing additional 6-MHO. 4-OPA reacts with both OH and NO_3 radicals, although the effect of these reactions is small on OH levels and negligible on NO_3 levels. Exhaled isoprene reacts moderately with ozone, but reacts faster with hydroxyl and nitrate radicals, forming formaldehyde, methacrolein, and methyl-vinyl ketone among other products (Atkinson and Arey 2003). Moreover, when isoprene reacts with OH, alkyl peroxy radicals are formed, which can then react with NO to form organic nitrates. NO reacts rapidly with ozone, generating nitrogen dioxide, but its contribution to indoor NO_2 levels is small. NO also reacts rapidly with NO_3 .

Measurements of total OH reactivity (total oxidation capacity) account for all reactive organic species in the air. Comparing it to the summed reactivity, anticipated from known individual trace gases reveals whether all relevant species are being measured. Wang et al. (2021) applied this method in a stainless-steel climate chamber occupied by four volunteers, along with measurements using a PTR-ToF-MS and fast GC-MS. Whole-body, exhaled, and dermal emissions were assessed separately, in a fashion described above (Li et al. 2020; Tsushima et al. 2018b). The directly measured OH reactivity was compared with the estimated sum of the OH reactivity of the individually measured species with and without ozone added to the chamber. The average total OH reactivity of the chamber increased with the presence of four persons by 14 s^{-1} under ozone-free environment and by 33 s^{-1} with ozone present. The calculated OH reactivity was 16 s^{-1} without ozone and 33 s^{-1} with ozone. Under ozone-free conditions hydrocarbons (HC), dominated by isoprene from breath, contributed with the largest fraction to the total OH reactivity. After ozone was added, carbonyl compounds especially from dermal emissions constituted the largest fraction of the doubled total OH reactivity (Fig. 3). The reactivity

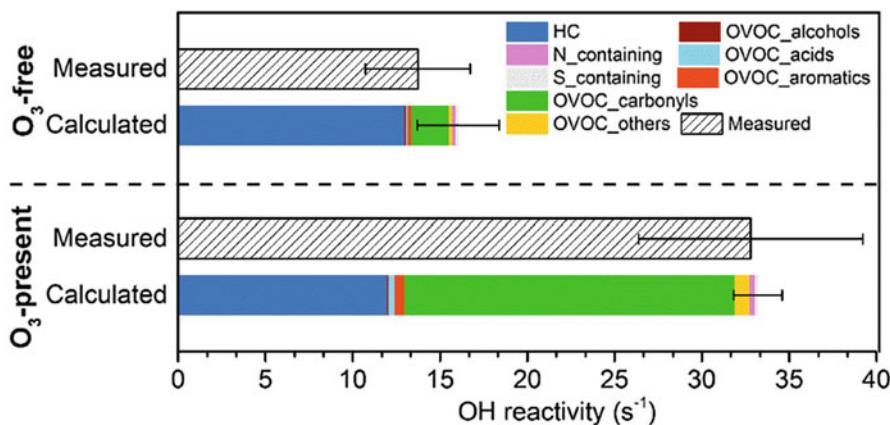

Fig. 3 Calculated and measured OH reactivity of adult whole-body emissions under ozone-free and ozone-present conditions. Error bars represent the standard deviation derived from the data of four identical experiments with three different groups of volunteers. (Reprinted with permission from “Wang et al. (2021) Total OH reactivity of emissions from humans: In situ measurement and budget analysis. Environ Sci Technol 55:149–159, <https://pubs.acs.org/doi/10.1021/acs.est.0c04206>,” Copyright (2020) American Chemical Society)

attributed to carbonyl compounds increased by almost an order of magnitude, with 6-MHO alone accounting for the largest fraction. For breath emissions alone, the total OH reactivity without ozone was similar to that with ozone present. For dermal emissions alone, the total OH reactivity without ozone was low. It increased significantly when ozone was present.

Human occupancy can also meaningfully alter the air concentrations of some volatile and semi-volatile organic compounds, for example, by removal via dust ingestion, inhalation, and dermal absorption. Some chemicals removed by the presence of occupants are known to participate in indoor chemistry, and their removal by occupancy therefore reduces product concentrations. Occupancy may reduce indoor concentrations of certain chemicals by up to 60% (Weschler 2016). He et al. (2019) recruited 98 healthy, non-smoking subjects and measured the concentrations of a range of organic compounds in their inhaled and exhaled breath at various locations including well-ventilated offices, classrooms, gas stations, and laundry rooms. Correlation coefficients between inhaled and exhaled breath concentrations varied between -0.03 and 0.96. Human breath was shown to be a source for some compounds and a sink for others. The authors observed that with increasing toluene concentrations, human breath turned from source to sink. It has been suggested that humans act as sinks for toluene when at sufficiently high ambient concentration toluene molecules diffuse from alveolus into the capillary and pulmonary veins driven by the partial pressure gradient. They can then reach all organs, while some may be stored in the periphery of the human body. The stored toluene can then be excreted via breath or other pathways when the external concentration is relatively low.

Secondary Organic Aerosols

Occupant related chemical reactions may contribute to indoor concentrations of ultrafine particles, as the reaction products condense on existing particles or nucleate to form new particles. Fadeyi et al. (2013) observed higher concentrations of secondary organic aerosols (SOA) from ozone-terpene reactions when a space was unoccupied, compared to when it was occupied. When occupants are present, less ozone is available for SOA generation. As semivolatile organic compounds (SVOCs) partition between the gas-phase and airborne particles, these changes in SOA levels caused by the presence of occupants alter the ratio of particle-phase to gas-phase SVOC, which has consequences for indoor air chemistry.

Although skin oil-ozone reactions can themselves be a source of SOA (Wang and Waring 2014), SOA produced from ozone-initiated reactions with limonene outweighs any SOA produced by ozone reacting with the surfaces of the human occupants. Humans may, however, meaningfully contribute to indoor SOA concentrations in indoor environments with low levels of terpenoids and other ozone-reactive pollutants. Submicron particles were also shown to be generated during ozone reactions with skin-oil-soiled t-shirts; higher particle production occurs at higher ozone levels and when the T-shirts are worn for a longer period of time (Rai

et al. 2013). In the outdoor environment, large isoprene emissions have been shown to significantly inhibit new particle formation correlated to the monoterpene emissions from vegetation. This may be due to the high reactivity of isoprene with the hydroxyl radical (OH). It is currently unclear if isoprene emissions from breath could suppress new particle formation in indoor air.

Modifying Factors

The types of pollutants and their emissions vary with differences in nutrition, health condition, menstrual cycle, age, sex, hygienic standards, environmental exposure, and even addiction to alcohol and cigarette smoking (Wallace 1987; Kuukasjarvi et al. 2004; Penn et al. 2007; Havlicek and Saxton 2009; Schwarz et al. 2009). For example, Sukul et al. (2018) examined the exhaled VOCs throughout menstrual cycles in 24 young and healthy women using high-resolution real-time mass-spectrometry. The changes in exhaled VOC concentrations were pronounced throughout all cycles. Intra-individual variations were low. The largest changes were observed at the ovulation phase. Ammonia and acetone concentrations decreased, while isoprene concentrations significantly increased compared to initial menstruation. Some menstrual effects on exhaled VOCs disappeared with the use of oral contraception. Natural menstrual cycle and contraceptive therapy may affect metabolic processes, some of which regulate or produce endogenous VOCs.

Evidence of genetic influences on axillary emissions has been reported. Variants in the ABCC11 gene are thought to play a key role. The study used GC-MS to study axillary odorant VOCs from 30 individuals of African-American, East Asian, and Caucasian descent and found that characteristic odorants varied quantitatively with respect to genetic origin (Preti and Leyden 2010; Prokop-Prigge et al. 2016). The odor produced in the axillae has also been shown to differ under stressful conditions compared to normally produced axillary odor (Chan and Haviland-Jones 2000).

Sun et al. (2017) found that age influenced the breath emissions of most measured VOCs. The emissions of, for example, acetone, isoprene, decanal, benzene depended on sex, while smoking status influenced the emissions of, among others, nonanal, toluene, benzene, 1-(methylthio)-propane, and cyclopentane. Isoprene, which is a major VOC constituent of exhaled breath, exhibits large variability with age and sex. Concentrations may become reasonably stable after reaching adulthood (Lechner et al. 2006; Sun et al. 2017; Taucher et al. 1997). Cardiac output, breathing pattern, sleep/wakefulness, physical activity as well as clinical conditions can further influence isoprene emission rates (Taucher et al. 1997; King et al. 2010). Levels of exhaled NO increase with upper respiratory tract infections, asthma, and certain other conditions. Changes in metabolism affect VOC breath and sweat composition (Pereira et al. 2015; Shirasu and Touhara 2011). Dimethylsulphone, benzothiazole, nonanal, and 2-nonenal were suggested to be biomarkers of increased age (Gallagher et al. 2008; Haze et al. 2001). Proposed gender markers from skin include pentadecanoic acid, hexadecenoic acid, heptadecanoic acid, nonadecane, and docosane (Penn et al. 2007).

No significant difference in OH reactivity could be identified between teenagers, young adults, and seniors (Wang et al. 2021). However, a possible trend of decreasing OH reactivity with increasing age in the presence of ozone has been observed. The OH reactivity of carbonyls was slightly lower for seniors. The OH reactivity of alcohols was lower for the senior group than for young adults, which was lower than for teenagers. The OH reactivity contribution from the nitrogen-containing species (dominated by ammonia) was highest for the teenager group. The senior group demonstrated the highest fractional reactivity for sulfur-containing species. The emission rates of skin lipids (primarily responsible for increased OH reactivity when ozone is present) tend to decrease with age (Waller and Maibach 2006). The proportion of different skin lipids is, however, similar regardless of age. In line with this, the top ten species contributing to the total OH reactivity were consistent across the three age groups.

Changes in environmental conditions such as temperature and relative humidity can affect the types of bioeffluents emitted as well as their emission rates. Metabolic rate and clothing change with temperature, and this can consequently affect human emissions. Moreover, higher temperatures may increase sebum secretion and consistency, increasing volatilization and consequently the emission and reaction rate of squalene. The number of resident skin flora can also increase with temperature. Moreover, temperature increases the rate of oxidation reactions. Tsushima et al. (2018b) measured dermal emissions and exhaled breath emissions from human subjects at chamber temperatures 23 °C and 28 °C. Higher concentrations of squalene and an unknown hexanedioic acid ester were observed at 28 °C. Acetic acid level was higher in the chamber when the temperature was 23 °C. Higher temperatures were shown to be strongly correlated also with higher emission rates of ammonia from people (Li et al. 2020). Ammonia concentrations in a climate chamber with no other sources were approximately three to four times higher at higher temperatures (~32 °C) than at lower temperatures (~28 °C).

Humidity is an important factor that can influence VOC emissions and compete with VOCs for sorptive uptake. It affects squalene ozonolysis. The reactions between ozone and squalene and between ozone and skin oils present on soiled t-shirts have been shown to be humidity dependent (Arata et al. 2019). The concentrations of some reaction products followed the variations in relative humidity deliberately changed in a climate chamber in a series of steps. In another study, increasing RH from 10% to 50% doubled the emissions of most ozonolysis by-products from a cotton surface. Nonanal and decanal emissions increased by a factor of five (Coleman et al. 2008). Humidity may also affect the distribution of squalene-ozone reaction products that are generated on indoor surfaces. This may be due to different pathways from the Criegee intermediates. Zhou et al. (2016b) found that at RH below 5%, the major condensed-phase products were levulinic acid and succinic acid. Under humid conditions (50% RH), the major products were 4-OPA, 4-oxobutanoic acid, and levulinic acid. High-molecular weight products were observed under dry conditions with indications that levulinic acid was involved in their formation. Higher RH also increases secondary organic aerosol formation from the ozonolysis of surface-film squalene (Wang and Waring 2014).

Ventilation can act as a source of reactive species (e.g., ozone), lower the concentration of reaction products, and reduce the time available for gas-phase reactions. Higher ventilation rates will thus result in a smaller impact of occupants on indoor chemistry. Intermittent ventilation (e.g., turning ventilation off overnight or on weekends) may lead to the accumulation of indoor-generated pollutants, but also to lower indoor ozone concentrations, delayed generation of ozone-initiated reaction products when the ventilation is turned back on again, and lower product concentrations compared to continuous ventilation. On the other hand, ozone removal rates by humans are mass transport limited, and ventilation strategies will have a marginal effect on them (Salvador et al. 2019).

The external environment contributes significantly to the skin's chemical composition. Molecular features of the skin can be matched with hygiene, diet, clothing, beauty products, plasticizers (e.g., o-formylbenzoic acid) or food constituents (e.g., sinapinic acid and oxidized polyethylene). Molecular families that include constituents of personal care products (PCPs) (e.g., C12 lauryl ether sulfate surfactant, cocoamidopropylbetaine (shampoo), avobenzone, and octocrylene (sunscreens)) were found on skin (Bouslimani et al. 2015). Constituents of personal care products used by occupants can contribute to occupant-related gaseous indoor pollutants. These include, for example, monoterpenes, linalool, and cyclic volatile siloxanes. Limonene has been shown to be one of the most abundant compounds in the breath and skin, presumably originating from diet (flavoring agents) and scented personal care products (Sanchez and Sacks 2006; Mochalski et al. 2014). Cyclic volatile methylsiloxanes (especially decamethylcyclopentasiloxane (D5)) are abundant in PCPs (such as antiperspirants) and have been reported as dominating VOC emissions in an occupied classroom, but the emission rate declined over the course of the day as the products off-gassed (Tang et al. 2015).

Human skin and breath emissions strongly vary over the course of a day. For example, emissions of exogenous compounds like terpenes or siloxanes from personal care products depend on the time of their application. Emotional state can also influence emissions. Small scale variances in emission rates were found to occur reproducibly over multiple screenings of the same film in a cinema. The peaks occurring in the time series of a compound during the screening of the film were induced by the physiological response of the audience to audio-visual stimuli (Stönnér et al. 2018; Williams et al. 2016). Crowd-based breath analyses may in the future assess group-based behaviors, exposures, and perhaps opinions and changes in mood (Williams and Pleil 2016).

Clothing acquires skin oils, which can be altered via microbial activity or react with ozone. The reaction products can desorb into indoor air. Squalene, for example, reacts with ozone on T-shirts, producing the above-mentioned ozonolysis products (Coleman et al. 2008; Rai et al. 2014; Salvador et al. 2019). The formation of nonanal on skin-oiled clothing can be mainly attributed to reactions between ozone and unsaturated fatty acids such as 9-octadecenoic acid and (Z)-7-hexadecenoic acid and their derivatives, such as (Z)-13-docosenamide. 6-Hexadecenoic acid (the most abundant unsaturated fatty acid of skin-oiled clothing) and 8-octadecenoic acid are the main reagents that contribute to the generation of decanal

(Yang et al. 2016). Wax esters and triglycerides also contribute to the formation of nonanal and decanal. Ozone reactions with terpenes or sesquiterpenes transferred to clothing from PCPs produce low volatility oxidation products (carbonyls and carboxylic acids). Reactions that occur on clothing can also generate nonylphenol, from the degradation of nonylphenol ethoxylate detergent residues (Antal et al. 2016) and formaldehyde from constituents of anti-wrinkling agents (De Groot et al. 2010). C6–C10 straight-chain saturated aldehydes were the major by-products of the ozone reaction with unsoiled cotton T-shirt fabric. The secondary emissions from soiled fabrics can be higher than from laundered fabrics (Coleman et al. 2008; Rai et al. 2014). Ozone consumption and by-product formation on clothes are affected by various environmental factors. Ozone-initiated VOC emissions were generally higher at higher ozone, humidity, soiling of T-shirt, and air change rate (Coleman et al. 2008; Rai et al. 2014).

Clothing contains a variety of chemicals acquired during manufacturing processes, as a consequence of packaging, transport, and storage, or deliberately added, such as anti-wrinkling agents, flame retardants, and antimicrobial agents. Clothing also acquires chemicals from the air during use, or via contact with surfaces, personal care products, and laundry detergents. Under favorable conditions, some of these chemicals can be emitted into indoor air or can chemically transform to other species. A detailed description of chemical emissions from clothing falls outside the scope of this chapter. We refer to Licina et al. (2019) and to ► Chap. 36, “Role of Clothing in Exposure to Indoor Pollutants,” of this Handbook for a comprehensive summary of the literature on the role of clothing in chemical emissions and exposures.

Role of Microbial Population

Apart from odorous human emissions of fecal nature, odorous compounds in breath are attributable to the microbial population in the mouth, producing volatile sulfur compounds (thiols, sulfides), skatol, organic acids, ammonia, and amines (Phillips et al. 1999). Body odor is further generated when the microbial activity decomposes the sebum and sweat (lipid peroxidation). *Staphylococcus epidermidis* and lipophilic corynebacteria that dominate bacterial community in the axillary region of the skin degrade precursor compounds found in odorless apocrine gland secretions into volatile fatty acids and thiolalcohols that are associated with malodor (Barzantny et al. 2012; James et al. 2013). The yeast *Pityrosporum ovale* metabolizes lipid substances on the scalp to fatty acids and glycerol, which undergo ring closure to the volatile and odorous γ -lactones. γ -Decalactone was reported to be responsible for the smell of unwashed hair (Inaba and Inaba 1992). Foot odor is primarily attributable to methanethiol produced by *Brevibacterium epidermidis* present on the skin and to isovaleric acid produced by the degradation of leucine found in sweat by *Staphylococcus epidermidis* (Kusano et al. 2012; Ara et al. 2006).

Molecular signatures can be correlated with the local microbial community, indicating molecular interrelations among the microbiota, human skin, and the

environment. Bouslimani et al. (2015) visualized the chemical composition and microbiological community composition of human skin surface. Of human origin, members of the molecular families of phosphatidylcholine, phosphatidylserine, and sphingosine lipid, a sterol family that includes a match to cholesterol, were found on skin. Bile acids, glycocholic acid, and taurocholic acid were also detected. Tryptamine from the skin was identical to the molecular feature collected from the cultured microbe *Staphylococcus*. Components of acyl glycerols that make up membranes of human cells (lipids such as oleic acid, palmitic acid, and monoacylated glycerols monoolein and monopalmitin) were found in larger amounts on the head, face, hands, chest, and back. The localization of oleic acid, palmitic acid, mono-oleic, and palmitic acylated glycerols matched the localization of the genus *Propionibacterium*. Some of these products might result from hydrolysis of triacylglycerides or diacylglycerides mediated by *Propionibacterium*. *Propionibacterium acnes* and *staphylococcus epidermidis* indeed hydrolyze tri-glyceride to fatty acids.

Effects on Perceived Air Quality

The perception of body odor was first investigated systematically by Yaglou et al. (1936), who used human subjects to judge the odor intensity and the freshness of air polluted by bioeffluents. The results have been the basis of ventilation standards and guidelines for decades to come. Later studies of similar characters with a greater number of subjects used the acceptability of air judged by a sensory panel to measure the perceived air quality. The newly developed unit “olf” described the sensory pollution load from a standard sedentary adult person (Fanger 1988).

Tsushima et al. (2018b) separated the dermal and exhaled human emissions from five male subjects wearing a breathing mask in a twin chamber. Another 23 subjects were recruited to perform sensory evaluations of the air from the two chambers. This was done while ozone was present or absent in the chambers containing the emissions, as well as at temperatures 23 °C and 28 °C in the chambers. The perceived air quality of the unoccupied chambers was also assessed. No significant difference was observed between the acceptability and odor intensity of the empty chamber and those with exhaled bioeffluents. The odor intensity was higher and the acceptability of the air lower with dermally emitted bioeffluents than with no bioeffluents or exhaled bioeffluents. Similar air quality was observed with whole-body emissions (dermal and breath) as with dermal emissions alone. It was concluded that dermally emitted bioeffluents play a major role in the occupant-related sensory nuisance experienced in indoor environments. The presence of ozone did not affect the results significantly. However, the air quality was consistently perceived poorer at higher temperature. Dermal secretions and the number of resident skin flora increase at elevated temperatures. This may lead to increased production of odorous substances.

Burdack-Freitag et al. (2011) used gas chromatography-olfactometry to identify significant human-induced odorants in densely occupied rooms. Six such

compounds were correlated with poor indoor air quality. Hexanal and (Z)-4-heptanal originate from lipid peroxidation, 2,3-butanedione from glucose metabolism and enzymatic oxidation of pyruvate, and 3-(methylthio)-propanal is an enzymatic degradation product from protein metabolism. 3-methyl-2-butene-1-thiol, an off-odor of beer with very low odor threshold, was identified in spaces with adults, but not in classrooms with small children. Finally, 6-MHO may be among the compounds responsible for the attraction of mosquitoes (Meijerink et al. 2000).

Wysocki et al. (2009) studied odor perception with the aim of reducing the odor threshold of axillary emissions using structurally similar compounds to “cross-adapt” the olfactory system. They found that exposing volunteers to pleasant-smelling ethyl esters of the axillary odorant 3-methyl-2-hexenoic acid resulted in reduced sensitivity to the esters over time, and sensitivity to 3-methyl-2-hexenoic acid was subsequently reduced (i.e., cross-adapted by the esters). The authors concluded that some potential cross-adapting agents could reduce the impact of human stress-related odors; however, the same chemicals may not necessarily be effective for male and female odors. A gender-specific response to both the odor-stimuli and the fragrance chemicals used to cross-adapt it was suggested.

Health Effects of Human Emissions

The literature available on the health effects of emissions from humans and their reaction products is limited. Emissions from humans, and particularly body odor, have been considered nontoxic. A recent study showed, however, that bioeffluent levels with CO₂ of 3000 ppm can cause increased intensities of some acute health symptoms (sleepiness, headache, fatigue, and other neurobehavioral symptoms) (Zhang et al. 2017a). Diastolic blood pressure, end-tidal CO₂ level, and concentration of salivary a-amylase increased after exposure to a higher level of bioeffluents (Zhang et al. 2017b). Exposure to bioeffluents was also shown to reduce cognitive performance (Maddalena et al. 2015; Zhang et al. 2017a, b).

Some products of ozone reactions with skin oil constituents have low odor and sensory irritation threshold (Devos et al. 1990; Wolkoff 2013). In a simulated aircraft cabin, human subjects judged the air quality and 12 symptoms, including eye and nasal irritation, lip and skin dryness, headache, dizziness, and mental tension, to be significantly worse when ozone was present in the air, compared to when it was absent (Strøm-Tejsen et al. 2008). Although the air pollution in the simulated aircraft was not limited to human emissions, most products of ozone-initiated chemistry in the cabin were derived from surface reactions with occupants and their clothing (Weschler et al. 2007). When inhaled, some of the products of these reactions, especially dicarbonyls, may be respiratory irritants (Jarvis et al. 2005; Anderson et al. 2007). It can be assumed that secondary products of human-ozone chemistry may be more irritating than primary products, given their multiple oxygen-containing functional groups (Weschler 2016). Some of the less volatile products may be skin irritants (Thiele et al. 1997; Weber et al. 1999). Anderson et al. (2012) have reported that both dermal and pulmonary exposure to 4-OPA may give rise to

allergic responses in mice. Wolkoff et al. (2013) determined human reference values for airflow limitation due to inflammation in the airways, accumulation of mucus, and bronchial constriction (0.03 ppm and 0.5 ppm for 4-OPA and 6-MHO, respectively) and for sensory irritation for some of the ozone-skin lipid reaction products (0.3 ppm for 6-MHO). Moreover, squalene ozonolysis products may cause other health problems related to oxidative stress. Fu et al. (2013) observed that squalene's interaction with ozone considerably enhanced its hydrophilicity and redox activity. The authors speculated that this could affect the ability of condensed phase reaction products to penetrate through the skin and cell membranes, posing an increased health risk in indoor environments. Enhanced redox activity in cells can damage cellular components such as proteins, lipids, and DNA. It is associated with increased levels of reactive oxygen species and oxidative stress, which has been linked to various human diseases.

Experimental animal studies show that skin exposure to ozone results in signs of oxidative stress, including depletion of antioxidants and the appearance of lipid peroxidation products in the epidermis (Weber et al. 1999). Squalene oxidation products have been shown to be comedogenic and to cause skin irritation in rabbit models (Chiba et al. 2000). More recently, squalene ozonolysis products have been shown to accumulate in human skin oil that has been exposed to ozone (Zhou et al. 2016a). These reaction products can diffuse through the skin and enter the blood where they have potential to cause adverse health effects (Lakey et al. 2017).

Conclusions

Primary emissions from humans, especially via exhaled breath, have been studied for a long time with the purpose to identify disease biomarkers and advance disease diagnostics. This has been largely done with limited success for clinical applications. It is only recently that the scientific community began to appreciate the significant role occupants play in indoor air chemistry. Our understanding of this field of science is now rapidly improving with the development and availability of novel measurement techniques and instrumentation. New methodologies allow us to revisit some of the research questions that have been puzzling scientists for decades, such as the personal and environmental factors that may influence human emission (e.g., diet, stress level, hygiene habits, age, sex, health condition, activity level, personal care products, clothing, and its laundering and storage). The inter- and intrapersonal variability of emissions, as well as the influence of prior exposure on human emissions, will likely receive increasing attention. New research questions are also being generated. It is, for example, currently unclear whether indoor air quality affects the dermal and oral emissions. Real-time measurements of OH, NO₃, Criegee intermediates, and other short-lived, highly reactive species in occupied and unoccupied indoor environments will significantly advance our understanding of indoor air chemistry in the near future (Gligorovski and Weschler 2013; Weschler 2016).

Occupants remove chemicals from the air via inhalation, dust ingestion, and dermal absorption. Occupant presence can thus significantly reduce the

concentrations of volatile chemicals and compete with other removal mechanisms, reducing the reactive capacity and therefore decreasing the concentrations of reaction products. Whether this removal can outweigh the production of new species caused by the presence of occupants warrants further attention. Quantifying how indoor environments change with occupancy is generally not well established. Occupancy leads to changes occurring not only in the gas phase, but also on indoor surfaces. Little is known, however, about the accumulation on indoor surfaces of the less volatile products of ozone/skin oil chemistry. Aerosol mass spectrometry can be used to investigate the influence of occupancy on the composition of airborne particles. Additionally, some of the mentioned measurements have yet to be performed in parallel under both occupied and unoccupied conditions, in order to reveal potential connections between various species. Experimental studies should then be coupled to modeling studies in order to improve the models, which can then in return help design better experiments.

Abstract

The chemical complexity of indoor surfaces and air creates challenges for quantitative analysis. The air includes inert trace gases, reactive trace gases, oxidants and radicals in the gas-phase, as well as particles across many orders of magnitude in size distribution. Measurements techniques must be able to

capture the dynamic range and rapidly changing nature of indoor concentrations. Both passive and active sampling approaches are available, and chemical measurements may focus on speciated or bulk composition. The outdoor atmospheric chemistry community has established numerous on-line techniques for detecting trace gases and particles, and many of these techniques have been successfully applied to indoor environments. However, some of these techniques are subject to interferences in the indoor environment, requiring careful intercomparison. New frontiers in indoor analytical chemistry include development of new surface chemistry measurements, application of *in situ* chemical kinetics studies, development of low cost sensors, and closer linkage between health-relevant measurements and composition.

Analytical chemistry · Indoor chemistry · Aerosol mass spectrometry · Chemical ionization · Chemiluminescence · On-line measurement

Introduction

The indoor environment is chemically complex. Relative to the outdoor environment, the indoor environment contains high concentrations of a myriad of organic and inorganic compounds that exist in multiple phases (Abbatt and Wang 2020). Cataloguing these compounds presents an analytical measurement challenge due to the sheer number of distinct molecules, as well as the breadth of unknown, as-yet-unmeasured compounds (Farmer 2019). Quantifying the compounds presents an even greater challenge, as this requires standards that can be challenging to obtain.

Not only must researchers identify and separate a vast number of compounds to investigate indoor chemistry, but they must do this rapidly. The built environment can change quickly in terms of sources and parameters. People can walk into a room and act as immediate sources of exhaled compounds – or sinks of ozone (Wisthaler and Weschler 2010). The cycling of an air conditioning system causes changes in not only relative humidity, but also air composition on the timescale of seconds to minutes (Duncan et al. 2019). From an instrument’s perspective, these rapid changes of concentration can occur over a large dynamic range. A single cooking event can cause gas and particle concentrations to change by over two orders of magnitude on the timescale of seconds (Boedicker et al. 2021)! In addition, buildings possess multiple surfaces, each with its own distinct chemical and physical properties. These surfaces play an important role in the chemistry of indoor environments, but present a new analytical challenge for the environmental chemistry community (Ault et al. 2020).

This chapter outlines the principles of chemical measurement as they relate to the indoor environment, before diving into specific measurement types used to detect gases, particles, and surfaces – before highlighting open questions and new frontiers.

Measurement Principles

Instrumental Analysis

Modern analytical chemistry uses instruments that are built around fundamental principles of physical chemistry to detect and (ideally) quantify molecules of interest. The two underlying criteria for practical use of instruments are their *selectivity* and their *sensitivity*. Selectivity refers to the capacity of an instrument to measure one compound (or suite of compounds) in a well-known manner, free of interferences from other molecules (or groups of molecules). These target compound(s) of interest are “analytes,” and selectivity is typically determined through a combination of laboratory tests and field experiments.

Sensitivity refers to how well an instrument can detect a given analyte, typically in terms of the change in instrument signal per change in concentration. Sensitivity defines an instrument’s capacity to quantify analytes, with a higher sensitivity meaning that an instrument can more easily detect small changes in concentration. Sensitivity is typically determined by calibration – whether by external standards, internal standards, or standard additions. Both external standard and standard addition approaches require true standards of the analyte of known purity and delivered to the instrument in a quantifiable manner. In contrast, internal standard approaches require a proxy standard, such as an isotopically labeled version of the analyte or other substance of similar physical and chemical properties. While standards of some compounds may be commercially available, other compounds, such as isoprene oxidation products, require elaborate laboratory synthesis (Zhang et al. 2012). Even when purchased, many substances that are relevant to the indoor environment exist in solid or liquid phases when pure, so must be quantitatively volatilized and transmitted to instrumentation.

The sensitivity of a measurement can be used to calculate a limit of detection (LOD), which corresponds to the smallest detectable concentration above a defined threshold. For many chemical applications, the LOD is taken as the concentration corresponding to a signal that is three times the noise above the background (i.e. $S/N = 3$) although higher or lower thresholds are sometimes used. The pursuit of lower LODs often manifests itself in substantial instrument development to reduce background measurements, whether through cooling optical detectors, cleaning internal components, or isolating electronics from signal interference.

As noted elsewhere in this handbook, indoor environments are marked by highly concentrated, complex mixtures of molecules in multiple phases. This chemical system challenges analytical measurements by providing an array of potential interferences to different detection techniques (Farmer et al. 2019a). Several approaches have emerged to investigate whether interferences are impacting measurements. Standard additions enable small quantities of analyte standards to be added to the real sample during sampling, thus accounting for matrix effects; comparing sensitivities from standard additions relative to external standards generated in a synthetic, clean background directly probes whether interferences exist (Brophy and Farmer 2015). Intercomparisons across different instruments, all measuring the same analyte in the

same matrix, also often reveal interferences. For example, during the House Observations of Microbial and Environmental Chemistry (HOMEChem) study in 2018, two separate detectors of nitrogen dioxide (NO_2), a common air toxic, occasionally diverged during cooking events. One instrument used differential optical absorption spectroscopy to directly detect NO_2 , while the other used a photolytic converter to transform NO_2 to NO, which was then detected by chemiluminescence upon reaction with O_3 . Unfortunately, the complex mixture of trace gases produced during cooking events included photolabile oxidized organic compounds that were photolyzed in the chemiluminescence instrument converter to reactive RO_2 radicals, which were capable of reacting with the NO and thus interfering with the measurement (Farmer et al. 2019a). This case highlights the challenges of bringing instrumentation that is frequently used in outdoor air quality into the indoor environment: the complex mixture of indoor gases can create strong, unexpected interferences that are impossible to account for in post-acquisition data analysis.

One key feature in selecting instrumentation to measure indoor air quality is the time response of competing measurements. As noted earlier, indoor concentrations of trace gases or particles change over the timescale of seconds or minutes when a candle is lit or a window is opened. If one is interested in capturing those rapid changes, detectors must operate on even faster timescales. However, for many studies, slower time resolution is adequate to capture average conditions, and avoids challenges of data storage and management. The timescale of measurements must consider not only the speed of processes under investigation, but also the short- and long-term precision of the measurements. Some instruments are capable of making fast measurements, but their sensitivity or background also changes frequently and requires frequent maintenance and attention. Ozone sensors provide good examples of this challenge: many techniques for ozone detection are available (Clifton et al. 2020). For example, one particularly fast sensor is a dry chemiluminescence measurement using titration of ozone by a solid dye, such as coumarin. Unfortunately, these techniques require frequent maintenance as the dye degrades with time, and the sensitivity can change on the timescale of days. Ultraviolet absorption is a less expensive, lower maintenance approach to measuring ozone, but is subject to interference from high levels of ultrafine particles, which can occur during cooking events.

Measurement Strategies

Several strategies exist for measuring indoor air, all with different benefits and disadvantages. A few paired strategies are described below.

Bulk Versus Compound-Specific Measurement

While some measurements target specific molecules (e.g., NO radical concentrations), bulk measurements detect a suite of compounds without specific differentiation (e.g., NO_y , which is the sum of all nitrogen oxides including NO, NO_2 , nitric acid, and all organic nitrates and peroxy nitrates). This bulk approach is particularly common in aerosol composition studies, in which bulk components like “total

“organic aerosol” and “bulk oxygen to carbon ratios of organic aerosol” provide insight on particle sources in the indoor environment, but require less targeted instrumentation than measurements that quantify different molecules that contribute to organic aerosol. Bulk composition measurements are typically more complete in terms of capturing a given suite of compounds or mass in phases, but have lower chemical resolution than compound-specific measurement (Hallquist et al. 2009). Within compound-specific measurements that have higher chemical resolution, typically at the expense of measurement completeness for a class of compounds, many mass spectrometry systems are capable of identifying compounds by elemental composition (i.e., the number of carbon, oxygen, hydrogen, or other atoms in a molecule) (Farmer and Jimenez 2010; Hallquist et al. 2009). However, the arrangement of those molecules into different structural isomers can impact the reaction rates or properties of the molecule, and separation of these isomers creates additional analytical challenges. For example, during the HOMEChem study, aerosol mass spectrometers measured bulk sub-micron aerosol composition well (Katz et al. 2021), while softer ionization mass spectrometry techniques (e.g., extractive electrospray ionization mass spectrometry and iodide adduct chemical ionization mass spectrometry) enabled adequate molecular specificity to quantify siloxane and phthalate aerosol components (Brown et al. 2021).

Off-Line Versus On-Line Measurements

Off-line measurements involve sample collection followed by analysis by a separate instrument in a separate location, and thus separated in time. On-line measurements involve sample collection and analysis at the same time with one instrument system. Off-line sample collection is typically simpler to operate than on-line instrumentation, and can be less intrusive to a building or home in terms of space and noise, while on-line measurements provide faster data, both in terms of time resolution (less time between data points) and in terms of less time between sample collection and a numerical result (discussed in detail for surfaces by Liu et al. 2020). Sample collection for off-line analysis can use passive or active approaches. Passive samplers allow analytes to accumulate on a sampler with time, with no active or moving parts, while active samplers physically move air or sample into a collection system. Passive samplers are discussed in more detail in ► [Chap. 17, “Passive Samplers for Indoor Gaseous Pollutants.”](#)

Chemical Versus Physical Analysis

While many of the measurements described in this chapter focus on chemical measurement and quantitation, numerous methods exist to measure chemical or physical properties of gases or particles in the indoor environment. For example, while mass spectrometry, chromatography, and spectroscopy measurements exist for detection of different chemical components of indoor air, additional instruments can enable detection of the volatility of different components (e.g., thermal denuders coupled to aerosol detectors), or the reactivity of the system to oxidants (e.g., OH reactivity measurements). Detection systems that measure chemical properties, rather than just composition, have not been widely applied to indoor environments,

but results consistently provide new insights on indoor systems. For example, Wang et al. (2021) measured OH reactivity of human emissions, demonstrating significant increases in the presence of ambient ozone, which reacts with skin oils to produce a diverse array of reactive, gas-phase oxidation products.

Low Cost Sensors Versus Research Instrumentation

Numerous research-grade detection techniques exist to quantify gas and particle components of indoor air. However, despite being commercially available, many of these techniques are (i) expensive (thousands of dollars for simple infrared absorption CO₂ measurements to hundreds of thousands of dollars for high resolution mass spectrometers capable of differentiating organic aerosol and gases), (ii) challenging to run (requiring highly trained operators to maintain the instruments and analyze data), and (iii) noisy (using loud pumps to actively pull air into the instruments). Despite the fast time resolution and wealth of data, these features have inhibited widespread use of advanced chemical techniques to study the indoor environment. Low cost sensors are thus popular for indoor air quality studies. Low cost sensors (typically on the order of hundreds of dollars) provide lower time and chemical resolution, but are cheaper and easier to operate. Numerous “indoor air quality” sensors are commercially available, but can have limited accuracy and reproducibility thus providing caveats for research applications (Li et al. 2020; Wang et al. 2020c). However, recent publications have highlighted the research potential of low cost sensors when combined with extensive data analysis (Liang et al. 2021).

Analytical Chemistry Approaches

Instruments for measuring the quality of indoor air take advantage of different chemical principles.

- Spectroscopic measurements take advantage of the way light interacts with different molecules through absorption, fluorescence, or chemiluminescence. Infrared absorption is a well-established approach for measuring greenhouse gases, including CO₂ and CH₄, while other wavelengths are used for detection of trace gases like SO₂ or NO₂. Fluorescence and chemiluminescence use the light emitted from molecules following either absorption or chemical reaction, respectively, to detect and quantify compounds. Other optical techniques take advantage of light scattering to detect particles.
- Mass spectrometry uses electric or magnetic fields to separate gaseous molecules after charging them based on the resulting mass-to-charge ratio. Different ionization techniques target different types of molecules, with hard ionization approaches (e.g. electron ionization or laser absorption) fragmenting molecules and enabling bulk analysis (in the absence of pre-separation) or structural determination (when coupled to pre-separation via gas or liquid chromatography). Soft ionization approaches incorporating electrospray or chemical ionization are becoming widely used for compound-specific analysis.
- Chromatography systems enable separation based on chemical interactions between samples and either solid or liquid instrument components. These

separations are commonly used prior to analysis by another approach (e.g. mass spectrometry, flame ionization, or photoionization detectors), and enhance the specificity of the detection system.

- Devices based on electrochemistry often provide advantages of size and cost, with small and portable commercial sensors. However, these detectors are often subject to interferences and have not been extensively used in indoor chemistry studies.
- Off-line samples can take advantage of more complex microscopy approaches, including scanning electron microscopy or transmission electron microscopy.

All of these approaches provide different benefits and disadvantages – and different ways to compare and contrast sensors. The sections below provide more detailed discussion of measurement approaches by gases, particles, and surfaces.

On-Line Measurement of Gases

Inert Gases

Historically, indoor air quality has focused on radon, carbon monoxide (CO), and carbon dioxide (CO₂), with a plethora of low-cost commercial sensors available for measurements. However, these low-cost techniques are typically aimed at determining whether air concentrations are above or below a threshold, or what the time-integrated values may be. Infrared absorption spectroscopy offers a particularly sensitive and selective measurement of CO and CO₂, as well as methane (CH₄).

Reactive Gases

Reactive gases can be categorized by several methods, one of which is to consider measurements as being oxidants, reactive inorganic trace gases, or reactive organic trace gases.

Oxidants

In the indoor environment, ozone is often considered the dominant oxidant, and is typically detected by commercial ultraviolet absorption spectroscopy measurements, although other techniques are available (see Clifton et al. 2020 for a recent review). One challenge with ultraviolet absorption measurements of ozone is the potential for interference from ultrafine particles, which can scatter light and generate a false positive signal. However, the use of filters on inlets can remove this problem. However, ozone is not the only indoor oxidant, with various modeling and measurement studies indicating that hydroxyl radicals (OH·), nitrate radicals (NO₃·), and peroxy radicals (HO₂·, RO₂·) are also potential indoor oxidants (Young et al. 2019).

OH^{\cdot} and peroxy radicals can be measured by either laser-induced fluorescence, or chemical ionization mass spectrometry; however, these measurements require sophisticated, home-built instrumentation and are thus limited (e.g., Alvarez et al. 2013; Carslaw et al. 2017). These radical measurements are prone to interferences, which have been noted in outdoor atmospheric field measurements, but the paucity of indoor measurements creates the potential for unexplored indoor interferences. Nitrate radicals can be directly measured by sophisticated cavity ring-down spectroscopy, but few groups have the instrumental capability to conduct those measurements. One indoor field measurement in a home suggested a very low level of nitrate radicals under typical residential conditions, below the detection limits of most instruments (Arata et al. 2018). Substantial input of ozone combined with NO radicals from combustion sources were required to elevate NO_3 substantially.

Inorganic Trace Gases

Inorganic trace gases include oxidized nitrogen (NO_x , HNO_3 , HONO , etc), reduced nitrogen (e.g. NH_3), sulfur-containing compounds (e.g., SO_2), and halogenated species (e.g., HCl , Cl_2). Commercial spectroscopic instruments are available for many of these compounds, including NO and NO_2 , NH_3 , SO_2 , and HCl . However, these commercial instruments are typically designed for outdoor air quality applications. As described above, surprising interferences can be present in indoor environments. Further, while some of these compounds are relatively easy to transfer through inlets from room air to instrument, others are more challenging. For example, NH_3 and HCl are “sticky” compounds that rapidly partition to surfaces, including Teflon inlet lines; as a result of this potential loss mechanism, indoor measurements must use very short inlets with the instrument physically located in the desired sampling location (Dawe et al. 2019; Ampollini et al. 2019). One approach to preventing compounds from partitioning to Teflon lines includes adding passivants to inlet air, which occupy adsorption spaces and reduce line losses. However, these passivants are often fluorinated organic compounds (e.g., Pollack et al. 2019 describes using a perfluoroctylamine to minimize inlet losses of ammonia). However, one important challenge with using fluorinated organic compounds is their potential to be oxidized to perfluorinated acids, which are long-lived environmental contaminants (Young et al. 2007).

Commercial instrumentation is not readily available for many inorganic trace gas species. Chemical ionization mass spectrometry with various reagent ions is an increasingly common technique for measuring halogenated gases in indoor environments, as well as nitrous acid (Mattila et al. 2020a; Mattila et al. 2020b; Collins et al. 2018; Wang et al. 2019; Wang et al. 2020a). However, chemical ionization mass spectrometers are expensive, relatively large ($1\text{--}2\text{ m}^3$), require careful calibration, and frequent maintenance and monitoring to ensure high quality data.

Volatile Organic Compounds (VOCs)

Organic trace gases typically include both volatile organic compounds (VOCs) that are exclusively considered present in the gas phase, and semi-volatile organic compounds (SVOCs) that are considered to be present in both gas and solid/liquid phases due to equilibrium partitioning. However, recent work has shown that even high volatile organic compounds like formic acid maintain a surface-air equilibrium in indoor environments due to the high surface area to volume ratio inside buildings. This section thus considers gaseous indoor organic compounds collectively.

Indoor VOC measurements have historically been performed using offline sampling techniques, such as VOC canisters and thermal desorption methods with adsorptive materials (e.g., Schlink et al. 2004). These techniques allow for quantification of numerous non-methane aromatic hydrocarbons (e.g., benzene, toluene, xylene), chlorocarbons (chloroform, carbon tetrachloride), and simple oxygenates (alcohols, carbonyls, esters). These offline measurements offer users a snapshot of VOC concentrations experienced indoors, and are particularly useful for projects aiming to sample multiple buildings and locations due to their relatively low cost, ease of use, and portability. However, the prolonged sampling times associated with these methods usually result in relatively slow time resolution (typically tens of minutes to hours or days) that do not capture dynamic temporal trends associated with perturbations to the indoor environment (i.e., cooking a meal or opening a window). These methods rely on external analysis of samples in a separate laboratory, typically involving gas chromatography instrumentation.

Formaldehyde is a VOC of particular interest due to its potential toxicity coupled to potentially high concentrations in buildings (Salthammer et al. 2010). Formaldehyde has thus been the focus of much instrument development for indoor analytical chemistry (e.g., Maruo et al. 2010; Gillett et al. 2000; Van den Broek et al. 2020). Formaldehyde is challenging to measure in indoor environments due to its dynamic range (1–1000 ppb); highly volatile nature, which inhibits collection via passive sampling; and potential interferences in online measurements. For example, proton transfer reaction mass spectrometry can measure formaldehyde on-line with high sensitivity and in real-time, but is subject to interferences from relative humidity that can be challenging to correct (Vlasenko et al. 2010). Emerging instrumentation using cavity ring-down spectroscopy is one particularly promising method for formaldehyde measurement in indoor environments. Formaldehyde and other “very volatile” organic compounds are discussed in Chapter “Source/Sink Characteristics.”

Due to the vast number of volatile organic compounds present in indoor air, techniques that measure multiple compounds at once are particularly useful. Gas chromatography coupled to flame ionization or photoionization detectors are one approach to measuring hydrocarbons and small oxidized VOCs although this method can be challenging to operate and time-consuming to analyze data (Abeleira et al. 2017). Alternately, collection of water soluble organic gases using mist chambers followed by off-line mass spectrometry analysis also provides potentially vast datasets of water soluble organic gases (WSOG), but requires extensive post-sampling sample analysis with access to sophisticated instrumentation (Duncan et al. 2019).

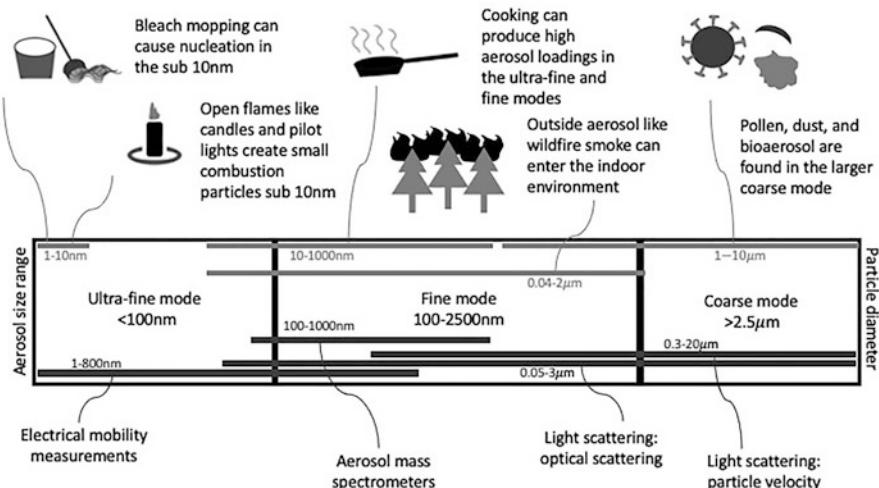

Fig. 1 Summary of particle size distributions and measurement approaches

Proton-transfer reaction mass spectrometry (PTR-MS) is a fast, field-deployable method for detecting and quantifying a multitude of indoor VOCs. This method accomplishes chemical ionization of analytes via proton-transfer from protonated water cluster reagent ions, allowing for subsequent detection via mass spectrometry. This method is sensitive and selective toward various reduced or lightly oxidized VOCs. A recent indoor field campaign in a California residence employed this instrumental method to probe background VOC emissions from building materials (formic acid, acetic acid, methanol), emissions from occupants (isoprene, siloxanes), and cooking (monoterpenes, ethanol, various O-, N-, or S-containing VOCs) (Liu et al. 2019). Other indoor field studies have used PTR-MS to measure chlorinated VOCs produced from bleach cleaning, including N-chloraldimines ($C_XH_YCl_N$), and toxic cyanogen chloride (ClCN) (Mattila et al. 2020a; Finewax et al. 2021).

In addition to PTR-MS, other chemical ionization mass spectrometry (CIMS) techniques have been successfully applied toward indoor air measurements. CIMS paired to iodide (I-) reagent ionization is sensitive and selective toward various oxygenated and nitrogenated VOCs, and inorganic chlorinated trace gases. Here, analyte ionization is accomplished via iodide-adduct formation driven by intermolecular forces between iodide and electropositive regions on the analyte (Lee et al. 2014). Iodide CIMS a powerful tool for studying indoor emissions from cooking (various O- and N-VOCs), bleach cleaning (HOCl, Cl₂, chloramines), and other WSOGs (Mattila et al. 2020b; Wang et al. 2020a; Wong et al. 2017; Duncan et al. 2019). Acetate (C₂H₃O₂⁻) reagent ions are effective for ionizing many gas-phase acids found indoors, including nitrous acid (HONO), isocyanic acid (HNCO), and various organic acids (Farmer et al. 2019a; Wang et al. 2020a; Wang et al. 2020b). Ionization with acetate CIMS occurs via proton-transfer, resulting in deprotonation of the gas-phase analyte (Brophy and Farmer 2016). Nitrate (NO₃⁻)

reagent ions have been utilized to detect low-volatility, highly volatilized gas-phase organics (Price et al. 2019), although the majority of these species likely reside in surface reservoirs and other condensed phases indoors, rather than indoor air. Combining CIMS measurements utilizing multiple reagent ion schemes allows users to capture a large fraction of indoor VOCs (Price et al. 2019). For instance, combining PTR-MS and iodide CIMS techniques likely captures a majority of the volatility space of atmospheric VOCs (Isaacman-VanWertz et al. 2017).

Modern field-deployable CIMS instruments used for atmospheric measurements are typically equipped with time-of-flight (TOF) mass analyzers, enabling mass resolutions orders of magnitude higher than quadrupole-based predecessors. The resolving power achieved by TOF instruments is crucial for fully characterizing complex atmospheric matrices, such as indoor air. Incorporating TOF mass analyzers in CIMS instruments also allows for collection of entire mass spectra at high (1 Hz) time resolutions, especially important for indoor environments where analyte mixing ratios can be highly dynamic on the order of minutes to seconds. These high sampling frequencies result in mass spectral ranges on the order of 500–1000 Da, which are usually sufficient for atmospheric trace gas applications.

Individual compounds detected by CIMS techniques can number in the hundreds to thousands. Many of these analytes may be calibrated using authentic gas-phase standards (i.e., VOC standard cylinders, permeation devices), but direct calibration of most compounds comprising CIMS spectra is infeasible. Bulk sensitivity estimations have been applied to CIMS field measurements, wherein instrumental sensitivity is parameterized to one or more controlling variable. For instance, PTR-MS sensitivities are routinely estimated based on the reaction rate coefficient between H₃O⁺ and the VOC of interest (Holzinger et al. 2019). Iodide CIMS sensitivity may be parameterized by the binding enthalpy of the iodide-analyte adduct (Lopez-Hilfiker et al. 2016; Mattila et al. 2020b). However, these methods have considerable uncertainty, and often yield order-of-magnitude sensitivity estimations at best.

CIMS instrumentation does not enable isomeric differentiation of detected chemical formulas, due to the inherent lack of sample pre-separation. Users will often have to rely on some a priori chemical knowledge of their sample to assume the structural identity of a detected chemical formula, i.e., if that compound is expected to be a prominent component of the sampled air. In most cases, the assigned empirical formula of a CIMS peak is some combination of different isomers. Some CIMS users have employed an in-line gas chromatography (GC) system for analyte pre-separation (GC-CIMS), although this invariably results in the loss of valuable time resolution due to extensive separation times.

The measurement of “total volatile organic compounds” remains an aspiration to indoor chemists. Such a measurement would provide useful context for even the most comprehensive measurements suites and determine the extent to which current measurements capture indoor organic carbon. “Total organic carbon” measurements are widely used in solid and liquid phases, and operate on the principle of combusting samples to CO₂. However, the gas phase has complications of a high CO₂ background (hundreds to thousands of parts per million CO₂ by volume), as well as methane and carbon monoxide. Thus any atmospheric total carbon

measurement requires subtraction of a very large and variable background signal to quantify the organic, non-methane component. Electrochemical sensors or other detection techniques may be useful. Alternative methods to constraining the extent to which air measurements capture the entire organic carbon budget include measuring the reactivity of air to OH radicals or ozone, and comparing model calculations of the lifetime of reactive components to measurements.

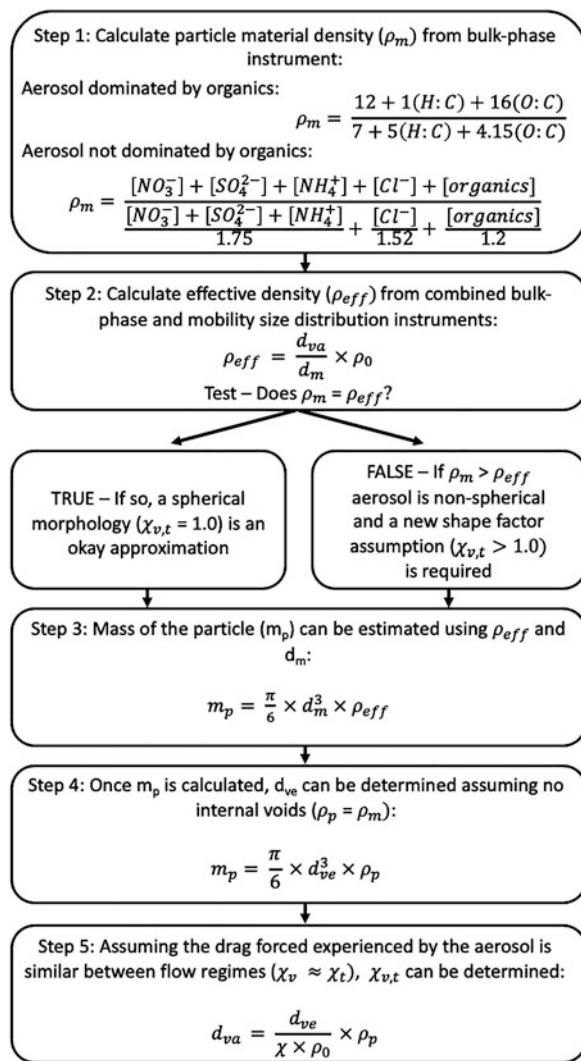

A substantial challenge of many of the techniques described above is the high cost. Many of the instruments described above are expensive and high-maintenance, and can require substantial electrical power and safety hazards (e.g., compressed gases, sealed radiation sources, calibration standards that include hazardous materials, etc.). These limitations prevent widespread application of detailed chemical assessment of indoor air across numerous buildings. Most detailed indoor chemistry studies are limited to laboratory environments, test houses, or single residences that are often occupied by individuals related to the study. To achieve a more widespread and long-term understanding of indoor air, lower cost and lower maintenance instruments that maintain the high quality data for at least a subset of measurements are essential. Low cost sensors are not the subject of this chapter, but are potentially exciting tools for understanding indoor air quality and chemistry.

On-Line Measurement of Particles

Particle Size Distributions

Indoor aerosols cover a range of sizes that include ultra-fine (particles 1–10 nm in diameter), fine (100–2500 nm in diameter), and coarse mode (>2,500 nm in diameter) (Fig. 1). Different subfields in aerosol science may have slightly different definitions of these modes, and are discussed in detail elsewhere in this book. Each mode has different sources in the indoor environment. For example, ultrafine particle sources include nucleation processes in which gas-phase molecules cluster to form new particles, as well as combustion sources (e.g., candle burning). Recent measurements show that bleach mopping can induce new particle formation, corresponding to increases in the ultrafine mode (Patel et al. 2020). Ultrafine particles typically experience substantial losses during transmission from outdoor air through engineered ventilation systems, but may enter indoor environments through open windows and doors. Sources of indoor fine mode aerosol include cooking and combustion sources, as well as infiltration of outdoor air. Coagulation and condensation processes can be substantial, and impact mass and composition of this mode. For example, ozonolysis of limonene can form fine mode secondary organic aerosol (Youssefi and Waring 2012). Coarse mode aerosol can include larger particles, such as oil droplets from cooking, skin flakes, and dust, which may be resuspended into the air from walking or vacuuming. Because the diameter of indoor particles spans orders of magnitude, no single instrument measures all particles. Instead, specific instruments focus on different aerosol modes, often measuring particle size distributions by number, which can then be converted to total mass

Fig. 2 Summary of approach for comparing size distributions derived from an aerosol mass spectrometer (d_{va}) and an SMPS (d_m). Note that this method systematically overestimates particle mass when effective density (ρ_{eff}) is used to determine particle mass. For smaller aerosol ($d_p < 80 \text{ nm}$) of mostly spherical shape ($\Sigma < 1.3$), the error is typically small and uncertainty in m_p will be accurate within 10%. However, for larger and more irregularly shaped aerosol, the uncertainty in m_p can be as large by up to a factor of 2

assuming density. Using multiple instruments with overlapping windows for size measurement can provide a more complete picture of aerosol size distribution, but measurements must be carefully seamed when instruments follow different measurement principles, which often results in slightly different definitions of particle diameter.

Aerosol counting and sizing instruments typically take advantage of light scattering of some form. For example, some instruments use light scattering to simply count particles, either irrespective of size or with a pre-measurement size selection, while others use scattering angles to derive size distributions. There are four

approaches to measuring and defining aerosol diameter, all of which make assumptions about the shape of sampled particles:

- Direct optical measurements detect size distributions as a function of *optical diameter* (d_o) uses light scattering and Mie theory to determine the size of the particle. Beyond assumptions about the shape of sampled particles, this approach also relies on assumptions about the refractive index. The refractive index of indoor aerosol can vary substantially from common calibration standards (Boedicker et al. 2021).
- Measurements that initially size select, and then count the resulting number of particles typically use differential mobility analyzers that define size distributions as a function of *electrical mobility diameter* (d_m). These separation techniques operate under atmospheric pressure, inducing the particle with a charge before moving the particle through a constant electric field. The size of particles that meet the criteria to pass through the electric field is determined from the force balance experienced by the charged particle between the constant electric field and the drag coefficient, which are dependent on particle shape (but not density). These techniques also typically assume that particles are only singly charged in the ionization system.
- Instruments that use the terminal falling speed (maximum velocity under atmospheric pressure) of particles provide size distributions based on *aerodynamic diameter* (d_a), which is a function of particle shape, size, and density. These distributions are derived from the time taken by individual particles to pass between two points, typically detected by light scattering by a pair of lasers. Measurements of aerodynamic diameter take place in a “continuum flow regime,” which is particularly effective for studying super-micron particles.
- Several newer instruments use the velocity of aerosol in a low pressure environment and thus provide distributions as a function of *vacuum aerodynamic diameter* (d_{va}). Size distributions in vacuum aerodynamic diameter are slightly different from aerodynamic diameter because the particles are in a transition or free molecular regime, rather than a continuum flow regime. These instruments have particle focusing lenses that dictate the size range and flow regime measured by the instrument. Aerodynamic measurements are functions of both density and particle shape.

It is important to remember that aerosol instruments are typically calibrated with spherical particles with a constant and known density. However, ambient aerosol can range from being simple spherical particles to large aggregates that are more challenging to define in physical diameter terminology. The physical particle diameter (d_p) is far simpler to define for a spherical particle than a nonspherical aggregate. More consistent definitions of particle size may be considered by the volume-equivalent particle diameter (d_{ve}), which represents the diameter of an irregular particle that is melted down to form a spherical particle while maintaining any internal voids, or the mass-equivalent diameter (d_{me}), which represents the mass but includes those internal voids (i.e., a particle with no internal voids would have a $d_{ve} = d_{me}$).

However, while d_{me} or d_{ve} may be more consistent across the irregularly shaped particles present in ambient air, these definitions do not correspond to direct measurements. For spherical particles $d_m = d_p = d_{ve}$; for irregularly shaped particles, d_m will always be biased to larger diameters ($d_m > d_{ve}$). Few studies test the underlying assumption that ambient aerosols are of consistent density and spherical shape, particularly in the indoor environment.

In considering how aerodynamic or vacuum aerodynamic diameter relates to volume equivalent particle diameter, one must consider both shape and density. Spherical particles have a proportional relationship between density and particle diameter:

$$d_a, d_{va} > d_{ve} \text{ for spherical aerosol with density greater than } 1.0 \text{ g/cm}^3$$

$$d_a, d_{va} < d_{ve} \text{ for spherical aerosol with density less than } 1.0 \text{ g/cm}^3$$

Increasing irregularity in particle shape (i.e., deviation from a spherical morphology) decreases both aerodynamic diameters:

$$d_a, d_{va} < d_{ve} \text{ for aerosol of unit density or lower with irregular particle shape}$$

$$d_a, d_{va} < \text{ or } > d_{ve} \text{ for aerosol of higher than unit density with irregular particle shape}$$

When density and shape assumptions are incorrect, datasets taken from different measurement approaches must be carefully considered to achieve self-consistent size distributions. DeCarlo, Slowik, and colleagues provide exceptional descriptions of the theory and application behind these comparisons (DeCarlo et al. 2004; Slowik et al. 2004). Figure 2 provides a flowchart to summarize steps in compare vacuum aerodynamic diameter to mobility diameter for two common instruments: the aerosol mass spectrometer (AMS), which measures vacuum aerodynamic diameter, and the scanning mobility particle sizer (SMPS), which measures electrical mobility diameter.

Overall, numerous instruments are capable of making particle size distribution measurements within different aerosol modes, although instruments typically only measure within about two decades of size range. However, care must be taken to understand the assumptions inherent in each measurement approach, particularly when synthesizing data into a single dataset or comparing size distributions of the same mode taken by different measurement approaches. Much of our understanding of these relationships and the importance of assumptions in influencing particle size measurements is driven by outdoor atmospheric chemistry studies. There is clearly great need to further test assumptions of particle shape and density in the indoor environment.

Chemical Measurement Techniques

Indoor aerosol composition is of emerging interest. While there is a strong history of particle collection for off-line measurements, real-time measurements of indoor

aerosol chemistry have emerged over the past decade. These measurements are typically grounded in techniques developed for outdoor atmospheric chemistry, and are summarized elsewhere (e.g., Farmer and Jimenez 2010; Pratt and Prather 2012). Most on-line aerosol composition measurements use mass spectrometry detection, although notable exceptions exist; for example, detection of oxidized nitrogen in particles by laser induced fluorescence (Rollins et al. 2012) following volatilization and thermal decomposition. This chapter focuses on the on-line aerosol composition techniques that have been applied to the indoor environment to illustrate principles of measurement. These instruments have typically measured aerosol composition for the entire population of particles within a given size range; single particle measurement techniques such as the aerosol time-of-flight mass spectrometer (ATOFMS) exist (Gard et al. 1997), but have yet to be applied to the built environment. This discussion is not an exhaustive compendium of techniques, in part because aerosol composition measurements are an active area of instrument development.

Aerosol composition measurements carry important restrictions; no on-line measurement detects the entire size range of ambient aerosol; inlet transmission and focusing lenses typically restrict the size window for analysis. Some techniques are further restricted by the method in which particles are transmitted into mass spectrometry detectors. Mass spectrometry requires analytes to be charged and in the gas phase. These requirements are particularly challenging for refractory material, including black carbon. Thus measurements that thermally volatilize aerosol to the gas-phase are usually considered non-refractory measures of aerosol composition, and separate measurements of refractory black carbon are required.

Bulk Aerosol Composition Measurements

Bulk composition measurements often use hard ionization coupled to mass spectrometry. These measurements are non-selective – that is, specific molecules are not identified because of the high degree of fragmentation induced by hard ionization. However, these techniques are typically considered quantitative, and provide an accurate mass of non-refractory aerosol. The Aerodyne Aerosol Mass Spectrometers and Aerosol Chemical Speciation Monitors have been widely used in indoor experiments (Avery et al. 2019; DeCarlo et al. 2018; Farmer et al. 2019b; Johnson et al. 2017; Dall’Osto et al. 2007; Klein et al. 2016; Joo et al. 2021). All of these instruments operate similarly, pulling air into the instrument through an aerodynamic particle lens, which focuses sub-micron aerosol ($d_{va} \sim 100\text{--}1000\text{ nm}$). This concentrated beam of aerosol passes through a differential pumping region; depending on the instrument, this pumping region can act as a particle time-of-flight tube that provides particle size information as the vacuum aerodynamic diameter. Particles then enter a vaporizer, where the non-refractory components are volatilized and ionized by electron ionization (70 eV). The resulting ions are dominated by fragments of the parent analytes,

and are detected by either a time-of-flight or quadrupole mass analyzer. The resolving power of the mass spectrometer depends on the instrument design; high resolution aerosol mass spectrometers usually have sufficient mass resolution ($m/\Delta m$ of ~ 4000) for elemental analysis of the peaks to directly determine the carbon, hydrogen, oxygen, and other heteroatoms in the aerosol. However, one specific challenge of applying aerosol mass spectrometry to indoor environments is establishing the relative ionization efficiency of indoor aerosol; indoor cooking organic aerosol shows an intriguingly high – but consistent – relative ionization efficiency (Katz et al. 2021).

Speciated Aerosol Composition Measurements

Where aerosol mass spectrometers use hard ionization and thus fragment aerosol components, soft ionization techniques minimize fragmentation and can provide molecular level information. For example, three instruments that have been used in indoor studies include: the semivolatile thermal desorption aerosol gas chromatography (SV-TAG) system (e.g., Lunderberg et al. 2020; Fortenberry et al. 2019), an extractive electrospray ionization mass spectrometer (EESI-MS) (Brown et al. 2021), and a high resolution time-of-flight chemical ionization mass spectrometer coupled to a filter inlet for gases and aerosols (FIGAERO-CIMS) (Brown et al. 2021). While instrument details are beyond the scope of this chapter, a few common principles are apparent. These measurements share the calibration challenges of the soft ionization systems used for gas phase measurements, and require careful consideration of instrument sensitivities for the range of analyte types being studied. The particle size range observed by these instruments is not as clear as the aerosol mass spectrometers with their aerosol lenses, so transmission efficiency and loss must be investigated based on inlet setups. These instruments are unable to provide size-resolved composition, but do provide molecular specification and, in the case of the FIGAERO-CIMS, profiles of volatility for each analyte.

Black Carbon

Black carbon measurements are typically optical in nature, and can include continuous filter measurements, laser-induced incandescence measurements, or thermal optical transmittance (Kondo et al. 2011). Each technique has advantages and disadvantages. For example, filter measurements can be subject to loading effects and humidity interferences in indoor environments (Sankhyan et al. 2021), although recent advances and careful operation may minimize these problems (Drinovec et al. 2015; Cai et al. 2013). Laser-induced incandescence measurements provide low detection limits with few interferences, and are capable of quantifying coatings on the black carbon particles but can have high maintenance needs.

Other Particle Measurements

Low cost sensors are not typically available for particle composition, but are available for PM_{2.5} mass and with some sizing information. While these measurements are becoming more widely used, care must be taken to account for different sensitivities to different types of aerosol, and there is need for addition work to validate measurement sensitivities for indoor air (Tryner et al. 2020; Wang et al. 2020d).

Instrument development for real-time, on-line measurement of coarse mode aerosol is a clear need for indoor chemistry. On-line bioaerosol measurements are scarce in indoor environments, but typically take advantage of fluorescent properties of biological particles combined with aerodynamic particle sizers (e.g., Tian et al. 2021).

Outdoor atmospheric chemists frequently couple on-line particle measurements with assessment of chemical or physical properties. For example, coupling measurements of aerosol size distribution and composition with thermal denuders enables measurements of particle volatility, while measurements of particle size distributions with and without dryers can provide aerosol liquid water content metrics. However, such measurements have not yet been widely deployed in indoor environments.

New Frontiers

Decades of instrument development for atmospheric chemistry research has provided an excellent opportunity for the field of indoor chemistry. These techniques enable not only quantitative, real-time measurements of indoor air gases and particles, but also intensive properties of those gases and particles. Emerging frontiers in analytical indoor chemistry include:

- Surface measurements. Surfaces play an integral role in the chemistry of the built environment: as mediators of gas concentrations through partitioning, as reservoirs for chemical compounds, and as sites for reactions. However, these surfaces are poorly characterized. Most existing techniques typically require surface sample collection for off-line analysis, but on-line measurement techniques would be exceptionally useful for improving our understanding of indoor chemistry.
- In situ chemical kinetics experiments that directly explore the rate constants of gases with oxidants (e.g., OH reactivity) have been useful in outdoor atmospheric chemistry to provide bounds on reactive carbon budgets. Such measurements would quantitatively describe the scope of indoor air composition, as well as the potential for indoor oxidation reactions and secondary organic aerosol formation. However, deployment of these measurements to indoor environments warrants caution as the substantial complexity and high concentrations present in indoor environments produce potential interferences. For example, OH reactivity measurements must account for interferences from NOx species, which rapidly change during cooking events.

- Low cost sensors have become more widely available and are essential for capturing spatial heterogeneity; both within single buildings and across multiple buildings and regions. However, these sensors are often subject to interferences and nuances that may be considered before widespread application to indoor chemistry research.
- The desire to link indoor chemistry to human health requires development of oxidative stress measurements. While such measurements have been used effectively in outdoor environments, they have not been extensively deployed in indoor environments, but present a unique opportunity.

Conclusion

The indoor environment is ripe for detailed chemical analysis. Most research to date has involved careful sample collection and off-line analysis, but recent work has increasingly transferred on-line measurements designed for outdoor atmospheric chemistry to indoor air. Due to the chemical complexity of indoor air, all indoor chemistry measurements require careful consideration of interferences and calibration sensitivity. There are many on-line, real-time instruments available to deploy in indoor environments from the field of atmospheric chemistry, and their successful implementation and careful consideration of analytical challenges will ensure new insights into the field of indoor chemistry.

Abstract

Indoor chemical processes can be successfully modeled using a variety of techniques. At the center of much indoor chemical process modeling is the mass or concentration balance, which can be used in single- or multizonal well-mixed models to predict the transient evolution of gas- and particle-phase species. This chapter first outlines the basic framework to simulate gas-phase chemical reactions, with a focus on ozone-driven reactions and the subsequent formation of

hydroxyl radicals (OH) indoors. Then, indoor particle chemical modeling is described, with a focus on predicting indoor secondary organic aerosol (SOA) formation. Finally, surface-phase reaction frameworks are presented, with a focus on modeling byproducts due to oxidant deposition and understanding surface reaction processes themselves. In each section, we also highlight relevant indoor air literature articles that provide richer detail.

Introduction

Previous chapters in this section have discussed the state of knowledge of various aspects of indoor chemistry, such as gas-phase chemistry, surface chemistry, aerosol chemistry, among others. The majority of the understanding in those chapters was the result of experimental or observational investigations. This chapter instead relays basic information on indoor chemistry modeling techniques. Modeling is an effective tool to further our understanding of indoor chemical processes (Shiraiwa et al. 2019). It can serve many functions, including investigating processes under a wide range of parameters not practical in experiments or testing the agreement between modeled and measured values so as to confirm process understanding.

This chapter on indoor chemistry modeling functions as a primer and is generally organized into the following categories: box model for indoor air pollutants, gas-phase chemistry modeling, particle-phase chemistry modeling, and surface-phase chemistry modeling (computational fluid dynamics (CFD) modeling example). In each section, typical methods of modeling are described, and important papers in the literature are highlighted.

Box Model for Indoor Air Pollutants

Indoor pollutant concentrations in the gas or particle phase may be computed with a box model, which assumes that the pollutants from outdoors or emitted indoors are uniformly mixed within a volume of indoor air (Nazaroff and Alvarez-Cohen 2001). Species concentrations are thus spatially homogeneous but can change in time. The box model framework is the most commonly used framework for indoor chemistry investigations since, in essence, a modeler must choose between modeling chemical complexity with a box model or spatial complexity with other methods. Lately, however, CFD has been used to simulate certain simple chemical situations which are likely to exhibit spatial variation, as discussed later in this chapter.

In the context of indoor air in a building, the box model framework can be applied to a single-zone or multi-zone paradigm. In a building, a zone is often defined as a space within the building that has different characteristics than other zones in the

buildings. For instance, zones can be due to physical separations in buildings, or zones are often dictated by heating, ventilation, and air-conditioning system (HVAC) design such that a zone is group of spaces that share common air distribution and thermal control settings.

For the case of indoor air in a single zone, the change in any generic concentration of gas-phase component i with time can be represented with a concentration balance for the change in concentration of any species, C (e.g., ppb, #/cm³, or µg/m³), with respect to time, t (h):

$$\frac{dC}{dt} = S - lC \quad (1)$$

where the resulting concentration is established by a combination of a total source, S (e.g., pph/h, #/cm³-h, or µg/m³-h), and total loss rate, l (h⁻¹), in the indoor environment (Nazaroff and Cass 1986, 1989).

Equation (1) can be solved in a transient manner in an analytical or numerical fashion, or at steady state. For the case with parameters that are set at constant values over time (except the concentration being computed), the analytical solution to Eq. (1) is:

$$C(t) = C_{(t=0)} e^{-lt} + \frac{S}{l} (1 - e^{-lt}) \quad (2)$$

where $C(t)$ is the species concentration of interest over time, and $C_{(t=0)}$ is the initial concentration at the time zero datum. In Eq. (2), the first term on the right-hand side represents the decay of any species concentration that is present at time zero when modeling commences, and the second term on the right-hand side represents the change in the species concentration indoors due to active sources from the onset of the time horizon of interest (with those additions also being acted on by current losses in the system).

For the case of parameters on the right-hand side of Eq. (2) not being constant and changing during the time horizon of interest, Eq. (2) can still be used, but one must conceive the time zero datum as changing throughout the time horizon with discrete time steps imposed so that the previous time step is effectively treated as the initial concentration, $C_{(t=0)}$. Otherwise, a more formal numerical solution to solving first-order ordinary differential equations (ODE) can be used, such as the Euler, midpoint, or Runge-Kutta methods.

When parameters in Eq. (1) are constant over a long enough time horizon, the solution approaches its steady-state value, meaning it reaches a constant value that does not change in time anymore. The steady-state solution can be determined by setting the differential term $dC/dt = 0$ in Eq. (1) and rearranging to solve for C , or by substituting $t = \infty$ in Eq. (2) and simplifying it. Either method yields the steady-state concentration, C_{ss} , as in Eq. (3):

$$C_{ss} = \frac{S}{l} \quad (3)$$

Whether a modeler should use time-varying or steady-state assumptions to predict the concentration of interest depends on the interplay between the total loss rate and the amount of elapsed time since the values for the source and loss conditions were at a constant condition. For instance, the time to reach any fraction of the steady-state concentration once constant conditions begin is given by Eq. (4):

$$t_{f,ss} = \frac{\ln(1-f)}{-l} \quad (4)$$

where f is a factor bounded between (0.1) and represents the fraction of which a concentration compares to the eventual steady-state value. As Eq. (4) demonstrates, $t_{f,ss}$ is a function of the total loss rate alone, so the time to approach to 0.95 or 0.99 of a steady-state concentration is $t_{0.95,ss} = 3.0/l$ or $t_{0.99,ss} = 4.6/l$. Consider an example in which source and loss conditions of ozone in a building were constant for 30 min (i.e., 0.5 h), and ozone had a total loss rate of 4 h^{-1} . In this case, the $t_{0.95,ss} = 0.75 \text{ h}$ and $t_{0.99,ss} = 1.15 \text{ h}$, so the ozone would not be at steady state and the transient solution should be used. However, if conditions had been constant for, say, 2 h then using a steady-state equation to compute the ozone concentration would be appropriate.

Furthermore, multizonal models are a group of single-zone models that have linkages between zones based on interzonal airflow rates. Modelers can write their own code to facilitate solutions or can use software meant for such purposes. For instance, a multizonal indoor air modeling program called CONTAM has been developed by NIST, which accounts for pressure-driven flow among zones (Dols and Polidoro 2020). This chapter does not discuss multizonal modeling explicitly. The following sections expand on using the single-zone box model for gas-, particle-, and surface-phase modeling.

Modeling Gas-Phase Chemistry

General Gas-Phase Chemistry Concentration Balance

Equation (1) can be cast in a form including relevant parameters for considering gas-phase modeling within a single zone. Let us discuss a few reactions so as to demonstrate the model framework, centered around simulating the fate of a generic molecule F. Consider F that can be generated indoors by a biomolecular reaction, such that:

In reaction R1, a molecule G reacts with a molecule H to yield a molecule F. The reaction R1 also contains a parameter y_F , called the molar yield of F, which is often unity or integer values for simple reactions but can be fractional if the reaction between G and H produces more than one molecular outcome from a branching

standpoint. Moreover, consider that F can be removed from the indoor air by reaction with another molecule J, such that:

In reactions R1 and R2, ellipses are shown as potential products because we are only concerned about the fate of F in this example, and not other products.

Considering R1 and R2, the concentration balance in Eq. (1) can be expanded into a framework accounting for those generic reactions to model the concentration of species F, C_F (ppb), with respect to time, t (h), as in Eq. (5) (Nazaroff and Cass 1986):

$$\frac{dC_F}{dt} = P_F + \lambda C_{F,out} + \frac{E_F}{V} - r_F C_F - \lambda C_F - v_{d,F} \frac{A}{V} C_F \quad (5)$$

where the terms in Eq. (5) that correspond to gas-phase chemistry are P_F (ppb/h), which is the formation rate of F due to gas-phase reactions of G + H (as in R1), and r_i (h^{-1}), which is the loss rate of F due to gas-phase reactions with J (as in R2). Also, $C_{F,out}$ (ppb) is the concentration of species F in outdoor air; λ (h^{-1}) is the air exchange rate of indoor with outdoor air, which is the volumetric air flow through the building, Q (m^3/h), normalized by volume, V (m^3); E_F/V (ppb/h) is the volume-normalized emission rate of species F; $v_{d,F}$ (m/h) is the deposition velocity of species F to indoor surfaces; and A (m^2) is the surface area indoors.

On the right-hand-side of Eq. (5), the first positive term is the source of formation rate of F by gas-phase reactions (P_F), and the first negative term is the loss of F by gas-phase reactions (r_F). Besides these processes, C_F may be influenced by other mechanisms. In Eq. (5), the other two sources of F are transport from outdoors to indoors and indoor emission, respectively; the other two losses are loss to outdoors with air exchange and irreversible reaction on indoor surfaces (this mechanism is discussed in detail below). Other processes could be included in Eq. (5), such as including sorptive effects of volatile compounds on building surfaces (Singer et al. 2004), or modeling different types of air exchange mechanisms, but these are omitted in this section for brevity (section on particle chemistry includes different air exchange mechanisms since particles have different losses in each type of air stream).

The specific formulation for the term in Eq. (5) of the gas-phase chemistry formation rate for the concentration C_F due to R1, P_F (ppb/h), is as in Eq. (6):

$$P_F = y_F k_{G-H} C_G C_H \quad (6)$$

where y_F is molar yield of F due to reactions between species G and H; k_{G-H} ($\text{ppb}^{-1} \text{h}^{-1}$) is the biomolecular reaction rate constant between species G and H; and C_G and C_H (ppb) are concentrations of species G and H. The reaction rate constant quantifies the rate and direction (positive or negative) of a chemical reaction, is typically first or second order for indoor air reactions, and is a strong function of temperature (Seinfeld and Pandis 2016).

The specific formulation for the term in Eq. (5) of the gas-phase chemistry loss rate for the concentration C_F due to R2, r_i (h^{-1}), is as in Eq. (7):

$$r_F = k_{F-J} C_J \quad (7)$$

where k_{F-J} ($\text{ppb}^{-1} \text{ h}^{-1}$) is the biomolecular reaction rate constant between F and J; and C_J (ppb) is the concentration of species J. Though this example focuses on only two reactions R1 and R2, multiple reactions can sometimes act on the same species indoors. In cases like this, the total formation rate and total loss rate can be modeled as the summation of the individual formation or loss rates, respectively. Moreover, sometimes modeling cases multiple differential equations that are joined by reaction parameters.

In Eqs. (5), (6), and (7), the concentrations, emissions, and rate constants are expressed in terms of mole fractions (e.g., ppb), but they may be expressed as alternative concentration units, such as molec/cm^3 or $\mu\text{g/m}^3$, where conversion between units requires the use of the ideal gas law with Avogadro's number and/or molecular weights. For different concentration units, the reaction rate constants must have their units translated as well, for example, $\text{cm}^3/\text{molec-s}$ and $\text{m}^3/\mu\text{g-h}$.

Simulating Important Gas-Phase Chemical Reactions

Indoor gas-phase chemistry is diverse and situation dependent, so this section discusses relevant reactions and parameters for modeling common situations, including the oxidation of volatile organic compounds (VOCs), the generation of hydroxyl radicals (OH), and reactions involving nitrogen oxides (NO_x). Primary oxidants indoors that react with VOCs are ozone (O_3), the hydroxyl radical (OH), and the nitrate radical (NO_3) under certain conditions.

Indoor ozone chemistry drives many chemical pathways, and indoor ozone concentrations are often at 20–70% of ambient values (Weschler 2000). Ozone reacts with alkenes, which are unsaturated organic molecules containing carbon–carbon double bonds. The most dominant indoor alkenes are terpenoids, which are unsaturated compounds consisting of two or more isoprene units. Reaction rates of ozone with many indoor-emitted terpenoids have been determined, such as those for d-limonene, α - and β -pinene, and α -terpineol (Atkinson 2000; Wells 2005). In situations with strong terpenoid emissions, such as with the use of cleaners or air fresheners (Nazaroff and Weschler 2004), a few terpenoids such as d-limonene or α -terpineol can dominate the indoor ozone total reactivity (Waring and Wells 2015).

When ozone reacts with alkenes, the Criegee mechanism commences, in which a primary ozonide is formed that cleaves to yield a carbonyl and an excited Criegee intermediate (CI^*) (Atkinson and Arey 2003; Criegee 1975). The CI^* can form a stabilized Criegee intermediate (SCI) that follows multiple reaction pathways (the “SCI channel”), or it can rearrange and decompose to form an alkyl radical ($\text{R}\cdot$) and OH (the “hydroperoxide channel”) (Kroll and Seinfeld 2008). Therefore, reactions of ozone and alkenes (and so especially of ozone and terpenoids) are often the most

dominant source of OH indoors, since OH is not meaningfully sourced from outdoors due to its short lifetimes (Weschler and Shields 1996).

For many years, ozone-alkene reactions were thought to be the only OH source indoors. However, another recently discovered indoor source of OH that can sometimes be meaningful is the photolysis of nitrous acid (HONO) by indoor light at wavelengths ≤ 405 nm (Gómez-Alvarez et al. 2013). HONO can be formed indoors from combustion processes or by nitrogen dioxide (NO_2) hydrolysis on indoor surfaces (Spicer et al. 1993). Indoor light at these wavelengths is due to the attenuation of sunlight through windows or due to the use of indoor light fixtures (J. Young et al. 2019; Kowal et al. 2017).

The source of the nitrate radical (NO_3) indoors is from ozone reactions with NO_2 to yield NO_3 and O_2 . Once NO_3 is formed, the NO_3 and remaining NO_2 coexist in equilibrium with dinitrogen pentoxide (N_2O_5) (Atkinson 2000; Weschler et al. 1994). NO_3 is quite difficult to measure. However, concentrations are estimated at an upper bound of ~ 1 ppt (Nøjgaard 2010), though it may be most often at $\sim 10^{-2}$ ppt indoors.

Ozone reactions with alkenes and also OH or NO_3 reactions with any VOC forms alkyl radicals ($\text{R}\cdot$) that will react with O_2 to yield hydroxy radicals ($\text{HO}_2\cdot$) and peroxy radicals ($\text{RO}_2\cdot$). These radicals react with other species to form alkoxy radicals ($\text{RO}\cdot$) or compounds such as alcohols, carbonyls, carboxylic acids, and hydroperoxides, or also organic or peroxy nitrates (Atkinson and Arey 2003; Kroll and Seinfeld 2008). The less functionalized and lower-molecular-weight compounds are more volatile and tend to exist in the gas, while the more functionalized and higher-molecular-weight ones are less volatile and tend to exist in the particle phase.

Other reactions involving oxides of nitrogen are important indoors. One very fast reaction is that of ozone with nitric oxide (NO) to yield NO_2 and O_2 , which dominates ozone reactions and also titrates all ozone if enough NO is present indoors. Also, if NO is present, it can react with $\text{HO}_2\cdot$ radicals to yield OH and NO_2 . This reaction serves to essentially “recycle” OH radicals, since OH reactions themselves can lead to the formation of $\text{HO}_2\cdot$ radicals. Additionally, OH reacts with NO to yield HONO, which can photolyze to reform OH and NO; OH reacts with NO_2 to yield the NO_3 radical and O_2 ; and OH reacts with HONO to yield NO_2 and water vapor.

These reactions, and all that have been discussed in this section, are summarized in Table 1, along with rate constants at a temperature of 298 K. Moreover, Table 2 shows a list of volatile alkenes from residences (Logue et al. 2011), along with rate constant data at 298 K and OH molar yields from ozone + alkene reactions. In Table 2, the alkenes are ranked from most reactive to least reactive with ozone. Many other reactions are important indoors. For seminal examples in the indoor chemistry literature of gas-phase modeling with detailed chemical mechanisms, see papers by Carslaw (2007) and Sarwar et al. (2002).

To conclude this section, we end with an example on modeling OH concentrations indoors, which was similarly performed by Weschler and Shields (1996) in a seminal paper that argued for the presence of OH indoors owing to ozone + alkene reactions. Following the basic gas-phase reaction framework in R1 and R2 above,

Table 1 Reactions discussed in this section and their rate constants at temperature of 298 K

No.	Reaction	Rate constant	Source
R3	$O_3 + \text{alkene}_i \rightarrow OH + \text{other radicals} + \text{stable products}$	Table 2	1
R4	$O_3 + NO \rightarrow NO_2 + O_2$	$k_{O_3-NO} = 1.6 \text{ ppb}^{-1} h^{-1}$	2
R5	$O_3 + NO_2 \rightarrow NO_3 + O_2$	$k_{O_3-NO_2} = 0.0028 \text{ ppb}^{-1} h^{-1}$	2
R6	$OH + VOC_i \rightarrow \text{other radicals} + \text{stable products}$	Table 2	1
R7	$OH + NO + M \rightarrow HONO + M$	$k_{OH-NO} = 2800 \text{ ppb}^{-1} h^{-1}$	2

Oxidant + alkene reaction rates from Atkinson (2000) and Master Chemical Mechanism v3.2, and molar yields for OH from Weschler and Shields (1996), with some estimated

the Weschler and Shields (1996) paper estimated OH in a low NO_x environment and only considered reactions R3 and R6 in Table 1. Further, due to its short lifetime indoors of about 1/10 of a second, OH can be computed as achieving as pseudo

steady-state concentration using concepts in Eqs. (5), (6), and (7), resulting in Eq. (8):

$$C_{\text{OH,ss}} = \frac{\lambda C_{\text{OH,out}} + C_{\text{O}_3} \sum y_{\text{OH,alk}} k_{\text{O}_3-\text{alk}} C_{\text{alk}}}{\lambda + v_{d,\text{OH}} \frac{A}{V} + \sum k_{\text{OH-VOC}} C_{\text{VOC}}} \quad (8)$$

The steady-state formulation in Eq. (8) contains sources of OH in the numerator and losses in the denominator (with general form as in Eq. (3)). The source of OH from outdoor air is shown, but it is negligible compared with that due to the totality of reactions of ozone with all alkenes indoors. The losses of OH of air exchange and surface deposition are also shown, but they are also practically negligible as compared to the loss of OH with reactions of VOCs indoors. Using an expression like this one with typical indoor alkene and VOC concentrations, Weschler and Shields (1996) estimated indoor OH concentrations at $\sim 10^5$ – 10^6 molec/cm³.

Modeling Indoor Particulate Matter Concentrations

General Particulate Matter Concentration Balance

The next few sections focus on the modeling of physical and chemical processes pertaining to particles in indoor environments. Particles are composed of organic and inorganic constituents that exist in a state of dynamic equilibrium between gas and particle phases, so aerosol mass is impacted by gas- or particle-phase reactions that cause chemical evolution of the aerosol and/or changes in thermodynamic states (e.g., temperature). Before discussing chemical transformation of aerosols, this section first outlines the modeling of particles considered as static entities (i.e., no phase change), offering an initial framework for elaboration.

Similar to the gas-phase chemistry modeling section above, Eq. (1) can be cast in a form indicative of parameters for the modeling of a well-mixed, static particle concentration, C_P ($\mu\text{g}/\text{m}^3$), with respect to time in a single zone, as shown in Eq. (9) (Nazaroff and Cass 1989):

$$\frac{dC_P}{dt} = s_{P,\text{out}} C_{P,\text{out}} + \frac{E_P}{V} - l_{AE} C_P - v_{d,P} \frac{A}{V} C_P \quad (9)$$

where $s_{P,\text{out}}$ (h^{-1}) is the source rate of outdoor particles, l_{AE} (h^{-1}) is the total loss rate due to all air exchange rates, and other parameters are analogous to previous equations but for particle concentrations. The parameters $s_{P,\text{out}}$ and l_{AE} account for an expanded air exchange framework from that shown in the gas-phase chemistry concentration balance in Eq. (5), since particle loss rates differ by airflow type (and different building types have different airflow types).

The parameter $s_{P,\text{out}}$ accounts for the various outdoor particle introduction possibilities with outdoor air exchange mechanisms, as shown in Eq. (10):

$$s_{\text{P,out}} = (1 - \eta)\lambda_{\text{mv}} + p\lambda_i + \lambda_{\text{nv}} \quad (10)$$

where λ_{mv} , λ_i , and λ_{nv} (h^{-1}) are mechanical ventilation, infiltration, and natural ventilation air exchange rates, respectively; η is the filtration efficiency; and p is the penetration of particles through the building envelope. Similarly, the l_{AE} parameter accounts for various losses due to air exchange mechanisms, as shown in Eq. (11):

$$l_{\text{AE}} = \lambda_{\text{mv}} + \lambda_i + \lambda_{\text{nv}} + \eta\lambda_r \quad (11)$$

where λ_r (h^{-1}) is the recirculation air exchange rate, and the product of η and λ_r is the loss rate by filtration in the recirculation air. Equation (9) can be written in terms of concentration of bulk particle mass ($\mu\text{g}/\text{m}^3$) or in terms of particle number ($\#/ \text{cm}^3$) on a number- or size-resolved basis (El Orch et al. 2014; Nazaroff 2004; Riley et al. 2002).

Simulating Indoor Secondary Organic Aerosol

Equation (9) is written for static particles sourced from outdoors or indoor emissions that do not undergo phase transformations. However, this chapter focuses on indoor chemistry modeling, so we now discuss modeling secondary organic aerosol (SOA), which is the most studied aspect of indoor chemistry with respect to particles. Organic aerosol is a system of compounds, ranging in volatility over many orders of magnitude, that are in a state of dynamic equilibrium between gas and particle phases. SOA is formed following oxidation of VOCs, generated when functionalized, low-volatility products like acids or peroxides undergo net partitioning from the gas-to-particle phase, thereby increasing OA mass. Indoors, SOA is likely most often due to reactions of ozone and terpenoids (Waring 2014).

Considering a particle population of only indoor formed SOA, a concentration balance for SOA, C_{SOA} ($\mu\text{g}/\text{m}^3$), with respective to time, t (h), as in Eq. (12):

$$\frac{dC_{\text{SOA}}}{dt} = P_{\text{SOA}} - l_{\text{AE}}C_{\text{SOA}} - v_{\text{d,SOA}} \frac{A}{V} C_{\text{SOA}} \quad (12)$$

where P_{SOA} ($\mu\text{g}/\text{m}^3\text{-h}$) is the source of net formation of SOA, and all other variables are the same or analogous to that in Eq. (9). The indoor-SOA formation rate can be modeled at various levels of complexity. As an example, for the reaction between concentrations of ozone, C_{O_3} (ppb), and a terpenoid, C_{terp} (ppb), the simplest way to represent P_{SOA} is:

$$P_{\text{SOA}} = Y_{\text{SOA}} k_{\text{O}_3-\text{terp}} C_{\text{O}_3} C_{\text{terp}} \Gamma_{\text{terp}} \quad (13)$$

where Y_{SOA} (–) is the SOA yield, and Γ_{terp} ($(\mu\text{g}/\text{m}^3)/\text{ppb}$) is a temperature-dependent conversion factor change units of the terpenoid from units of mixing ratio to mass concentration (Waring 2014; Youssefi and Waring 2012). By knowing Y_{SOA} along

with the reactant concentrations and the reaction rate constant between them, SOA formation can be estimated.

However, using a correct SOA yield, Y_{SOA} , for SOA formation is less straightforward than using a molar yield for product formation due to a single chemical reaction (e.g., y_F in R6). The earliest version of the SOA yield follows a format presented in the seminal paper, Odum et al. (1996), which derived a framework that builds upon the concept of absorptive partitioning theory developed by Pankow (1994a, 1994b), as in Eq. (14):

$$Y_{\text{SOA}} = \frac{\Delta C_{\text{SOA}}}{\Delta \text{ROG}} = C_{\text{OA}} \sum_i \left(\frac{\alpha_i K_{\text{gp},i}}{1 + K_{\text{gp},i} C_{\text{OA}}} \right) \quad (14)$$

where Y_{SOA} is defined as in the first equality as the change in SOA concentration, ΔC_{SOA} ($\mu\text{g}/\text{m}^3$), divided by the change in the reactive organic gas concentration, ΔROG ($\mu\text{g}/\text{m}^3$). The second equality in Eq. (11) was derived by Odum et al. (1996) and demonstrates that Y_{SOA} can be expressed as the summed effect of gas-to-particle partitioning of a set of individual reaction products, i , resulting from any organic gas oxidation. In that equality, C_{OA} ($\mu\text{g}/\text{m}^3$) is the concentration of any organic aerosol (i.e., not only SOA); α_i is the fractional mass yield of product i of the total ROG reacted; and $K_{\text{gp},i}$ ($\text{m}^3/\mu\text{g}$) is the gas-to-particle partitioning coefficient of product i to the OA phase at equilibrium.

As shown in Eq. (14), Y_{SOA} increases with the total organic particle concentration (C_{OA}), which includes any background OA in addition to the formed SOA, so Y_{SOA} is not a constant value, and yield curves vary non-linearly when the SOA or OA concentration changes. Yield curves are fit to data from SOA formation chamber experiments. Early papers fit data to Eq. (14) by assuming formation was attributable to just two hypothetical products (Griffin et al. 1999; Hoffmann et al. 1997; Odum et al. 1996)—with one being an average of lower-vapor-pressure compounds and the other being an average of higher-vapor-pressure compounds. However, this “two-product” approach was problematic because its parameters have high covariance (Presto and Donahue 2006) and fitted parameters could vary widely for the same SOA formation dataset.

To overcome this issue, Donahue et al. (2006) developed the “volatility basis set” (VBS) approach, which allows more hypothetical products but sets the volatility parameters for those products (represented by the $K_{\text{pg},i}$ in Eq. (14)) based on spacing organic matter product bins in a logical, constrained manner. In the VBS, the volatility parameter of choice is the effective saturation concentration, c_i^* ($\mu\text{g}/\text{m}^3$), which is the concentration above which condensation will occur (where $c_i^* = 1/K_{\text{pg},i}$). In the VBS, the SOA yield is typically called the aerosol mass fraction, ξ or AMF, and so Eq. (14) can be recast as Eq. (15):

$$\xi = \frac{\Delta C_{\text{SOA}}}{\Delta \text{ROG}} = \sum_i \alpha_i \xi_i = \sum_i \alpha_i \left(1 + \frac{c_i^*}{C_{\text{OA}}} \right)^{-1} \quad (15)$$

Table 3 Mass yields (α_i) over four c_i^* bins for common terpenoids for use in Eq. (15)

	$\log_{10}c^*$			
Terpenoid ¹	0	1	2	3
d-Limonene UB	0.34	0.28	0.32	0.59
d-Limonene	0.096	0.039	0.096	0.18
α -Pinene	0.055	0.09	0.12	0.18
β -Pinene	0.044	0.072	0.12	0.22
Camphepane	0.032	0.052	0.12	0.2
α -Terpinene	0.045	0.073	0.12	0.21
$\Delta 3$ -Carene	0.04	0.066	0.1	0.16

Mass yields from Lane et al. (2008); Waring (2014, 2016)

The VBS constrains the c_i^* bins at logarithmic spacing, for example, $c_i^* = (0.01, 0.1, 1, 10, 100, 1000 \mu\text{g}/\text{m}^3)$, and the number of bins can change depending on the data or application. Now, SOA formation chamber data is parameterized by only fitting α_i for each c_i^* bin.

Table 3 shows VBS data for SOA formation due to ozonolysis of select terpenoids, including the mass-based yields (α_i) over four c^* bins spanning 1 to $10^3 \mu\text{g}/\text{m}^3$. Each terpenoid has one set of α_i , except for d-limonene because unlike the other terpenoids it has two double bonds instead of one double bond. So, d-limonene mass yields fall between an upper and a lower bound (UB, LB), dictated by whether the reaction is ozone or limonene limited. Waring (2016) developed a parameterization of the AMF for d-limonene using UB and LB AMF values as a function of the initial ozone/limonene ratio and air exchange rate (see that paper for further details).

Volatility is a function of temperature, since higher temperatures increase vapor pressures of organic compounds. The VBS allows the shifting of c_i^* bins to account for any temperature likely to be encountered indoors with the Clausius-Clapeyron equation, as in:

$$c_i^*(T_{298 \text{ K}}) = c_i^*(T) \frac{T_{298 \text{ K}}}{T} \exp \left(\frac{\Delta H_i}{R} \left(\frac{1}{T_{298 \text{ K}}} - \frac{1}{T} \right) \right) \quad (16)$$

where $c_i^*(T_{298 \text{ K}})$ is the c_i^* at a reference temperature of 298 K; ΔH_i (kJ/mol) is the enthalpy of vaporization for product bin i , which has been parameterized as $\Delta H_i = -11 \times \log_{10}(c_i^*) + 129$ (Epstein et al. 2010); and R (kJ/K-mol) is the ideal gas constant. AMF values are typically reported for an assumed density of 1 g/cm³, and this so-called unit-density (ρ_{unit}) AMF can account for an actual measured or modeled density (ρ) by scaling it by ρ/ρ_{unit} .

The AMF approach (and SOA yield before it) is by far the most common way to model SOA formation in the indoor (and outdoor) air literature. For more details on this method, please see the papers Youssefi and Waring (2012) and Waring (2014). However, another approach has been used in conjunction with models that explicitly model chemical mechanisms (Carslaw et al. 2012; Sarwar et al. 2003; Sarwar and Corsi 2007). These papers predict a large set of organic products yielded by VOC oxidation (e.g., 100 s) and then predict kinetic partitioning of each compound to the

organic particle phase using the equilibrium partitioning parameter, $K_{\text{pg},i}$, and expressions to convert $K_{\text{pg},i}$ to absorption and desorption kinetic partitioning parameters. See those referenced papers for more details on this alternative method.

Simulating Indoor Organic Aerosol

All organic aerosols (OAs), not just SOA, exist as a system of 100 s or 1000 s of compounds in a state of dynamic equilibrium, with relative fractions of each compound in the gas versus particle phase determined by their volatility, which span over ten orders of magnitude from semivolatile to extremely low-volatile compounds (Seinfeld and Pandis 2016). Changes in thermodynamic state variables such as the temperature and relative humidity (RH) can cause net re-partitioning to occur, and so the relative fractions in gas versus particle phase will redistribute.

The VBS approach was introduced in the previous section to model SOA formation indoors. However, the VBS framework can also be used to model any OA type by lumping the entirety of the available organic material (OM) that can partition, no matter the source of the OM, into the set of log-spaced volatility bins constrained at log-spaced intervals of c^* . With any OM VBS, the partitioning can be predicted with a more general form of Eq. (15), as in Eq. (17):

$$\xi_i = \left(1 + \frac{c_i^*}{C_{\text{OA}}} \right)^{-1} \quad C_{\text{OA}} = \sum_i \xi_i C_{\text{OM},i} \quad (17)$$

where $C_{\text{OM},i}$ ($\mu\text{g}/\text{m}^3$) is the indoor OM mass concentration at a particular c_i^* , considering the total OM in both gas and condensed OA phases (Donahue et al. 2006). Equation (17) must be solved iteratively for C_{OA} . The total indoor $C_{\text{OM},i}$ in each bin is the sum of any OM present due to all OA factors, which considered together yield a single AMF and absorbing OA mass indoors.

As stated, the VBS considers the presence of multiple OA factors indoors, where each OA factor is the result of a different source. OA factors can be resolved from measurements with aerosol mass spectrometry (AMS) using positive matrix factorization (Cappa and Jimenez 2010). For instance, ambient OA resolves into VBS factors of hydrocarbon-like OA (HOA, a surrogate for freshly emitted OA due to anthropogenic activity), biomass burning OA (BBOA, a surrogate for OA associated with combustion and woodsmoke), oxygenated OA (OOA, a surrogate for SOA formed by reactions in the atmosphere), among others. This OOA can be further resolved into semivolatile (SV-OOA, surrogate for OOA that is fresh due to recent reactions) and low-volatility (LV-OOA, surrogate for OOA that is older and aged) subsets. Furthermore, indoor VBS OA factors can include those from cooking OA (COA, surrogate for OA due to cooking activities) or indoor-SOA (SOA-in, surrogate for OA due to chemical reactions occurring indoors). VBS profiles for some of these OA factors are demonstrated in Fig. 1.

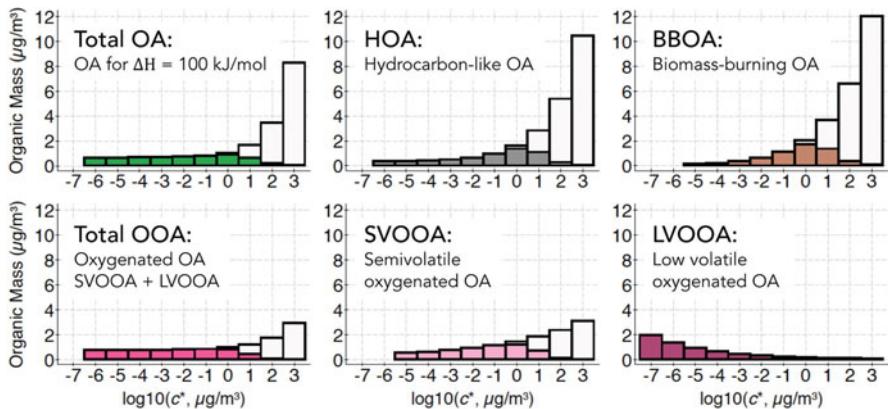

Fig. 1 Volatility basis set (VBS) profiles for organic material (OM) for six different OA factors, with each scaled to realize an OA concentration of $6 \mu\text{g}/\text{m}^3$ (from Cappa and Jimenez 2010)

Figure 1 was constructed using outdoor OM profiles determined from AMS measurements along with a thermodenuder during the MILAGRO outdoor air quality study in Mexico City (Cappa and Jimenez 2010). In Fig. 1, there are 11 c^* bins for OM that range in volatility \log_{10} spaced from 10^{-7} to $10^3 \mu\text{g}/\text{m}^3$. Cappa and Jimenez (2010) provided exponential fits that describe the VBS shapes of the OM distributions as a function of c^* , and those were used to scale the total OM such that the partitioning Eq. (9) yielded a COA for each VBS case of $6 \mu\text{g}/\text{m}^3$. As defined, the lower-volatility OM has an AMF of unity and resides totally in the particle phase, while the high-volatility OM is in the gas phase. When a bin's c^* equals the OA concentration, the OM is half in the gas and half in the particle phase.

The VBS approach outlined so far is also called the one-dimensional VBS (or 1D-VBS), since it organizes the OM into bins based on only one parameter, c^* . Therefore, all of the individual compounds comprising the OM with a particular volatility are lumped into the appropriate c^* bin without any information about the molecular properties or chemical composition. This approach is rather coarse, since, for example, OM in a higher-volatility c^* bin could comprise fresh, unoxidized HOA or low-molecular-weight, highly oxidized compounds.

To resolve this issue and provide more detail, a second-generation VBS framework was developed, called the two-dimensional VBS (or 2D-VBS), which allows tracking and accounting of the average chemical composition of OM in each c^* bin. In addition to organizing compounds by volatility (c^*) alone, the 2D-VBS adds a second organizing dimension of degree of oxygenation, which is parameterized by the ratio of oxygen atoms to carbon atoms (O:C) or average oxidation state (Donahue et al. 2011, 2012). Though the partitioning of the OM into the OA phase is still only a function of c^* alone in the 2D-VBS, the knowledge of the fractional amount of OM with a particular O:C in each c^* bin allows the calculation of other aerosol parameters, such as aerosol density, water content, or phase state

(Cummings et al. 2020). It also allows the computation of the evolution of bin-resolved OM as it reacts with OH indoors (Cummings and Waring 2019).

Under the VBS framework, rather than tracking the concentration of aerosol indoors, the concentration of OM due to different OA factors (e.g., HOM for HOA factor, BBOM for BBOA factor, OOM for OOA factor) is tracked using mass balance techniques, using modified forms of Eq. (1). Doing so requires resolving the OM into aerosol- and gas-phase constituents at each modeled time, since the aerosol portion of the OM (i.e., the OA) experiences different loss rates than the gas-phase OM portion. For instance, OA is lost irreversibly to surface deposition and filtration, while gaseous OM is not. See Cummings and Waring (2019) and Cummings et al. (2020) and the supplemental information within those articles for more detailed modeling of indoor OA using the 2D-VBS in indoor settings.

Simulating Indoor Inorganic Aerosol

Particulate matter broadly consists of a mix of organic compounds, inorganic compounds, and in most cases with appreciable humidity, aerosol associated water. While the previous sections discussed indoor organic aerosol treatments, this one discusses inorganic aerosol modeling. Inorganic aerosol components are fewer in number than organic ones, but with a mass often on the same order. The primary inorganic aerosol components are salts such as ammonium nitrate and ammonium sulfate (these are most common, but there are others), elemental carbon, and geologic minerals. Particle-phase ammonium nitrate (NH_4NO_3) is in thermodynamic equilibrium with its related gas-phase compounds of ammonia (NH_3) and nitric acid (HNO_3), and ammonium sulfate ($(\text{NH}_4)_2\text{SO}_4$) is in a similar condition with ammonium and sulfuric acid (H_2SO_4).

The inorganic salts may exist in the aerosol in a dry form in their crystalline phase, or they may exist in the aerosol as dissociated ions in aqueous solutions, where the state is determined by the relative humidity (RH) of the surrounding air, as the aerosol can take on water. Moreover, the mass of water associated with inorganic aerosols exposed to RH increases and decreases exhibits hysteresis. That is, dry salt aerosol takes up no water with increasing humidity until a critical RH is reached. At this point (i.e., at the deliquescence RH, DRH), the salt deliquesces and suddenly takes on a discrete amount of water. After the DRH, further RH increases incrementally enhance the aerosol water mass. However, with decreasing RH, an aqueous salt gradually loses water until crystallization occurs at an RH value lower the DRH, when its particular efflorescence RH (ERH) is reached. At this point below the ERH, the inorganic salt no longer attracts water, and the aerosol water mass approaches zero (Seinfeld and Pandis 2016).

Inorganic aerosol modeling indoors is less developed than organic aerosol modeling. The first models attempted to simulate ammonium nitrate behavior indoors, since ammonium nitrate partitioning between particle- and gas-phases exhibits a strong temperature dependence and indoor-outdoor temperature gradients are common in winter and summer seasons (Avery et al. 2019; Johnson et al. 2017).

For instance, Lunden et al. (2003) derived methods to describe the evaporation indoors of particle-phase ammonium nitrate to NH₃ and HNO₃ gases as a function of indoor temperature and relative humidity, and the developed model well recreated experimental data measured in a residence. Recently, Xie and Zhao (2020) adapted this method to account for size-resolved ammonium nitrate behavior.

Newer generation indoor inorganic models are likely to follow the frameworks used outdoors; that is, they may use the inorganic aerosol simulation tools of ISORROPIA and AIOMFAC. The first, ISORROPIA (Fountoukis and Nenes 2007; Nenes et al. 1998, 1999), is commonly used in outdoor chemical transport models. ISORROPIA considers inorganic aerosol components alone, by simulating thermodynamic equilibrium aerosol partitioning in the H₂SO₄, NH₃, HNO₃, HCl, Na⁺, H₂O system, and its newer version ISORROPIA-II additionally considers Ca²⁺, K⁺, and Mg²⁺ and their related salts. The second model, AIOMFAC (Zuend et al. 2008), is a more detailed benchmark style tool, and it considers inorganic and organic compound interactions in aqueous aerosol and allows determination of gas-liquid, solid-liquid, and liquid-liquid equilibria conditions in organic/inorganic multicomponent aerosol solutions.

Surface Chemistry Modeling

The remainder of this chapter largely focuses on the modeling of physical and chemical processes occurring on surfaces indoors. Due to high surface-to-volume ratios in buildings, interactions of gaseous species and indoor surfaces are abundant indoors. Gas-surface interactions consist of several physicochemical processes: turbulent and gas diffusion in the boundary layer, sorption to and desorption from the surface, surface-bulk exchange, bulk diffusion, as well as chemical reactions at the surface and in the bulk. For the description of heterogeneous and multiphase chemistry on indoor surfaces, a yield-based, surface byproduct chemistry modeling framework and also kinetic flux model framework with universally applicable rate equations and parameters for mass transport and chemical reactions can be applied (Pöschl et al. 2007).

Simulating Surface Chemistry Byproduct Formation

Let us again discuss a reaction so as to demonstrate the model framework, this time centered around simulating the fate of any reactant O and formed byproduct K. Consider that K that can be generated indoors by O reacting on a surface, such that R3 can be cast as:

In reaction R3, a molecule O reacts with molecules sorbed to an indoor surface or a molecule that is a constituent of the surface material itself, but R3 shows a

simplified representation as O reacting with a generic molecule on the surface, called Y_{surf} . R3 contains a parameter y_K , called the molar yield of K, which is typically fractional and is the molar ratio of the molar change of product to reactant in R3.

Similar to the gas-phase and particle-phase chemistry modeling sections above, Eq. (1) can be cast in a form indicative of parameters for the modeling of a well-mixed zone with byproduct K formation at values of concentration, C_K (ppb), this time due to surface reactions as in R3, with respect to time, as shown in Eq. (18):

$$\frac{dC_K}{dt} = P_{\text{surf},K} + \lambda C_{K,\text{out}} + \frac{E_K}{V} - r_K C_K - \lambda C_K \quad (18)$$

where the terms in Eq. (18) that correspond to surface-phase chemistry are $P_{\text{surf},K}$ (ppb/h), which is the formation rate of K due to occurrences as in R3. Other terms in Eq. (18) are analogous to those in Eq. (5), so they are not redefined.

The specific formulation for the term in Eq. (18) of the surface-phase chemistry formation rate for the concentration C_K due to R3, P_F (ppb/h), is as in Eq. (19):

$$P_{\text{surf},K} = y_K v_{d,O} \frac{A}{V} C_O \quad (19)$$

where the strength of the byproduct K formation is due to the combination of parameters of the concentration of O, C_O (ppb); the reaction rate of O on surfaces, which is the combination of the deposition velocity of O to surfaces, $v_{d,O}$ (m/h), and the surface-to-volume ratio, A/V ; and the molar yield of K due to that surface reaction of O, y_K . Therefore, the rate of overall byproduct K formation increases as the yield increases, as the deposition to the surface increases, or as the total amount of available surfaces increases.

This framework was primarily developed to accommodate treatment of ozone reactions on indoor surfaces and associated byproduct formation. As demonstrated above, ozone reacts in the gas phase with unsaturated VOCs (primarily terpenoids), but ozone also strongly reacts on surfaces indoors. Indeed, absence of large indoor VOC emissions, surface reactions are typically the dominant loss mechanism of ozone in buildings (Weschler 2000), and aldehydes are a common byproduct of this reaction. See Wang and Morrison (2006) for the measurement of molar yields of aldehydes due to ozone reactions on surfaces in real homes, and Waring and Siegel (2013) and Wang and Waring (2014) for chamber measurements of SOA formed by ozone surface reactions. This byproduct formation framework just offered is the simplest treatment of indoor surface reaction modeling, and the next sections explore other issues in more detail.

Modeling Transport Within Boundary Layer

To interact with surfaces, reactants must transport from the bulk air to surface through the fluid mechanical boundary layer, which is composed of a region of

slower-moving air adjacent to the surface that transitions to a region of higher-velocity air in the bulk phase. In the upper/outer region of the boundary layer, transport may be dominated by turbulent eddy dispersion or for laminar flow, shear dispersion, while transport of molecules is dominated by molecular diffusion in the quiescent region nearest the surface. The boundary layer theory simplifies the system by assuming that there is a well-mixed region outside the boundary layer, but the air within the boundary layer is quiescent and diffusion dominates transport (Morrison et al. 2019).

The governing equation of the fluid mechanics of the boundary layer with a gradient of turbulent eddy diffusion is described as follows (Lai and Nazaroff 2000):

$$\frac{d}{dy} \left((D_{g,X} + \varepsilon_p) \frac{d[X]}{dy} \right) + R_X = k_X [X] \quad (20)$$

where $[X]$ (cm^{-3}) is the concentration of a species X; k_X (s^{-1}) is the decay rate constant by all mechanisms of species X (s^{-1}); D_X (cm^2/s) is the gas-phase diffusivity of species X; and R_X ($\text{cm}^{-3} \text{s}^{-1}$) is the production rate of species X. Also, ε_p is the eddy diffusion coefficient, where it has the formulation of $\varepsilon_p = K_e y^m$ and K_e is the turbulence intensity, which may vary from ~ 0.1 to 10 s^{-1} indoors and m is in the range of 2 to 3 and is often valued at 2 (Lai and Nazaroff 2000).

In the absence of turbulence (e.g., $K_e = 0$) in a quiescent boundary layer, diffusion is the dominant transport mechanism, and net transport only occurs perpendicular to the surface. Equation (20) is simplified so the concentration $[X]$ is given by:

$$D_{g,X} \frac{d^2[X]}{dy^2} + R_X = k_X [X] \quad (21)$$

The concentration at the upper limit of the boundary layer is equal to the concentration in the well-mixed region of room air (e.g., bulk room air), as expressed in Eq. (22):

$$[X] = \frac{R_X}{k_X} \text{ at } y = \delta \quad (22)$$

The boundary layer thickness, δ (cm), is typically from 0.5 to > 2 cm, depending on the mixing conditions or temperature gradients between surface and room air (Cano-Ruiz et al. 1993). The concentration at the surface for a species with a very high uptake coefficient (e.g., hydroxyl radicals, OH) may be assumed to be equal to 0, so that:

$$[X] = 0 \text{ at } y = 0 \quad (23)$$

With these boundary conditions, Eq. (19) can be solved analytically to yield $[X]$ throughout the boundary layer, with the following solution in Eq. (24) (Morrison et al. 2019):

$$[X] = \frac{R_X}{k_X} \left(1 - e^{-\sqrt{\frac{k_X}{D_{g,X}}} y} \right) \quad (24)$$

In the presence of eddy turbulence and complex boundary conditions, Eq. (20) may need to be solved numerically. Additionally, instead of solving partial differential equations, recently a kinetic multilayer modeling approach has been used that allows to describe and simulate the system with multiple species and chemical reactions in the boundary layer (Morrison et al. 2019). The model treats gas-phase boundary layer with a number of layers, and the mass balance of species is described with a series of ordinary differential equations, which can be solved numerically. Depending on the complexity of the system of interest, unlimited numbers of species and chemical reactions can be flexibly added and treated.

Modeling Surface Processes

Once the gas molecules are transported through the boundary layer to the near-surface gas phase which is one mean free path away from the surface, they may collide to the surface. Based on kinetic theory and model framework (Pöschl et al. 2007), the gas kinetic flux of X colliding with the surface $J_{\text{coll},X}$ ($\text{cm}^{-2} \text{ s}^{-1}$) can be expressed as in Eq. (25):

$$J_{\text{coll},X} = \frac{[X]_{\text{gs}} \omega_X}{4} \quad (25)$$

where $[X]_{\text{gs}}$ (cm^{-3}) is the near-surface gas-phase concentration of X; and ω_X (cm/s) is the mean thermal velocity given by $\omega_X = (8 RT / (\pi M_X))^{1/2}$, where M_X (g/mol) is the molar mass of X; R is the gas constant; and T (K) is the absolute temperature. The flux of adsorption of gas molecules $J_{\text{ads},X}$ ($\text{cm}^{-2} \text{ s}^{-1}$) on the surface can be expressed as:

$$J_{\text{ads},X} = \alpha_{s,X} J_{\text{coll},X} \quad (26)$$

where $\alpha_{s,X}$ is surface accommodation coefficient, which represents the probability that X undergoes adsorption upon collision with the surface. The parameter $\alpha_{s,X}$ is determined by the surface accommodation coefficient on an adsorbate-free surface $\alpha_{s,0,X}$ and the sorption layer coverage θ , which is given by the sum of the fractional surface coverage of all adsorbate species:

$$\alpha_{s,X} = \alpha_{s,0,X} (1 - \theta) \quad (27)$$

The parameter $\alpha_{s,0,X}$ can be addressed by molecular dynamics simulations, and for instance, $\alpha_{s,0,X}$ is close to unity for indoor-relevant semivolatile compounds on skin lipids (von Domaros et al. 2020). For a single adsorbate system, $\theta = \sigma_{s,X} [X]_s$,

where $[X]_s$ (cm^{-2}) is the surface concentration of X; and $\sigma_{s,X}$ (cm^2) is the molecular cross section of X.

The adsorbed molecules can thermally desorb back into the gas phase. Desorption, the inverse of adsorption, can be described by a first-order rate coefficient. The flux of desorption of gas molecules, $J_{\text{des},X}$ ($\text{cm}^{-2} \text{ s}^{-1}$), can be expressed as in Eq. (28):

$$J_{\text{des},X} = k_{d,X}[X]_s \quad (28)$$

where $k_{d,X}$ (s^{-1}) is a first-order desorption rate coefficient. Since molecules are desorbed thermally, the parameter $k_{d,X}$ depends strongly on temperature, which can be described by an Arrhenius equation, as in Eq. (29):

$$k_{d,X} = A \cdot \exp \left(\frac{\Delta H_{\text{ads},X}}{RT} \right) \quad (29)$$

where A is a pre-exponential factor, which is approximately the vibrational frequency of a molecule bound to the surface (typically $\sim 10^{12}$ to 10^{14} s^{-1}); $\Delta H_{\text{ads},X}$ (kJ/mol) is adsorption enthalpy. The parameter $k_{d,X}$ is an inverse of the desorption lifetime $\tau_{d,X}$ ($= 1/k_{d,X}$), which is the mean residence time on the surface in the absence of surface reactions and surface-bulk transport processes. The parameter $\Delta H_{\text{ads},X}$ can be measured experimentally, and $\tau_{d,X}$ can be estimated by molecular dynamics simulations. For example, limonene adsorbs on a silica (SiO_2) surface with $\Delta H_{\text{ads},X} = 55 \text{ kJ/mol}$ and $\tau_{d,X} = \sim 25 \mu\text{s}$ (Fang et al. 2019).

In the presence of surface reaction with the loss rate of $L_{s,X}$ ($\text{cm}^{-2} \text{ s}^{-1}$), the surface mass balance and rate equation for surface concentration of X can be described as in Eq. (30):

$$\frac{d[X]_s}{dt} = J_{\text{ads},X} - J_{\text{des},X} - L_{s,X} \quad (30)$$

For a system with single adsorbate X under steady-state conditions ($d[X]_s/dt = 0$) in the absence of surface reactions ($L_{s,X} = 0$), the surface coverage θ can be described by combining Eqs. (23), (24), (25), and (26), with the result as in Eq. (31):

$$\theta = \frac{K_{\text{ads}}[X]_{\text{gs}}}{1 + K_{\text{ads}}[X]_{\text{gs}}} \quad (31)$$

where K_{ads} ($= \alpha_{s,0,X} \omega_X \sigma_{s,X} / (4 k_{d,X})$) is the Langmuir adsorption equilibrium constant. Equation (31) describes the Langmuir adsorption isotherm, which indicates that surface coverage saturates at high gas-phase concentration.

The uptake coefficient of X, a probability that a collision of X with the surface leads to net uptake of X, can be expressed as a ratio between the net flux of X from the gas phase to the condensed phase, $J_{\text{net},X}$ ($\text{cm}^{-2} \text{ s}^{-1}$), and $J_{\text{coll},X}$, as in Eq. (32):

$$\gamma_X = \frac{J_{\text{net},X}}{J_{\text{coll},X}} = \frac{J_{\text{ads},X} - J_{\text{des},X}}{J_{\text{coll},X}} \quad (32)$$

Bear in mind that the parameter γ_X is time dependent, and it reaches eventually zero for non-reactive uptake at equilibrium. For reactive uptake under steady-state conditions (e.g., $d[X]_s/dt = 0$), the parameter $\gamma_X = L_{s,X} / J_{\text{coll},X}$; hence, γ_X is also termed as reaction probability, which is often reported in experimental studies, and is a component in the deposition velocity theory.

The deposition velocity is a mass transfer coefficient used to describe irreversible removal of reactive gases at indoor surfaces. A conceptual model was developed by Cano-Ruiz et al. (1993), which combines mass transport and surface kinetics under three model airflow conditions: (1) forced laminar convection flow parallel to a flat plate, (2) laminar natural convection flow along an isothermal vertical plate, and (3) homogeneous turbulence in an enclosure. For the third case, the deposition velocity, $v_{d,X}$ (cm/s), of X can be described by a combination of the transport-limited deposition velocity, v_t (cm/s), and surface uptake deposition velocity, v_s (cm/s), as (Cano-Ruiz et al. 1993):

$$v_{d,X} = \left(\frac{1}{v_{t,X}} + \frac{1}{v_{s,X}} \right)^{-1} \quad (33)$$

where the transport-limited deposition velocity is:

$$v_{t,X} = D_{g,X}^{(1-1/m)} K_e^{(1/m)} \quad (34)$$

and the surface uptake deposition velocity is:

$$v_{s,X} = \frac{\gamma_X \omega_X}{4} \quad (35)$$

With above equations, the uptake coefficient and deposition velocity are shown to be related. Particularly, surface reaction rates are one of two rate-limiting aspects of the overall deposition velocity, with boundary layer transport being the other. At a particular transport condition, when the uptake coefficient is large and exceeds a certain threshold value, the deposition velocity reaches a constant value, with its overall rate being mainly controlled by transport through the boundary layer and thus depending on the flow conditions.

Finally, bulk diffusion is an important mechanism for species transport in bulk compartments such as in surface reservoirs or human skin, and it can be described with Fick's law of diffusion. Fick's first law indicates that the diffusion flux is proportional to the concentration gradient. The bulk diffusion flux of X, $J_{b,X}$ ($\text{cm}^{-2} \text{s}^{-1}$), can be expressed using a bulk diffusion coefficient, $D_{b,X}$ (cm^2/s), as in Eq. (36):

$$J_{b,X} = -D_{b,X} \frac{d[X]_b}{dx} \quad (36)$$

where $[X]_b$ (cm^{-3}) is the bulk concentration of X at any position x . Fick's second law describes the time evolution of $[X]_b$ with a partial differential equation, in the case of one-dimensional diffusion, as in Eq. (37):

$$\frac{\partial [X]_b}{\partial t} = -D_{b,X} \frac{\partial^2 [X]_b}{\partial x^2} \quad (37)$$

For the description of bulk diffusion within spherical particles, $[X]_b$ can be described as:

$$\frac{\partial [X]_b}{\partial t} = -\frac{D_{b,X}}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial [X]_b}{\partial r} \right) \quad (38)$$

To solve these partial differential equations, the following boundary conditions are often employed: (1) the concentration at the surface (or near-surface bulk) is fixed over time at equilibrium value, as determined by vapor pressure, solubility, or partitioning coefficient; (2) the flux of X at the core is zero ($\partial[X]_b/\partial r|_{r=0} = 0$), and (3) the flux of X at both surface and core is zero ($\partial[X]_b/\partial r|_{r=r_p} = \partial[X]_b/\partial r|_{r=0} = 0$).

Modeling Skin Chemistry Example

As a good example for indoor surface chemistry modeling that integrates different modeling approaches with molecular to room scales, let us discuss ozone reactions with human skin lipids, which affect concentrations of ozone and organic compounds (byproducts) substantially (Wisthaler and Weschler 2010). The skin is covered by $\sim 0.45 \mu\text{m}$ thick skin oil, of which a large component is squalene (Kligman 1963). The stratum corneum is the outermost part of the skin and consists of 15–20 layers of dead flattened cells with a thickness of $\sim 25 \mu\text{m}$ (Egawa et al. 2007). The viable epidermis is the skin below the stratum corneum and consists of living cells with a thickness of $\sim 100 \mu\text{m}$ (Reddy et al. 2000).

Force field-based molecular dynamics simulations can be applied to simulate ozone interactions with squalene (proxy for skin oil), as in Fig. 2a (von Domaros et al. 2020). The surface mass accommodation coefficient can be calculated from the statistical fates of hundreds of ozone impingement trajectories, and the desorption lifetime from the statistics of the lifetime that ozone resides on the squalene surface before desorbing. Henry's law constant for ozone entering squalene can be calculated using an enhanced sampling method wherein external forces are used to pull the ozone molecule from the gas phase through the squalene-air interface and into the bulk squalene liquid.

The kinetic multilayer model of surface and bulk chemistry of the skin and clothing was developed, which explicitly resolves mass transport and chemical reactions in the gas phase, in clothing, in the gap between clothing and skin and in the skin, as in Fig. 2b (Lakey et al. 2019). The model includes different layers: a gas phase, a boundary layer, the clothing, the gap between the clothing and skin, a

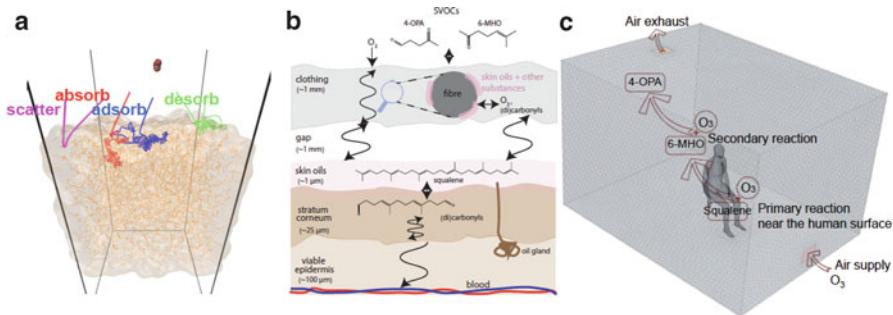

Fig. 2 Modeling skin ozonolysis with different approaches, bridging molecular to room scales. **(a)** Molecular dynamics simulations of ozone molecules in squalene, showing fates of trajectories of ozone molecules directed at the surface of a slab squalene from the gas. **(b)** A schematic of the kinetic multilayer model for interactions of O₃ with skin and clothing. Ozone can react with squalene forming volatile and semivolatile carbonyl products such as 4-OHA and 6-MHO. **(c)** Illustration of the geometry input to the computation fluid dynamics model for chemical reactions near and at the human surface. Reproduced from Shiraiwa et al. (2019) with permission from the Royal Society of Chemistry

sorption layer, the skin oil, the stratum corneum, the viable epidermis, and a layer of blood vessels (Lakey et al. 2017, 2019). It can simulate ozone reactions with human skin by treating chemical reactions and mass transport of ozone, skin lipid squalene, and oxidation products at the skin and in the gas phase (Lakey et al. 2017). It enables the spatial and temporal concentration profiles of species in the skin oil and underlying skin layers to be resolved. In the clothing, diffusion can be slowed down due to partitioning of chemical species to skin oils and other substances covering the fibers, as simulated by human envelope models by Morrison et al. (2016, 2017). Contact transfer between the upper layer of the skin and the clothing is also treated. Required kinetic parameters included surface accommodation coefficients, desorption lifetimes, gas-phase and bulk diffusion coefficients, partitioning coefficients, contact transfer rates, and reaction rate coefficients.

For examination of the spatial distributions of ozone and ozonolysis products, computational fluid dynamics (CFD) modeling can be applied to simulate surface reactions and gas-phase chain reactions in indoor environments. Outputs from the kinetic flux model including the ozone uptake coefficient and the product yields can be used as inputs in a CFD model, allowing analysis of spatial distribution of ozone, and primary and secondary carbonyl products throughout a room (Won et al. 2019, 2020). The CFD model solves time- and space-resolved concentrations iteratively based on heat, momentum, and mass balances in the discretized space with specific convergence criteria (Nielsen 2015; Rim et al. 2009; Sørensen and Weschler 2002). The model results reveal non-uniform indoor airflow distribution and transport of oxidants and reactants under different ventilation conditions (Rim et al. 2009). Figure 2c shows a CFD model that simulates the perihuman environment. The computational grids and the boundary conditions are treated to predict local velocity gradient near the human body and recirculating indoor airflow with reasonable

accuracy. Mass transport equations considering chemical reaction can be applied to each cell of the simulation domain (Launder and Spalding 1974), as in Eq. (39):

$$\frac{\partial}{\partial t}(\rho C_i) + \frac{\partial}{\partial x_j}(\rho u_j C_i) = \frac{\partial}{\partial x_j}\left(\rho D_i \frac{\partial C_i}{\partial x_j}\right) + R_i + S_i \quad (39)$$

where ρ is air density, u_j is air velocity, C_i is the mole fraction of chemical species, R_i is the reaction source term, D_i is molecular diffusion coefficient, and S_i is source term. The CFD solution calculates the effects of convection, diffusion (both molecular and turbulent), chemical reaction, and source emissions. The CFD modeling demonstrated that primary product concentrations are elevated in the breathing zone compared to the rest of the room (Lakey et al. 2019). Overall, the novel combination of MD simulations to constrain parameters, the kinetic model, and the CFD simulations resulted in insights into how to improve indoor air quality, reduce exposure, and design future experiments.

Abstract

This chapter is an overview of exposure concepts related to indoor air pollutants and serves as an introduction to the other chapters in this section. Other sections of this handbook provide details on sampling, analysis, and/or monitoring of pollutants in the indoor environment. This chapter focuses on inhalation exposure, although the concepts can be applied to dermal and non-dietary ingestion exposure routes. To estimate inhalation exposure, it is necessary to combine

pollutant concentrations with the time for which an individual or group of people are in contact with that concentration. The estimate of exposures allows the determination of the relationships between exposure to the pollutant and the potential adverse outcomes. Exposure is the link between the built environment and health effects due to the conditions within that built environment and the time-activity patterns of the occupants.

Keywords

Exposure · Concentration · Time-activity · Models · Measurements

Introduction

Quantifying human exposure is critical for many indoor air quality investigations, including supporting epidemiology studies, risk assessments, development of mitigation strategies, and sustainability efforts for cities and communities. Exposure science puts the target, or receptor, at the center of the investigation and enables the comparison of multiple exposure pathways for prioritizing pollutant sources, informing mitigation strategies, and outlining future research. The exposure science approach is especially important as we address emerging environmental contaminants (e.g., DeLuca et al. 2021). This chapter will define exposure science concepts and review current measurement and modeling methods for estimating inhalation exposure in nonindustrial indoor microenvironments, such as homes, schools, hospitals, and commercial buildings. We will discuss existing as well as promising future approaches for quantifying inhalation exposure.

What Is Exposure Science?

Exposure science is an interdisciplinary field investigating the contact between living organisms and chemical, physical, and biological stressors. Exposure science draws from the disciplines of biology, chemistry, ecology, toxicology, epidemiology, bioethics, medicine, behavioral science, environmental engineering, and others. In 1991, the US National Research Council (NRC) Committee on Advances in Assessing Human Exposure to Airborne Pollutants defined human exposure to a contaminant as “contact at a boundary between a human and the environment with a contaminant of a specific concentration for an interval of time” with units of exposure defined as concentration multiplied by time (NRC 1991). In 2012, the NRC Committee on Human and Environmental Exposure Science in the 21st Century defined exposure science as “the collection and analysis of quantitative and qualitative information needed to understand the nature of contact between receptors (such as people or ecosystems) and physical, chemical, or biologic stressors” (NRC 2012). The exposure science community, primarily led by the International Society for Exposure Science (ISES) and governmental related organizations such as the NRC and World Health

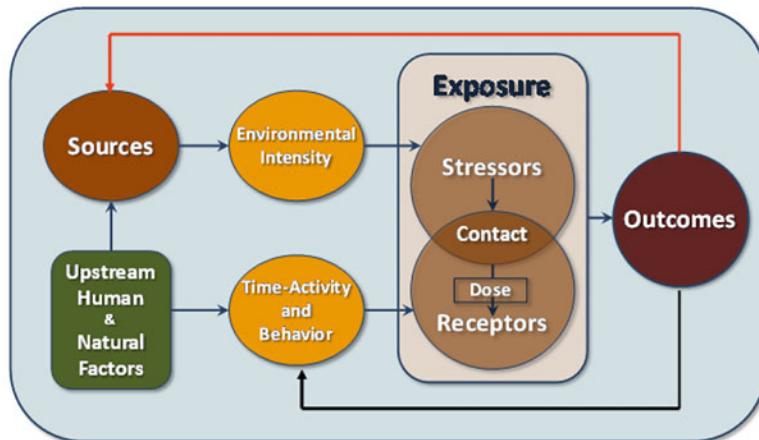

Fig. 1 Core elements of exposure science in conceptual framework. (Reproduced from NRC (2012) and used with permission)

Organization (WHO) International Programme on Chemical Safety (IPCS), have made efforts to identify priorities, enable progress, and standardize terms and definitions related to exposure science, and enable progress (NRC 2012; Zartarian et al. 2005; Environmental Protection Agency 2015).

The exposure science conceptual framework and its core elements are summarized in Fig. 1. Exposure occurs when the stressors are in contact (overlap in space and time) with the receptors. The earlier, classic version of the conceptual framework showed a linear continuum from source to health outcomes, without the feedback loops that impact both the stressors and receptors (NRC 2012). In this handbook, the stressors would be considered indoor chemical, biological, or physical agents that expose an individual. However, lifestyle, social conditions, and behavior are additional stressors that can affect health outcomes, and the study of these factors is an active area of exposure research (Lioy and Smith 2013).

Link Between Exposure Science and Indoor Air Quality, Toxicology, and Epidemiology

Exposure science is closely linked with indoor air quality (IAQ), toxicology, and epidemiology. IAQ links sources to environmental intensity (the top left two bubbles in Fig. 1), characterizing emissions, fate, and transport in the environment. For example, an IAQ study may model or measure the indoor concentration of particulate matter (PM) from an outdoor or indoor source, such as an operating cookstove. Exposure science adds the person or other living entity to determine the overlap between the stressor and receptor in time and space. The field of toxicology links the dose with health outcomes, while the field of epidemiology links the environmental intensity, exposure, or dose (either estimated or measured via

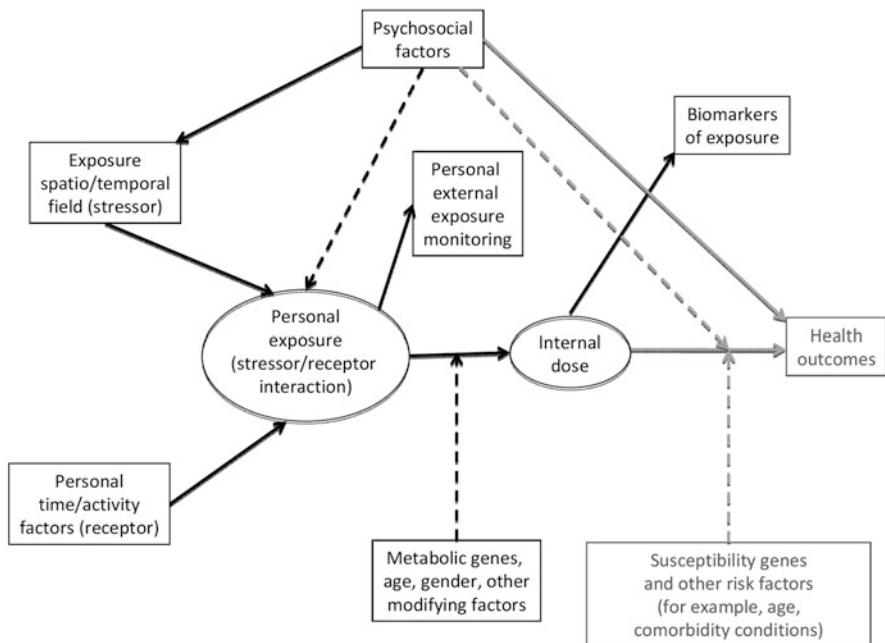

Fig. 2 General schema of exposure assessment in environmental epidemiology (Reproduced from NRC (2012) and used with permission). Items in gray related to health outcomes are considered to be outside the field of exposure science. “Boxes represent measurable quantities, and ovals denote hypothetical intermediate variables that can be assessed only indirectly. Solid arrows denote direct effects, and dashed arrows indicate modifying effects” (NRC 2012)

biomarkers) with health outcomes. As shown in Fig. 2, the conceptual framework from exposure to health effects also incorporates psychosocial and genetic factors. Accordingly, the “exposome” was defined as the “life-course environmental exposures (including lifestyle factors), from the prenatal period onwards” (Wild 2005). As sensor technology, biomonitoring, human genome mapping, geoinformatics, and data analysis techniques explode, big data is bringing these fields closer together.

Exposure Definitions

Efforts to standardize exposure terms and definitions have been ongoing (e.g., Zartarian et al. 1997, 2005; World Health Organization 2001; NRC 2012). Most recently, the US Exposure Science in the 21st Century (ES21) Federal Working Group compiled “The Glossary of Exposure Science Terms,” which is intended to be a living document (EPA 2015). Several exposure terms and definitions are included below (EPA 2015):

Exposure concentration: The exposure mass divided by the contact volume or the exposure mass divided by the mass of contact volume depending on the medium (Zartarian et al. 2005).

Exposure duration: The length of time over which continuous or intermittent contacts occur between an agent and a target. For example, if an individual is in contact with an agent for 10 min a day, for 300 days over a 1-year time period, the exposure duration is 1 year (Zartarian et al. 2005).

Exposure pathway: The course an agent takes from the source to the target (Zartarian et al. 2005).

Exposure route: The way an agent enters a target after contact (e.g., by ingestion, inhalation, or dermal absorption) (Zartarian et al. 2005).

Exposome: As a complementary approach to the genome, the totality of exposures over a lifetime, which predispose and predict health effects in an individual. This assumes that exposure begins in utero, encompasses environmental (including occupational) sources of injuries, irritations, and other stressors including lifestyle and diet, and is dependent upon characteristics of the individual. The exposome is the record of all exposures both internal and external that people receive throughout their lifetime.

Time-averaged exposure: The time-integrated exposure divided by the exposure duration. An example is the daily average exposure of an individual to carbon monoxide. (Also called time-weighted average exposure) (Zartarian et al. 2005).

Time-integrated exposure: The integral of instantaneous exposures over the exposure duration. An example is the area under a daily time profile of personal air monitor readings, with units of concentration multiplied by time (Zartarian et al. 2005).

Basic Exposure Model

Models provide estimates of personal or population exposures by estimating concentrations and by linking concentrations with activity patterns. The most basic exposure model is provided in Eq. (1), where the exposure for person i is calculated by summing the product of the concentration of the stressor in each microenvironment by the time spent by that person in the microenvironment over a designated period (Duan 1982):

$$E_i = \sum_{k=1}^K C_k t_{ik} \quad (1)$$

where:

E_i = total integrated exposure of person i

C_k = concentration of stressor in microenvironment k

t_{ik} = amount of time spent by i in k

K = total number of microenvironments

Direct Versus Indirect Exposure Assessment

There are two key elements to determining exposure to a pollutant: its concentration and the extent of contact by the individual with that specific concentration. Since the focus is on air exposures, the extent would typically be the length of time in a microenvironment in which the airborne pollutant concentration has been measured or modeled. The development of time-activity patterns that can be used to estimate the time duration spent in a specific microenvironment are described in ► [Chap. 37, “Time-Activity Patterns.”](#) This section deals with how the concentration that give rise to exposures can be determined or estimated.

Direct Exposure Assessment (Measurement)

Contributions from Indoor Sources

There are multiple chapters in this handbook describing a variety of indoor air pollution sources including cooking/heating appliances, cooking, consumer products, etc. The issue is then to convert the emissions rates from such sources into indoor air concentrations to which the room occupants are exposed. These models typically apply a mass balance model to estimate the effects of infiltration, exfiltration, sources, indoor chemistry, and sinks on the resulting pollutant concentrations. They can be single or multiple room models and have become more sophisticated as the interest in indoor air quality has increased. Various organization have developed models. The US National Institute of Standards and Technology (NIST) developed Fate and Transport of Indoor Microbial Aerosols (FaTIMA) (Dols et al. 2020) as a well-mixed, single zone simulation model. Another NIST model, CONTAM is a multizone indoor air quality and ventilation analysis program (<https://www.nist.gov/services-resources/software/contam>) described by Dols and Polidoro (2020). Analogous models have been developed for the European Union (MOEBIUS 2017).

The mass balance model (Nazaroff and Cass 1986) provides reasonable long-term simulations of indoor air pollutant concentrations. However, there are other models that attempt to deal with the issue of inhomogeneities and short-term variations in indoor air pollution. Near the source while emissions are occurring, the well-mixed assumption is clearly invalid. For example, Cheng et al. (2011, 2014) describe stochastic modeling of exposure near a source in a naturally ventilated room while Furtaw et al. (1996) modeled indoor air concentrations of a tracer gas at various distances from the source. The effect of the source could be modeled adequately using a two-compartment model. A tiered approach to modeling indoor air concentrations is provided by Keil (2000). The tiered approach begins with simpler models when they are sufficient and develops toward more complex models as needed for the purposes at hand.

Finally, more detailed concentration location information can be derived using computational fluid dynamics models. CFD can be used for detailed analysis that includes pollutant concentration distributions. It can simulate the shape of indoor

spaces and model pollutant diffusion (Murakami et al. 2003; Deng and Kim 2007). CFD can be calculated based on either steady- or unsteady-state behavior depending on the time being simulated. Unsteady CFD simulations are usually used to simulate the change of pollutant concentrations over time. Zhang et al. (2009) used it to analyze airflow and pollutant diffusion in passenger aircraft. Davardoost and Kahforoushan (2018) analyzed acetone, benzene, and toluene concentrations in a laboratory driven by temperature. These models are complex and computationally intensive to provide long-term exposure estimates, but they can provide detailed, time-varying concentration distributions that can be used in other types of models to provide distributions of exposures.

Contribution from Ambient Pollution

Although the focus of this handbook is on indoor air, the ambient (i.e., outdoor) air typically contributes substantially to indoor pollutant concentrations. Indoor concentrations of ambient air pollutants can roughly be predicted via ambient concentrations and the outdoor to indoor air infiltration rate. Infiltration rates are discussed in detail in ► Chap. 10, “Impact of Outdoor Particles on Indoor Air.” Other approaches to estimating outdoor contributions to indoor air are available (e.g., Tang et al. 2018; Taylor et al. 2019). Thus, to provide those ambient concentrations needed to estimate their contribution in indoor pollution, measurements are needed across a spatial domain for the time during which exposures are to be estimated. These data can be obtained in multiple ways.

Regulatory monitoring networks: The focus of almost all monitoring to enforce air quality regulations or guidelines is on ambient air concentrations. Many countries have established air quality monitoring networks to provide data on the concentrations typically of particulate matter (PM_{10} and $PM_{2.5}$), ozone, nitrogen oxides (NO_x), sulfur dioxide (SO_2), carbon monoxide (CO), and in some cases, specific toxic species in PM such as lead in total suspended particles (TSP). In most cases, these networks are maintained and operated by governmental agencies at the national or local levels. However, some jurisdictions contract the operations to private companies or nonprofit groups. An advantage of these networks is that they are generally operated over long periods so that it is possible to assess trends and examine long-term exposures.

Generally, there are well-defined protocols for operating the equipment including appropriate quality assurance/quality control processes and subsequent data validation that provides data with relatively well characterized uncertainties. However, there are also a number of networks where the quality efforts are limited or nonexistent, and thus, it is important to assess the data quality before utilizing it in any modeling on likely indoor air concentrations.

Nonregulatory networks: In the absence of regulatory networks or to supplement them given the expense on establishing and maintaining a regulatory quality network, other monitoring efforts can be mounted ranging from single monitors in a location of interest such as the regulatory quality monitors at many embassies of the United States to networks of low-cost sensors deployed across a large urban area. For example, the South Coast Air Quality Management District (SCAQMD)

that manages air quality in the Los Angeles California area has deployed a network of around 150 low-cost PM sensors. Many of these are deployed at the fence line of possible emission sources to assess the contribution of that facility to local air pollution. However, combining the data from these units with the regulatory monitoring stations can provide a more comprehensive assessment of pollutant concentrations across a complex urban area. The details of measurement methods in low-cost sensors are presented in ► Chap. 19, “Measuring Particle Concentrations and Composition in Indoor Air.” These monitors do not provide as accurate data as regulatory grade units, but their data can be useful if appropriate care is taken in maintaining and calibrating them. SCAQMD has developed a laboratory- and field-testing capability for low-cost monitors. Evaluations of monitors submitted to them for testing are provided at a website they established (<http://www.aqmd.gov/aq-spec>).

The United States Department of State identified air quality as an important issue for its personnel posted to embassies and consulates in cities with substantial air pollution. Their initial monitoring focused on particulate matter starting with a regulatory quality beta attenuation monitor (BAM) installed at its embassy in Beijing in 2008. The data are made publicly available through the US Environmental Protection Agency’s AirNow website (<https://www.airnow.gov/international/us-embassies-and-consulates/>). Although the website presents Air Quality Index (AQI) values, the actual hourly PM_{2.5} data are available for download. In 2021, there were over 60 locations with PM_{2.5} monitors with plans to continue to expand the network. Subsequently, they began adding regulatory ozone monitors at embassies that might have high values.

Satellite data: Another way to account for the spatial variation across an urban area that cannot be determined from a limited regulatory monitoring network is to utilize satellite observational data to estimate ground level PM concentrations. There are now multiple agencies that have launched satellites and provide observational products of airborne pollutants. The most commonly used products are aerosol optical depth (AOD) and gaseous pollutants (CO, O₃, and SO₂). These data are often column depth data meaning that they provide the total concentration per unit area integrated from the ground to the top of the atmosphere. For example, aerosol optical depth is a measure of the extinction of the solar beam by airborne particles that block sunlight by absorbing and/or scattering light. AOD is a measure of the extent to which direct sunlight is prevented from reaching the ground by the particles. There are also estimated surface concentrations. The data from the US National Aeronautics and Space Administration (NASA) can be freely downloaded (<https://search.earthdata.nasa.gov/search?fst0=Atmosphere>).

However, since the satellites are only over any given location typically one time per day, continuous data are not available. New geospatial satellites are being launched to provide continuous, higher resolution data. Generally, these results are processed further to provide higher spatial resolution data. There is an extensive literature on estimating ambient air concentrations from such data. For example, Shin et al. (2020) reviewed approaches to estimating ground-level PM concentrations from satellite data.

Direct Measurement Campaigns

Microenvironment (e.g., *indoor, in-cabin*): People spend their time in a series of microenvironments ranging from the places they sleep and eat to methods of transport to where they work and return to their dwelling. Thus, they may be indoors at home, in a vehicle, or in a workplace. “Indoors” may range from spaces well isolated from the ambient environment to open vehicles or work areas with only a roof to fend off rain. Microenvironments may need to be heated, cooled, and ventilated. Exposures only occur when these spaces are occupied, and the occupants modify the air quality by their emissions such as breathing and sweating as well as from the emissions they induce while there (emissions/chemical reactions on skin; resuspension from clothing and indoor surfaces, etc.) as well as other indoor sources. Thus, there are distributions of pollutant concentrations that need to be determined in all of the potentially inhabited microenvironments. Depending on the objectives of the exposure assessment being done, there can be measurement campaigns in a series of microenvironment using more complex and expensive systems that cannot be extensively replicated, networks of low-cost sensor monitors that can be deployed in multiple locations, or directly monitoring the exposure of specific individuals that can be aggregated to provide likely distributions of exposure for further analysis.

Field Campaigns

Field campaigns can be of relatively short duration or cover extended periods of time in a single location. As an example of short-term characterization of a specific microenvironment, Xu et al. (2010) measured the concentrations of PM₁₀, CO, CO₂, total volatile organic compounds (TVOCs), temperature, and relative humidity in the bedrooms of asthmatic children to test the effectiveness of an in-room air cleaner/ventilator over 6-week periods of the filter in place and another 6 weeks when the filter was removed and the vent blocked with a 2-week washout period in between. Thus, such short-term measurements coupled with physiological measurements allowed the determination of the efficacy of this treatment in reducing their symptoms.

Another example of short-term (several weeks to a few months), single location measurement campaigns is the measurement of the size distributions of the indoor radioactive aerosol produced by the decay of ²²²Rn. Using a unique monitoring system (Ramamurthi and Hopke 1991), measurements were made for 1–2 months) in six houses (Hopke et al. 1995) providing detailed size-dependent exposure data. These data were suitable to estimate the dose from the alpha particles deposited in the respiratory tract of the building occupants, the lung cancer risk, and the resulting uncertainties (Krewski et al. 1999).

An alternative approach is to instrument a building and make measurements in multiple locations over extended periods (several months or longer). Nazaroff and coworkers (Arata et al. 2018; Farmer et al. 2019; Kristensen et al. 2019; Liu et al. 2018, 2019; Lunderberg et al. 2019; Patel et al. 2020; Tian et al. 2018; Wang et al. 2020) made a comprehensive analysis of a single-family residence in Northern California from the ventilation system to the concentrations of various contaminants

(mostly organic) to assessing some of the reservoirs and physical processes that control the airborne concentrations. Thus, detailed exposure assessment to a variety of specific indoor air contaminants can be determined over a sufficient period to provide useful distributions of exposure that can then be part of statistical approaches to exposure and risk assessments.

Sensor Networks

The recent development of low-cost sensors for air pollutants like particulate matter have opened the opportunity for building networks of sensors throughout a building. More information about low-cost sensors is provided in ► Chap. 19, “[Measuring Particle Concentrations and Composition in Indoor Air](#).” Sensor networks can now be deployed to monitor a variety of gaseous pollutants and PM concentrations in multiple rooms with the data reported to a central database via WiFi connections. Commercial systems are being developed and marketed, but they are not yet in widespread use. These systems can be integrated with the building management system to adjust ventilation rates to reduce the pollutant concentrations below preset limits. The current primary use is to ensure CO₂ concentrations do not exceed control limits, but similar control strategies could be applied for PM or any of the other monitored gases including CO, VOCs, etc.

Hegde et al. (2020) describe their study in which a network of research-grade instruments and low-cost sensors were deployed in a home. They used this combination of tools to evaluate the low-cost sensor performance and then characterized the activities and conditions that increased the PM concentrations, and identified how these activities affected the PM levels in different rooms of a home. These data could then be used to estimate exposures if the time spent in each microenvironment during a given type of activity (cooking, cleaning, etc.) could be estimated.

Bi et al. (2021) report indoor/outdoor PM_{2.5} concentration relationships based on low-cost sensor data from 91 buildings (41 residential houses and 50 public/commercial buildings) that were publicly available from the sensor vendor. Thus, a “network” of monitors were available from which infiltration factors could be calculated and the distributions for specific buildings or across areas where multiple monitored buildings were present. Thus, additional spatial and temporal information on pollutant concentration may be available to support exposure assessments in areas being studied and where enough of the residents have installed their own low-cost monitors.

Personal (Breathing Zone)

In the studies described in the preceding section, the exposures would need to be estimated based on some type of measure of occupancy of the subject within given rooms at given times. Thus, these exposures would have some associated uncertainty, but could be extrapolated to multiple individuals. Personal monitoring provides direct measurements in breathing zone for specific environmental agents to provide the exposures to the subjects. These people would generally be enrolled in a cohort study of pollution and resulting health outcomes. This approach has been

used in many prior health effects studies, typically using a pump and instruments contained in a backpack or similar wearable housing. However, now new lighter and more portable systems are available that are more sensitive, able to detect a greater variety of chemical species, and provide geographical locations so that the concentrations of the species measured in specific environments can be determined. In addition, passive samplers for agents like VOCs can provide integrated exposure estimates although it would then not be possible to assign fractional exposures in the various microenvironments that the person occupied.

It is not feasible from a cost or logistical prospective to individually monitor large populations. Some information becomes available from publically available data such as that described by Bi et al. (2021). However, such measurements do not typically cover the entire range of microenvironments in which people may reside. However, if a personal monitoring campaign is properly planned with good information on the locations occupied and the duration of those microenvironmental stays are measured, a database of exposure concentrations for different microenvironments can be developed. Then, modeling of the likely exposures can be performed from the distributions of concentrations and occupancy durations as described in the next section.

Indirect Exposure Assessment (Modeling)

Exposure to an airborne pollutant is the sum of the product of the concentration in a microenvironment times the time spent in that microenvironment for all of the occupied microenvironments. If this information is available for a given individual, then the exposure can be fully assessed. Similarly, if personal monitoring has been done, then again the total exposure for that individual is known although the exposures in any given microenvironment cannot be determined. However, it is not normally possible to obtain such detailed exposures for a large population of individuals. Thus, to assess exposures to be able to relate exposure to health outcomes, it is necessary to model exposures.

Klepeis (2006) provides an introduction to modeling of human exposures to inhaled air pollutants. There needs to be estimates of air pollutant concentrations in the possibly occupied microenvironments and estimates of the time spent in those microenvironments. The time element is provided by time-activity data and is covered in ► [Chap. 37, “Time-Activity Patterns,”](#) of this handbook. To estimate the microenvironmental pollutant concentrations, several different modeling approaches may be needed.

Contribution of Ambient Pollution to Indoor Concentrations

The penetration of ambient pollutants indoors is dealt with in detail in ► [Chap. 10, “Impact of Outdoor Particles on Indoor Air.”](#) Ambient concentrations can be obtained through the measurement approaches described above. However, it is generally not possible to operate spatially detailed monitoring networks over a long time period since they are not part of a regulatory network with government

support to maintain them. To obtain the necessary concentration estimates, these data can be modeled using several types of models.

Land-Use Regression Modeling

Field measurements and detailed geographic information can be combined in land-use regression models to estimate concentrations at specific locations and times within a given spatial domain. These models have been increasingly used over the past 20 years becoming increasingly sophisticated in the amount of input data used and the mathematical tools used to build the models. Masiol et al. (2018) developed a land-use regression (LUR) model from low-cost PM monitor data that predict hourly PM_{2.5} values across Monroe County, New York, while Masiol et al. (2019) used low-cost ozone monitor data to develop a parallel LUR for ozone. Many other similar models have been developed such as for PM and a number of its components across Pittsburgh, PA, based on a network of low-cost monitors for PM and pollutant gases (Jain et al. 2021).

Air Quality Modeling

Alternatively, chemical transport models (Seinfeld and Pandis 2016) can be used to model ambient pollutant concentrations over a spatial domain for extensive periods. The commonly used models are the Community Multiscale Air Quality (CMAQ) model and the Comprehensive Air Quality Model with extensions (CAMx). These models are commonly used by regulatory agencies to assess the impacts of existing or planned new sources of air pollution. It can be used to estimate concentrations down to grid cell sizes of 4 × 4 km. The results have been used in a number of ambient health effects assessments (e.g., Rich et al. 2013). Although there is less spatial specificity than is available from LUR results, the models do not require any monitoring data other than for model evaluations.

Statistical Modeling

In many cases, the interest is in developing distributions of exposure from the distributions of concentrations in multiple microenvironments and the time spent in those environments. The basic concept of this modeling approach is to randomly select a concentration from the distribution of concentrations in a given microenvironment and multiply it by a randomly selected duration of occupancy obtained from the distribution of occupancy times from the time-activity data. These are then averaged over a number of possible occupancies to obtain a distribution of likely exposures. The distributions from multiple environments can be combined to obtain a distribution of total exposures. Clerc et al. (2015) reports the development of statistical models based on 19,000 measurements of 26 common chemical compounds. The model provides geometric means and standard deviations, and a software tool is described that provides rapid estimation of exposures. Keller et al. (2020) report a hierarchical model to estimate exposures to indoor stove emissions in Nepal based on temporally sparse, clustered longitudinal observations.

Intake Fraction

The intake fraction (iF) metric provides a source-to-intake relationship that allows prioritization of sources based on their relative contributions to the intake of a particular pollutant as well as a comparison of multiple exposure routes: inhalation, dermal, and non-dietary ingestion for the same pollutant. Bennett et al. (2002) defined the intake fraction (iF) as “the integrated incremental intake of a pollutant, summed over all exposed individuals, and occurring over a given exposure time, released from a specified source or source class, per unit of pollutant emitted” (Bennett et al. 2002). Here, intake is the crossing of the exposure contact boundary, for example, inhalation through the mouth or nose into the respiratory system (Zartarian et al. 2005). The calculated intake dose does not require diffusion through the subsequent resisting layer, for example, the pollutant may or may not diffuse through the pulmonary region of the respiratory system into the blood stream. For inhalation, iF can be calculated as shown in Eqs. (2) and (3):

$$IF = \frac{\int_{T_1}^{\infty} \left(\sum_{i=1}^P (C_i(t)Q_i(t)) \right) dt}{\int_{T_1}^{T_2} E(t) dt} \quad (2)$$

$$= \frac{COP}{E} \text{ for constant C} \quad (3)$$

where:

C_i = concentration (mass vol⁻¹)

Q_i = breathing rate (vol person⁻¹ time⁻¹)

P = population (persons)

E = emission rate (mass time⁻¹)

T_1 = start time for emission

T_2 = end time for emission

To estimate the health impact of the source, the iF is multiplied by the health impact per mass inhaled and the mass emitted (emission rate in mass per time multiplied by the amount of time the source was emitting). Thus, the change in health impact for various mitigation strategies can be calculated using the iF metric.

Since its introduction, iF has been estimated for many different indoor and outdoor sources with various modeling approaches. For example, Shin, McKone, and Bennett (2012) applied a fugacity-based approach to estimate indoor concentrations and compare iF for a suite of compounds released indoors. In their study, the iF values varied by chemical application mode, with iF values for air release of 10^{-3} , carpet application 10^{-5} to 10^{-3} , and vinyl application 10^{-5} to 10^{-2} . Gao et al. (2013) used real-time measurements and a dispersion modeling approach to calculate iF for different ventilation and found iF values ranging from 10^{-3} to 10^{-5} . Jolliet et al. (2015) used the iF approach to calculate and compare overall exposure to

consumer products. Licina et al. (2017) found a higher iF for seated versus walking persons.

The iF for a pollutant source released indoors is typically three orders of magnitude, or 1000 times, that of a pollutant source released outdoors due to the smaller mixing volume, slower air exchange rate, and large amount of time people spend indoors (Smith 1988; Lai et al. 2000; Nazaroff 2008). Thus, while both indoor and outdoor sources impact indoor air quality, indoor sources have much larger impacts on exposure per gram released.

Conclusions

This section includes chapters that provide more details on many of the topics needed to estimate the exposure of individuals and groups to indoor air contaminants. Details of measurement techniques, monitoring tools, and models are provided elsewhere in this handbook.

Abstract

Exposure to indoor air contaminants occurs not just through inhalation but also via dermal absorption of vapors or when touching surfaces that air contaminants deposit on, and by inadvertent ingestion of contaminated settled dust from hand to mouth behaviors, especially for children. Sources of indoor pollutants include penetration of outdoor air, emissions from indoor use of consumer and personal products, furnishing and building materials, resuspension of house dust, and indoor air chemistry. Multiple sources, limited ventilation, and finite volume of buildings results in higher air concentrations of many volatile and semi-volatile organic compounds within homes than outdoors. When personal products are used near the breathing zone, the concentration of the air breathed, and therefore the resulting inhalation exposure, can be higher than estimated from the indoor air concentrations. Semi-volatile organic compounds (SVOCs) partition between indoor air and surfaces, particularly into house dust which serves as a reservoir for many compounds. The partitioning of SVOCs between indoor air and surface/dust results in their having multiple exposure routes. This chapter presents examples of exposures that occur to various chemicals representative of broad categories of compounds, thereby providing general concepts that should be considered when evaluating potential exposures to indoor air pollutants. Since people spend, on average, more than 90% of their time indoors, indoor air is often the largest contributor to total exposures for volatile, semi-volatile, and particulate air contaminants.

Keywords

Inhalation exposure · VOCs · SVOCs · House dust · Indoor sources · Indoor chemistry

Introduction

During the average lifespan of a human of 79 years, an average of 69 years will be spent in an indoor environment, of which 54 years will be spent at their place of residence and 26 years will be spent sleeping, while only 6 years will be spent outdoors, and 4 years will be spent in a vehicle (calculated from the exposure factors handbook (U.S. Environmental Protection Agency 2011)). Since people spend a large percentage of their time (~90%) indoors (Brasche and Bischof 2005; Matz et al. 2014) and air concentrations of chemicals and biological agents indoors are often higher than outdoors (Azuma et al. 2016), characterization of exposures within the indoor environment is needed to protect public health. Penetration of chemical and biological agents from outdoor air to indoors provides the baseline levels present indoors, with the final outdoor contribution dependent upon losses for reactive or soluble volatile/semi-volatile compounds and for particles onto surfaces indoors or within the building's envelope. Higher indoor air concentrations compared to

outdoors can result when there are indoor or personal sources emitting pollutants or from chemical reactions indoors (Fig. 1). Unlike the outdoor environment, the indoor environment is a defined, finite space often with limited ventilation or air exchange and thus, the chemical or biological agents released or formed indoors do not dissipate as quickly as they do outdoors. This impact of indoor sources on air quality and exposure is particularly pronounced in buildings with insufficient air exchange rates to remove pollutants emitted or formed indoors. In 1981, the shift to lower air exchange rates to create more energy efficient buildings in the United States began (American Society of Heating, R. a. A.-C. E., Inc 1989). Lower air exchange rates can trap agents indoors leading to exposure to potentially harmful pollutants. There are numerous indoor sources of pollutants that can affect indoor air quality (Table 1). During the 1980s, the first comprehensive study comparing personal air to outdoor air was conducted by the US Environmental Protection Agency, as part of the Total Exposure Assessment Methodology (TEAM), initially examining a subset of volatile organic compounds (VOCs) and expanding to include particulate matter (PM) (Wallace et al. 1987, 2017). In subsequent years, studies comparing outdoor air to indoor and/or personal air have been carried out throughout the world. A consistent finding across these studies is that there is a stronger relationship between personal air, i.e., the levels in the breathing zone – air within 0.3 m of the nose and mouth, and indoor air concentration than between personal air and outdoor air, and that indoor and personal air levels for many air contaminants exceed their outdoor levels. Therefore, the indoor air levels have become

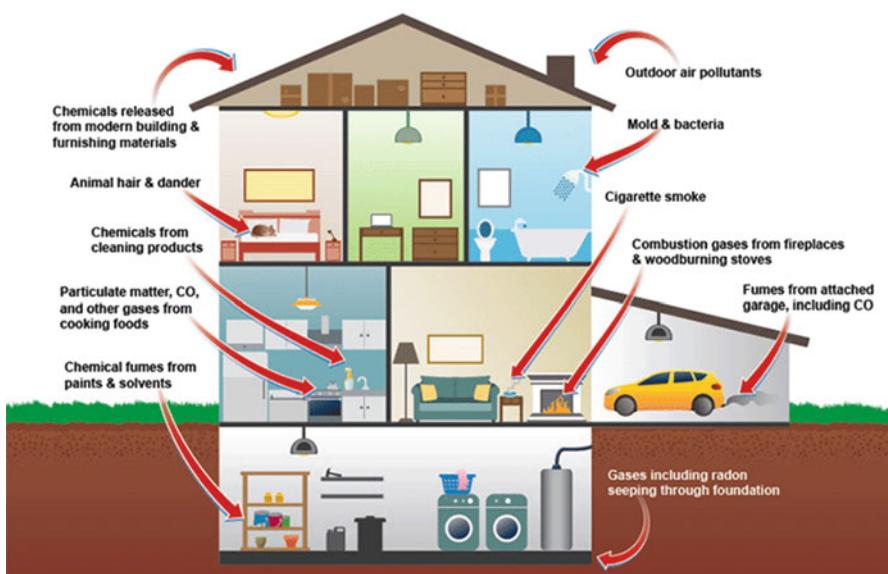

Fig. 1 Indoor and Outdoor Sources of Pollution affecting indoor air quality. (Source: <https://www.epa.gov/expobox/exposure-assessment-tools-media-air#indoorair>)

Table 1 Common sources of indoor air toxicants (Abdullahi et al. 2013; Destaillats et al. 2008; Liu et al. 2016, 2017; Nazaroff and Weschler 2004; Odabasi 2008; Schettler 2006; Seaman et al. 2009; Stönnér et al. 2018; Tang et al. 2015, 2016; Wang and Morrison 2006; Weschler 2009; Weschler and Carslaw 2018)

Source	Associated toxicant(s)
Building materials (i.e., paint, wood, PVC pipes, cable insulation)	Formaldehyde, Benzene, Toluene, Ethylbenzene, Xylenes (BTEX)
Cleaning agents and air fresheners	Terpenes, Ammonia, Chlorinated hydrocarbons, Disinfectants, Organic Solvents, Fragrances, Particulate Matter (PM)
Combustion appliances, cooking and heating	Polycyclic Aromatic Hydrocarbons (PAHs), Carbon Monoxide (CO), Nitric Oxides (NOx), Acrolein, PM
Disinfectants	Bleach, Quaternary Ammonium Compounds (QACs), Alcohols, Vinegar
Electric equipment (i.e., laser printers, photocopiers)	Ozone
Furniture, floor (i.e., carpets, vinyl) and wall coverings	Formaldehyde, Poly and Per-Fluorinated Alkyl Substances (PFAS)
Moist areas, uncleared areas	Microbial organics (Bacteria, Fungi, and Molds)
Personal care products (i.e., perfume, make up, lotion)	Phthalates, Parabens, Nanoparticles, Fragrances
Pesticides (Insecticides, fungicides, rodenticides)	Permethrins, Pyrethroids
Pets	Dander, Pollen, Tracked in Soil/dirt
Smoking	BTEX, PM, Formaldehyde, Furans

increasingly recognized as an, if not the most, important contributor to total exposure to air contaminants potentially affecting health.

Sources of Indoor Air Exposure

Many sources contribute to poor indoor air quality resulting in exposures to pollutants in the indoor environment. These include combustion processes (e.g., tobacco smoking, vaping, cooking, heating), off-gassing from building materials and furnishings, emissions from consumer products (e.g., household cleaners, cleaning activities, personal care items, solvents and glues used in hobbies, air fresheners), release of bioeffluents, evaporative releases from engines, solvents and paints stored in attached garages, contaminated soil gas, and penetration of outdoor air pollutants (Fig. 1). A listing of some common major sources with their associated toxicants are given in Table 1. Several of the chemicals indoors can react with oxidants present in the indoor air, such as ozone, which comes predominantly from outdoor air penetration, and with nitrogen dioxide, from outdoor air and combustion processes indoors, forming secondary chemical vapors and organic aerosols that can contribute further to the indoor air pollution. When considering exposure to indoor air pollutants, understanding both the relative contribution from different sources and

exposure routes are important. One approach to facilitate that comparison is to use an Intake Factor (*iF*). An *iF* describes the mass intake of a pollutant by individuals or population per mass unit of the pollutant released into the environment (Bennett et al. 2002). *iF* has been used in life cycle analysis assessments and risk assessments to identify the exposure pathways and design effective approaches to reduce exposure. *iF* values have identified pathways for chemicals that include those from consumer products and often result in greater exposure than industrial emissions for the same chemicals, even though the mass released into the air is orders of magnitude smaller. This is premised on the sources being “near field” rather than “far field” sources, i.e., indoor (“near field”) emissions have much higher *iF* than outdoor (“far field”) emissions, since the portion of a chemical emitted indoors resulting in an exposure will be much greater than from outdoor emissions (Jolliet et al. 2015). *iF* values can be calculated for individual exposure routes (inhalation, dermal, ingestion) and then summed to determine the total *iF* (Bennett et al. 2002; Jolliet et al. 2015). Based on the relationship between uses/properties of chemicals and their *iF*, the *iF* can be used to predict exposures to new chemicals that are to be introduced into the environment (Bennett et al. 2002).

Routes of Exposure

In a National Academy of Sciences report, exposure was defined “as a person’s contact with the concentration of a material before and after it crosses a boundary (nose, skin, mouth) between the human and the environment over an interval of time leading to a potential biological effective dose” (Lioy and Weisel 2014; National Research Council 2012). Exposure to agents in the air can occur through three routes: inhalation, dermal, and ingestion; since not only is the air directly breathed (inhalation) but air contaminants can be absorbed through the skin or deposited/absorbed onto dust or surfaces within a home that are touched (dermal) and hands or objects containing deposited or absorbed pollutants are placed in the mouth (inadvertent ingestion). The generic equation to calculate external inhalation exposure from pollutants in indoor air is to sum the time spent in different locations/activities multiplied by the average air concentration encountered in each locale, though this approach does not consider breathing rate which affects the amount of an agent that reaches the lungs (Eq. 1):

$$\text{External Inhalation Exposure} = \sum_{i=1}^n C_i \times \Delta t_i \quad (1)$$

where *i* is the location or activity (often referred to as the microenvironment) over *n* locations/activities, C_i is the air concentration in the *i*th microenvironment, and Δt_i is the time spent in the *i*th microenvironment. Different indoor locations or activities with different indoor air concentrations are represented as distinct microenvironments and the relative contribution of each to the exposure determined. Defining the

relevant microenvironments and sources of pollutants an individual or population are potentially exposed to can provide guidance in designing a questionnaire and time activity surveys, to assess the time spent in different microenvironments, the level of exertion which alters the breathing rate as described below, and where air concentrations should be measured – these elements are essential in calculating inhalation exposure across multiple indoor settings. Time activity patterns are discussed in detail in ► [Chap. 37, “Time-Activity Patterns,”](#) of this Handbook.

Equation 1 relates an estimate of inhalation exposures but does not fully account for multi-route exposures or the amount that enters the body.

External dermal exposure needs to consider there are different contacts at the skin depending upon the source as outlined in Eq. 2:

$$\text{External Dermal Exposure} = \sum_{i=1}^n (C_i \times SA_i \times EF_i \times \Delta t_i) \quad (2)$$

where C_i is the concentration in the medium contacting the skin, SA_i the surface area of the skin exposed, EF_i the frequency of exposure, and Δt_i is the duration of exposure for the i th dermal exposure event. For indoor air this will include a continuous exposure to contaminants in the air to exposed skin areas, in analogous fashion to inhalation exposure but also to contact with surfaces that have absorbed chemicals from the air and contact skin in a noncontinuous fashion.

External ingestion exposure is a noncontinuous exposure and has a mathematical construct similar to dermal exposure as shown in Eq. 3:

$$\text{External Ingestion Exposure} = \sum_{i=1}^n (C_i \times IR_i \times EF_i \times \Delta t_i) \quad (3)$$

where C_i is the concentration in the food or liquid consumed, IR_i the amount ingested, and EF_i the frequency of exposure, and Δt_i is the duration of exposure for the i th ingestion exposure event.

Calculating external dermal and ingestion exposure and combining the exposures among different exposure routes based on the contact at the body surface is not readily done since the units of external exposures vary by route. To better compare the exposures across routes and estimate total exposure, it has been proposed that the amount that enters the body (internal exposure or internal dose) be calculated (Lioy and Weisel 2014) or an iF be used. The internal exposure includes the external exposure, i.e., the amounts at the body boundary over time, and factors that depend on the exposure route: the breathing rate, deposition pattern in the lungs, and transport across the lung membrane for inhalation exposure, the parts of the body and surface area contacted and permeability coefficient across the skin for dermal exposure, and the bioavailability of the chemical in the media ingested and gastrointestinal absorption rate for ingestion exposure. The absorption rate varies with the lung > gastrointestinal tract > skin for most chemicals, though the form of the chemical (e.g., ionic vs non-charged) and matrix it is in can affect the rate. The

internal exposure can be expressed in the same units for the three exposure routes, typically as total mass (e.g., milligrams) absorbed during a set time period such as a day or as mass per body weight to facilitate comparison of potential impacts from exposure across individuals. Therefore, the total internal exposure can be calculated by summing the values across the three exposure routes.

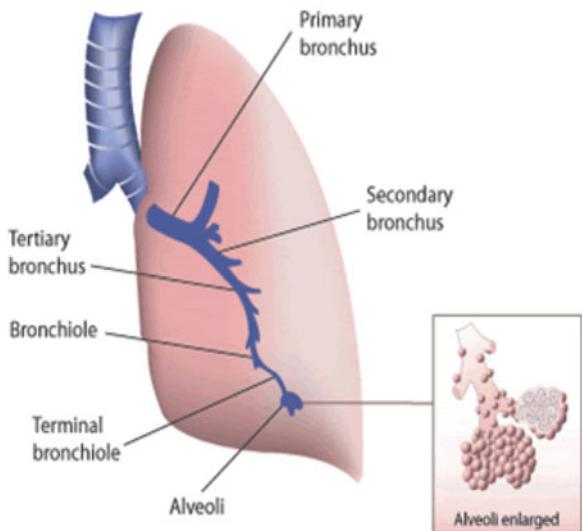

The *iF* includes the same parameters listed above for internal dose so the value from different routes can be summed after being normalized to the amount released from a source. *iF* values have been incorporated into multimedia, multi-pathway exposure models to assess the source-to-intake relationship (Bennett et al. 2002) and, for example, fine particulate matter ($PM_{2.5}$) from indoor air and outdoor indoor in urban and rural settings on a population basis (Fantke et al. 2016). The latter study found that the location, indoor air exchange rate, and level of occupancy affected the *iF* with indoor $PM_{2.5}$ exposure typically contributing “91–99% to effective intake fractions across indoor source environments.” A comprehensive review of factors that affect the *iF* for PM across different indoor environments was published by (Hodas et al. 2016).

As mentioned previously (Table 1), there are an abundance of indoor sources that can release chemicals into the air. Notable sources of indoor air pollution include off-gassing from furniture and building materials, personal care product use, pesticide applications, resuspension of dust, indoor air chemistry, and combustion sources (Biesterbos et al. 2013; Garcia-Hidalgo et al. 2017; Matt et al. 2004; U. S. Environmental Protection Agency 2018; Wu et al. 2010). An important, but avoidable combustion source leading to exposure to multiple pollutants is smoking indoors. Smoking is a major source of formaldehyde, benzene, and PM to name a few of the toxicants it releases into the air. Formaldehyde can also off-gas from furniture, building materials, and carpets. Personal care products including lotions, make-up, and perfumes, are sources of nanoparticles, phthalates, and parabens. Air fresheners and cleaning products contain multiple classes of potentially harmful chemicals including but not limited to PM, nanoparticles, disinfectants, chlorinated hydrocarbons, and various organic solvents that are released into the air during their use. Pesticides, such as insecticides, fungicides, and rodenticides, are a source of exposure for permethrins and pyrethroids. The following sections describe the routes these chemicals take to enter the human body.

Inhalation Exposure

Indoor inhalation exposure results from breathing an agent (chemical/physical/biological) while indoors (U.S. Environmental Protection Agency 2019). Indoor contaminants include: PM, vapors, VOCs, semi-volatile organic compounds (SVOCs), and biological agents. The size of the aerosols that comprises the PM affects its penetration indoors and whether/where it is deposited in the lungs. PM10, (particulate matter $<10\ \mu m$ in aerodynamic diameter) are inhalable, cross the mouth/nose barrier while smaller sized particles will penetrate more deeply in the lungs,

Fig. 2 Diagram of the lung.
(Source: <https://www3.epa.gov/region1/airquality/pm-human-health.html>)

into the alveoli (Figs. 2 and 3b). Changes in respiration rate can affect exposure, with people exercising having higher breathing rates leading to a larger intake of air and deeper penetration of the toxicants into the lungs. Elevated breathing rates likely occur in indoor gyms, recreational facilities, and schools. Besides exercise regimens done in those locations and in homes, higher ventilation rates compared to sedentary rates (Metabolic Equivalent (MET) <1.5) occur when performing many common activities (e.g., house cleaning, gardening, walking stairs) which results in breathing rates associated with light intensity activities (MET 1.5 to 3.0). Moderate intensity activities result in a further doubling of the breathing rate compared to light intensity activities (MET 3.0 to 6.0) and another doubling is associated with vigorous intensity activities (MET >6.0) (Lioy and Weisel 2014; U.S. Environmental Protection Agency 2011). Thus, the appropriate breathing or respiratory rate should be selected for the activity of the person being considered when estimating or comparing inhalation exposures.

Inhaled contaminants can reach different parts of the respiratory tract depending upon their physical form and chemical properties. Vapors that are highly soluble in aqueous solutions, (e.g., ammonia, acetone, formaldehyde) deposit into the mucus or thin layer of fluid covering the luminal surface of the airway toward the upper part of the respiratory tract. Non-polar VOCs and the vapor phase of SVOCs will penetrate to the alveoli where gas exchange occurs. The deposition of particles in the lung depends upon the breathing pattern, particle size and shape, flow dynamics, and the lung morphology. The respiratory tract is highly branched beginning at the bronchi which bifurcates to the two lungs. The respiratory tract has sequentially small diameter tubes (bronchioles) ending in the alveoli or air sacs where gas exchange occurs (Fig. 2). Particles deposit onto the walls of the respiratory tract via a number

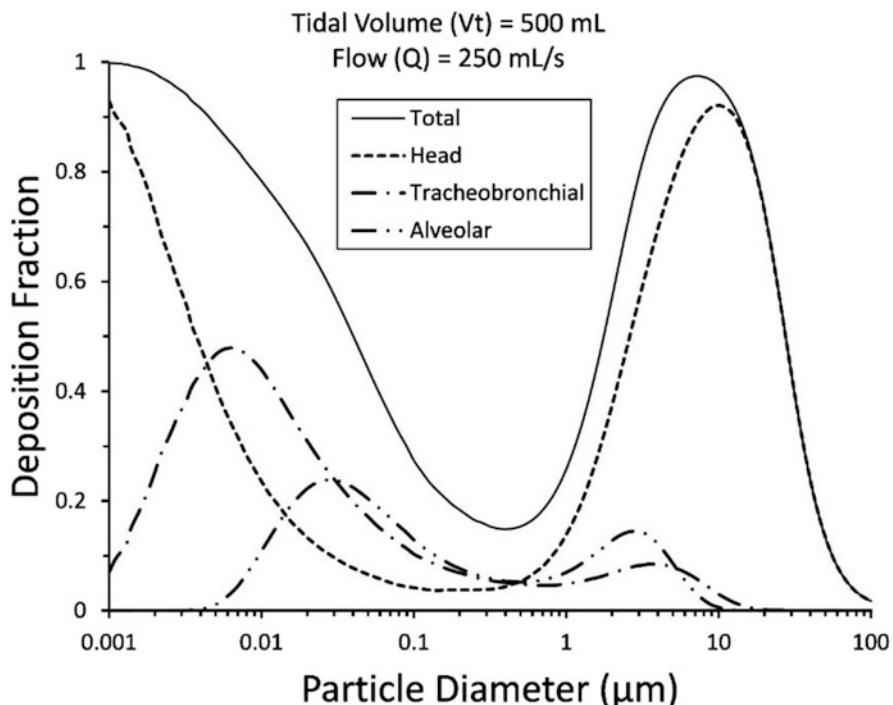

Fig. 3 Mathematical model of particle deposition via nasal breathing in the whole lung (Total), nose, naso-pharynx, and larynx (Head), tracheobronchial airways, and alveolar region in healthy adults. Tidal volume (V_t) is 500 mL, frequency of breathing is 15 bpm, and flow rate (Q) is 250 mL/s. Deposition was adjusted for particle inhalability, which is why particle deposition decreases for particles greater than 10 μm . Particles in the 0.3 to 0.5 μm range show the lowest deposition for any of the regions. (Above simulation conducted using the Multiple-Path Particle Dosimetry Model v3.01, Applied Research Associates © 2015). (Source: <https://www.epa.gov/pmcourse/particle-pollution-exposure>)

of processes: interception (by touching the wall surface – particularly important for fibers); impaction (particles that cannot stay within the air stream as it curves, $>10 \mu\text{m}$ in the nose and throat); sedimentation (when gravitational forces and air resistance exceed their buoyancy, particles $>0.5 \mu\text{m}$ in the bronchi); and diffusion (particles $<0.5 \mu\text{m}$ in the smaller bronchioles and alveoli) (Heyder 2004). Very small particles referred to as nanoparticles or ultrafines ($<100 \text{ nm}$) can be found in consumer products. Nanoparticles deposit mainly through diffusion and a portion can reach the alveolar sacs, though they also coagulate into larger agglomerates resulting in deposition in the upper section of the respiratory tract. A sharp particle size cutoff does not exist for deposition into different sections of the respiratory tract, rather particle properties such as hygroscopicity and particle shape, and physiological properties, lung morphology and minute ventilation, can affect their transport within the lungs (Oberdörster et al. 2005) (Fig. 3). The relatively high humidity and

temperature within the respiratory tract compared to the indoor environment can cause hydroscopic particles to grow, changing their effective size compared to their size in indoor air and therefore their lung deposition site (Azuma et al. 2018; Heyder 2004; Löndahl et al. 2014). Indoor air particles have sources of penetration from outdoors, resuspension of dust, human activities, and chemical formation.

Dermal Exposure

Indoor dermal exposure to air pollutants occurs via direct skin contact by vapors and by touching surfaces which particles have deposited or SVOCs have absorbed/adsorbed (Shi and Zhao 2014). Dermal exposure can result in skin irritation and/or absorption into the body through the epidermis. Dermal exposure can be determined from the duration/frequency of contact with surfaces/objects multiplied by the chemical's concentration on those surfaces/objects and the transfer rates from surfaces to the skin (Ott et al. 2006). For uptake of volatile compounds from the air, clothing can alter the surface area of exposed skin and therefore the dermal exposure. Some agents, with low gas-to-fabric partition coefficients, can penetrate through clothing, while others, with high gas-to-fabric partition coefficients, will adsorb to clothing and delay exposure to the skin. Agents with intermediate gas-to-fabric partition coefficients can accumulate on clothing prior to being worn, resulting in a higher dermal uptake (Liu et al. 2021; Morrison et al. 2016). If the clothing becomes wet, hydroscopic pollutants or particles may be absorbed or adhere to the clothing causing higher dermal exposure over a longer duration than would occur otherwise. The absorption of SVOCs into other fabrics that contact skin, such as bedding and furnishings can also result in dermal exposure. Transdermal absorption of the vapor phase of some SVOCs in the indoor air can exceed the dose associated with inhalation exposure. The compound's physiochemical properties, such as molecular weight and stratum corneum/air partition coefficient, influence the extent of vapor absorption (Weschler and Nazaroff 2014). Examples of the semi-volatile compound classes for which dermal absorption of vapors can exceed uptake from inhalation of vapors include parabens, low molecular weight phthalates, phenylphenols, and terpene alcohols.

Dermal exposure will also result when touching surfaces or settled dust that have absorbed/adsorbed volatile and semi-volatile compounds from the air. Transfer of SVOCs occurs from the dust and surfaces into the skin lipids. House dust has been shown to be a reservoir for many VOCs and SVOCs (Lioy et al. 2002). Surface films can absorb hydroscopic compounds (Duncan et al. 2018) or surfaces can become coated with a thin organic matter film which absorb SVOCs from the air based on its octanol-gas-phase partition coefficient and into skin oils (Weschler and Nazaroff 2014). These authors found a linear relationship between their predicted abundance of a range of SVOCs with levels measured in hand wipes for both children and adults, supporting the premise that SVOCs are transferred from indoor air-surface to film-skin and directly from air to skin through an equilibrium controlled pathway. This results in dermal exposure of SVOCs from indoor air. These processes can also

contribute to inadvertent ingestion. Intake fractions for SVOCs identified a number of indoor sources dominated the indoor air levels and provided estimates of the inhalation, dermal and non-dietary ingestion contributions which varied across compound (Shin et al. 2014).

Non-dietary and Indirect Ingestion Exposure

Ingestion exposure associated with indoor air contaminants ensues through the consumption of re-suspended contaminated soil and house dust and from large particles deposited in the respiratory tract that move with the mucous to the GI tract. Hand-to-mouth activities, especially for infants and children, can lead to inadvertent ingestion exposure (U.S. Environmental Protection Agency 2018). The activities that children engage in that can lead to non-dietary and indirect ingestion exposure include playing with toys or crawling on the floor then touching their mouths or eating with their hands. Infants and children are notorious for putting everyday items in their mouth including their own clothing and toys; and infants are given teething rings and pacifiers which are intended to be placed into the mouth, each of which may have absorbed SVOCs. It is estimated that hand-to-mouth activity and object-to-mouth activity occur at frequencies of 42–75 and 17–34 times/h, respectively (Kwong et al. 2020). Contaminants in the PM of indoor air settle and absorb onto multiple surfaces, including kitchen counters, which can be in contact with food, leading to ingestion exposure. Plastic toys and stuffed animals containing synthetic fibers are materials known to absorb semi-volatile and volatile organic compounds. When these items are placed in the mouth the saliva can extract the absorbed chemicals. Microorganisms can also deposit onto surfaces and then be ingested. These activities put children at a higher risk of exposure to harmful pollutants such as pesticides and house dust containing lead.

Biological Agents

While the focus of this chapter is on chemical agents that affect air quality, biological contaminants also contribute to poor air quality and can have multi-route exposures. Biological contaminants include bacteria, viruses, fungi, mold, dander, dust mites, pollen, and insect parts/dropping. These agents can elicit allergic and respiratory responses, such as exacerbation of asthma. They also move through the air within the indoor environment. Moist or wet materials and surfaces within a home composed of a matrix that can provide nutrients for growth (e.g., drywall, wallpaper, insulation, dust, fabric, upholstery), along with indoors having moderating temperature, can serve as a breeding ground for many biologics, particularly mold and fungi. Biologics that grow on surfaces can become airborne, (i.e., bioaerosols – aerosolized liquid droplets containing biological agents, microbes or cell fragments), from multiple sources. The pathways include: being released in or near the vents of an air handling system which blows air into the home; as part of resuspended house

dust; emitted from cold air or ultrasonic humidifiers; and from mechanical process that disturb growth surfaces. In addition, microbes and pollen can be blown indoors from outdoor sources. Bioaerosols are often small enough to be inhaled (inhalation exposure) and can be deposited on surfaces or in-house dust, resulting in dermal and ingestion exposure.

Since moisture is an important factor affecting the growth of mold and fungi in homes, exposures to mold and fungi can be reduced by keeping surfaces dry, through fixing water leakage problems, having adequate ventilation in areas where hot water or steam is produced, and by removing or cleaning water damaged carpets, furnishing, and building materials. Some biologics release spores ($\sim 10\text{--}100\ \mu\text{m}$ in size) into the indoor air which are distributed within homes and serve to seed new areas for growth. Human airborne transmission of viruses ($\sim 20\ \text{nm}$ to $400\ \text{nm}$ in size) and bacteria ($\sim 200\ \text{nm}$ to $100\ \mu\text{m}$ in size (Nazaroff 2016) between people can occur via coughing, sneezing, laughing, and even talking, particularly in crowded, inadequately ventilated rooms. These transmissions are more problematic indoors than outdoors, since indoor settings have limited volume and lower ventilation than outdoors. Taking steps to limit inter-individual transmissions and therefore the spread of infectious diseases, should rely on understanding of their exposure pathways which typically occur indoors. Exposure pathways include: airborne via micron or submicron particles which have different residence time in the air, dermal contact after viruses or bacteria are deposited on surfaces that are subsequently touched with hands that then touch eyes, nose, or the mouth providing an entry point into the body, or by depositing on food or dust that might be ingested. When the exposure pathways and routes for infectious agent transmission are identified, guidance on intervention steps can be provided.

Pollen and pollen grains, biologics with size ranges $<10\text{--}200\ \mu\text{m}$ (Miguel et al. 2006) have inhalation as their primary exposure route, affects the subpopulation sensitive or allergic to it. Pollen mainly has outdoor sources but can have indoor ones like flowering plants. Pollen types and levels vary seasonally, and exposure can be decreased by limiting window opening during periods of high pollen. It should be noted, though, that opening windows increases ventilation and decreases indoor air concentrations of agents released indoors. Thus, there needs to be an appropriate balance of when to open windows based on indoor air contaminant sources, outdoor biologic and chemical contaminants for a particular time and location, and how household residents may be exposed. Animal dander, insect parts, and dust mites have indoor sources with the exposure typically occurring by being in close proximity to the source. Sources often include bedding, mattresses, upholstered furnishing, carpeting, stuffed toys, etc. where people, often children, will generally have their face in close contact. Keeping these items clean by frequent washing can reduce exposures. Vacuums used to clean carpets and furnishing that have a High Efficiency Particulate Air (HEPA) filters trap small (<3 microns) particles with an $>99.9\%$ efficiency and can be effective to limit resuspension and exposure via an indoor air pathway. However, vacuums with low efficiency for small particles could result in resuspension of those particles, thereby potentially increasing inhalation exposure and spreading the dust to other parts of a home. In addition to direct exposure to the

biological agents, some mold, bacteria, and fungi emit VOCs which include mycotoxins, carbonyls, alcohols, terpenes, thiols, ethers, and esters, which can also be irritating or cause respiratory reactions.

Examples of Common Toxicants in Indoor Air

The following sections provide examples of compounds and their pathways that can lead to exposures within the indoor environment. It is not meant to be comprehensive but rather illustrative of pathways that could result in exposures to indoor air pollutants and the types of agents or activity scenarios that lead to those exposures.

Penetrations of Vapors from Outside

The outdoor air provides the baseline for indoor air concentrations for non-reactive, volatile pollutants. For reactive and water-soluble compounds losses occur during transport indoors as they react with or absorb onto surfaces within a building's interior or the building's envelope, the part of the structure separating the controlled inner environment from the ambient atmosphere. Volatile pollutants also enter buildings in soil gas that penetrates through cracks or openings in a building's foundation.

Volatile Organic Compounds (VOCs)

Mobile vehicles, commercial enterprises, and industries emit a plethora of VOCs into the air. These emissions result in ambient air having concentrations at the sub to tens and occasionally hundreds of $\mu\text{g}/\text{m}^3$ level, particularly in urban and suburban settings. Ambient pollutants enter buildings through ventilation systems (active and passive) and via natural air exchange processes, since buildings are not typically air-tight, and when windows are open. Common VOC pollutants in outdoor air include aromatic and aliphatic hydrocarbons, terpenes, chlorinated hydrocarbons, alcohols, ethers, nitriles, and carbonyls (See EPA Hazardous Air Pollutants (U.S. Environmental Protection Agency 2020)). Often, these compounds have indoor/outdoor (I/O) ratios in many homes exceeding unity (Dodson et al. 2009), indicative of indoor sources in addition to the contribution from the penetration of outdoor air. For VOCs that are banned in consumer products and therefore have no indoor sources, such as carbon tetrachloride, the I/O ratio is uniformly close to unity. Activities and materials that are sources of VOCs within buildings include: smoking (aromatic and aliphatic hydrocarbons, furans, nitriles, carbonyls, etc.), cleaning and air freshener products (terpenes, chlorinated hydrocarbons, hydrocarbon solvents, ethers, etc.), and chlorinated or contaminated tap water (disinfection by-products, volatile contaminants in water supply). Exposure to VOCs are typically governed by the indoor air concentrations encountered more than ambient outdoor air

concentrations since people spend most of their time indoors. However, for some VOCs, the indoor air concentrations could underestimate exposure. This occurs when the VOC is in a consumer product that is used in close proximity to the individual's breathing zone. The concentration of air breathed is higher than average room concentration, since as the compound diffuses and becomes mixed with room air its air concentration declines. Studies that have evaluated indoor and personal air often identify higher VOC air concentrations in the personal air that are associated with specific product use (Dawson and McAlary 2009; Weisel et al. 2008).

Formaldehyde

An example of a VOC with large indoor sources in some homes is formaldehyde. This single carbon carbonyl is present in many furnishings that contain foams, wood products, and combustion processes. It off-gasses from resins used in particle board, plywood, and fiber board, insulating materials that use urea formaldehyde foam, glues, adhesives, varnishes, etc. The emissions are particularly prevalent in new materials. While the emission rate decays with time, the emissions can continue for months to years and can fluctuate with relative humidity and indoor temperatures (Liu et al. 2006).

One example of a major incident involving an exposure to high concentrations of formaldehyde was during the clean-up of hurricane Katrina in New Orleans (ATSDR 2007). Temporary housing in the form of FEMA trailers was put up to shelter individuals whose homes were flooded. These trailers were off-gassing toxic levels of formaldehyde inside the trailers, which led to high exposures and adverse health outcomes (ATSDR 2007).

Radon

Radon is rarely a problem outdoors, but due to vapor intrusions into homes in areas with uranium geological features, radon levels can be problematic indoors (National Research Council 1999; Samet 2001). Radon penetrates through building foundations into basements and ground floor rooms as part of soil gas. If those spaces have poor ventilation, radon can increase to levels that have been linked to lung cancer (Alavanja et al. 1999; U.S. Environmental Protection Agency 2016). Radon and its progenies are particularly dangerous indoors because they can go undetected due to being odorless and colorless. The exposure of concern is the inhalation of radon decay products that adhere to particles which can be trapped in the lungs and further decay radioactively, providing a dose directly to lung tissue. The highest cancer rates associated with radon are when there is smoking in a home that also have elevated radon levels, as these hazards act synergistically.

VOCs vapor intrusion occurs in an analogous fashion to radon when a building is above an aquifer or soil contaminated with VOCs, e.g., from gasoline spills, leaking superfund sites and industrial spills. This can result in elevated VOC inhalation

exposures indoors. As with radon, the lowest floors in the home often have the highest air concentrations and are where the greatest exposure occurs, though VOCs will be distributed throughout a home more than radon since they do not radioactively decay and adhere to particles and surfaces as quickly as radon.

Semi-volatile Organic Compounds (SVOCs)

SVOCs include multiple classes of compounds. Exposures to SVOCs within indoor settings occur through inhalation, dermal, and ingestion routes due to the redistribution of the SVOCs between the air and surfaces. An important indoor reservoir for SVOCs is house dust. Some broad compound classes of SVOCs with indoor sources are pesticides, phthalates, flame retardants, poly and perfluoroalkyl substances (PFAS), polycyclic aromatic hydrocarbons (PAHs), and polychlorinated biphenyls (U.S. Environmental Protection Agency 2017a, b). SVOCs are often released into the indoor home environment during consumer product use. Following their initial release indoors, SVOCs have a dynamic lifecycle as they continually volatilize from and condense onto surfaces dependent upon their air concentration and the temperature of the air and room surfaces (Bi et al. 2015; Wallace et al. 2017; Weschler and Nazaroff 2014). House-dust serves as an important vector mediating this process due to its high surface area and organic content. Further, house dust can be resuspended within a home furthering the movement of SVOCs and providing additional exposure routes to the occupants, which includes inhalation of the dust, skin contact, and incidental ingestion after the dust adheres to hands, food, or objects placed in mouths (Little et al. 2012).

Pesticide applications are done indoors and outdoors immediately next to buildings by commercial applicators and residents, both on a scheduled and as-needed basis. The amount released into indoor air can vary greatly and is dependent upon the application method, ranging from minimal amounts for pesticides sprayed at small, localized areas, to levels that may cause health concern when released as a “fog”. Potentially hazardous exposures can occur if occupants are present during and/or shortly following the application when recommendations to avoid being indoors during those times are not followed. Redistribution of pesticides in a residential setting extends the time of exposure beyond the original application period and locations (Lioy et al. 2002). Health effects from pesticides and the susceptible populations vary, e.g., children and pregnant women. Thus, exposure pathways and routes for these groups need to be identified. When evaluating potential exposures to pesticides both historically available pesticides and new formulations should be considered, as well as application methodologies. In practice, actual application by untrained applicators or homeowners may differ from manufacturer’s recommended instructions or not understood, which can result in higher exposures (Grey et al. 2005).

Phthalates are incorporated into the plastics of many consumer products, home furnishings, vinyl flooring and wall coverings (Bornehag et al. 2005; Otake et al. 2004). The most common are: benzylbutylphthalate (BBP), dibutylphthalate

(DBP), di-(2-ethylhexyl)-phthalate (DEHP), di-isodecylphthalate (DIDP), and di-isonylphthalate (DINP) (Abb et al. 2009), though other phthalates have been detected in house dust (Kubwabo et al. 2016). They are present in house dust and air. Flame retardants have been incorporated into home furnishings, electronics and even clothing for babies to forestall the initiation or spreading of fires in homes beginning in 1975. These include brominated compounds, polybrominated diphenyl ethers (PBDEs), tetrabromobisphenol A, hexabromocyclododencane, and organophosphate flame retardants (OPFRs). Their use in the United States started to decline in 2015 when the adverse health outcomes of some chemical flame retardants were identified and their effectiveness for fire prevention was questioned. Since home furnishing continued to be used for years and these chemicals do not readily decompose, continued exposures occur as these compounds become continually incorporated into dust and have a vapor phase within buildings (Stapleton et al. 2008).

Role of House Dust

House dust can contain a wide array of toxicants that are present in the indoor air and absorbed onto the dust particles or have been tracked in from the outside on the bottom of shoes. Dust born toxicants include non-volatile metals and organic species, VOCs, and SVOCs. Multiple indoor surfaces accumulate dust including carpets, countertops, and floors. House dust exposure occurs via inhalation, dermal, and indirect/non-dietary ingestion. Carpeting has been demonstrated to be a reservoir for house dust (Lioy et al. 2002). Inhalation exposure to house dust can occur when it is resuspended into the air, such as through vacuuming or peoples' physical activities such as walking (Lewis et al. 2018; Pavilonis et al. 2015; Rasmussen et al. 2018; Shalat et al. 2011; Wang et al. 2012; Zhou et al. 2017, 2019). Depending upon the vacuum type, larger pieces of house dust are trapped by the vacuum filter but smaller ones can pass through the vacuum bag and become re-suspended into the air. While the particles will settle back down on surfaces over time, an individual within the indoor environment will still inhale the particles (U.S. Environmental Protection Agency 2018). The redistribution of house dust within an indoor setting can lead to inadvertent ingestion exposure and dermal exposure, especially to children who tend to put a lot of items into their mouths and have more contact with the floor than adults, where dust naturally accumulates (Kwong et al. 2020).

Indoor Chemistry

Reactions between ozone and unsaturated hydrocarbon-based compounds (having at least one double or triple carbon-carbon bond) are well known to occur outdoors forming secondary organic aerosols but also contribute to indoor chemistry (Weschler and Carslaw 2018). Nitrogen oxides (NO_x) from natural gas combustion and hypochlorite, from cleaning products, can also react with unsaturated

hydrocarbons. Short lived, intermediate species such as nitrous acids (HONO), and free radicals such as hydroxyl (OH), hydroperoxy (HO_2), organic peroxides (RO_2), as well as nitrate radicals formed from ozone and nitrogen oxides may play a role in indoor air chemistry. Ozone and nitrogen oxides penetrate from outdoors, with indoor sources existing (e.g., photocopies for ozone, combustion of gas for cooking and heating for nitrogen oxides). Unsaturated compounds have multiple sources indoors that include outdoor penetration, consumer and cleaning products (e.g., fragrances – terpenes, ammonia), building materials (e.g., wood-terpenes, plastics), cooking (e.g., oils and spices – terpenoids), and skin oils (e.g., squalene, unsaturated fatty acids, isoprene). Reactions with unsaturated hydrocarbons reduce indoor ozone air concentrations, which is a respiratory and ocular irritant, but the chemical reaction products may also be irritants or have other adverse health effects (Nazaroff and Weschler 2004). The extent that these reactions occur indoors is related to a home's air exchange rate. Higher air exchange rates bring more ambient ozone indoors while lower rates provide more time for the reaction to occur and the buildup of the unsaturated hydrocarbon precursors and reaction products.

Ozone-driven reactions incorporate an oxygen into the carbon structure forming aldehydes, ketones, and carboxylic acids of various carbon lengths and structure. Nitrogen containing moieties can be produced when nitrogen oxides are present. Both volatile and indoor secondary organic aerosols (SOA) are formed. Since skin oil compounds contain double bonds that react with ozone, the air concentration of their reaction products are higher surrounding an individual than elsewhere in the indoor environment, leading to higher inhalation exposure or dermal contact than might be estimated from room air measurements. Among the compounds observed from ozone-squalene reactions to which individuals are exposed are volatile species: 6-methyl-5-heptene-2-one (6MHO), geranyl acetone and 4-oxopental (4-OPA) (Wisthaler and Weschler 2010), and SOA containing levulinic, succinic, adipic, and suberic acids (Zhou et al. 2016).

Consumer Goods and Personal Exposures

According to the US EPA, consumer products contain more than 49,000 chemicals in 16,000 products (www.EPA.gov/chemical-research/chemical-and-products-data-base-cpdat accessed 1/20/21). While not all chemicals will be released into the air and some may be at very low concentrations and/or in a limited number of products, consumer products can be a source of multiple contaminants to the indoor air thereby exposing people via multiple routes. New furniture and building material which contain glues/adhesives, pressed wood, flame retardants, stains and sealers, dyes, stain treatment, etc. continuously release VOCs and SVOCs into the indoor air, with the amount emitted typically declining over time as the product ages and the amount of the agents present in the product declines. It is not unusual to smell chemicals emitted when new products are first brought into a home or after walls are painted, affecting air quality and leading to exposures. The amount released can vary over a day and seasonally due to temperature changes within a home, with more emissions

at higher temperatures. However, the temperature range indoors is not as great as outdoors so the cycling of emissions may be limited. Furniture containing polyurethane or other foams can absorb SVOCs from the air and subsequently release them, moderating and extending the time that SVOCs affect the indoor air concentration after the SVOCs are introduced into a home from a consumer product. The use of the plethora of personal, consumer products categorized as cosmetics and personal care products, cleaning and home maintenance products, pesticides, disinfectants, and scented candles and air fresheners, (e)-cigarettes, etc. contribute chemicals and particles, including nanoparticles, into the indoor air. The releases from consumer products typically occur sporadically, depending on how and when they are used. Some products are intentionally sprayed into or through the air. Others have evaporative emissions after the product is applied to the body or surfaces. Dust and particles containing residue from consumer product are resuspended from floors or surfaces when perturbed by physical movement.

Chemicals emitted from personal consumer products initially results in a non-uniform air concentration within a room and throughout a home. This is due to it having a localized source, i.e., product use, and incomplete mixing of air throughout a room and house, though over time a more uniform indoor air concentration is reached. Since many products are used in close proximity to people, the air concentration in the breathing zone resulting from that use is typically higher than in the “background” indoor air and drives the inhalation exposure. Studies that have examined both indoor and personal air concentration typically find that the daily average personal air concentrations are higher than the daily average indoor air concentrations (Turpin et al. 2007; Weisel et al. 2005). However, the ratio of the daily average personal to indoor air is smaller than the ratio that would be calculated for short-term peak exposures, as many products result in brief, large increases in breathing zone air concentration before the agents diffused throughout the room elevating the “background” indoor room air concentration by a smaller amount.

An evaluation of the impact of consumer products emissions on breathing zone air concentrations requires an understanding of the human activity patterns and actual product use. Some of the broad classes of agents in these products were given in Table 1, but that list represents only a portion of the agents released and to which people are exposed. Consumer product emissions can cause acute or chronic elevations of the breathing air concentrations and exposures depending upon the product and its use. Acute exposures can result from spraying of products such as hair and cosmetic products, pesticides, and cleaning products. Personal care products are typically sprayed toward the direction of a person presenting instantaneous, elevated inhalation exposures. Pesticides and cleaning products should be sprayed away from the face but create aerosols that drift toward the breathing zone prior to being dispersed throughout the room. For cleaning products, the person applying it often stays in close proximity to the area sprayed while cleaning the surface it was applied to, extending the time of elevated breathing zone air levels. Personal or breathing zone air samples have not been collected in many studies for some specific activities, such as showering and bathing, due to logistic issues. The activities can release contaminants into breathing zone air, such as disinfection by-products from

chlorinated water while showering, at levels much above the “background” indoor air, again presenting an exposure that is not captured from “background” indoor air concentration measurements. Smoking and vaping causes high exposures to many air contaminants, particularly to the individual smoking or vaping due to direct inhalation of the smoke and vapors and from the resulting contaminated breathing zone air. Other individuals who are in close proximity to the smoker or person who vapes will also encounter elevated breathing zone air levels compared to the “background” indoor air, prior to the smoke or vaping emissions being dispersed. Many indoor air studies have excluded homes with smokers from their target population because smoking often is the dominant indoor air source of particles and many gases.

Longer duration (subchronic and chronic) elevation of breathing zone air also occurs due to the proximity of people to some consumer product sources. These can include emission from products that are directly applied to the body, from clothing, and from furniture. Products applied to the skin can contain SVOCs that evaporate from the skin and will penetrate the breathing zone. Clothing can contain cleaning chemicals, fragrances, and surfactants present in detergents used to wash clothes and from dry cleaned clothes will off-gas the dry-cleaning chemicals, such tetra-chloroethene, for several days. Nanoparticles are being added to clothes to lessen odors by limiting bacterial growth (sliver nanoparticles) and to repel water and stains (silica nanoparticles), which can be released from mechanical abrasion. SVOCs and particulate emissions from furniture may also elevate breathing zone air since sitting on upholstered furniture or bedding often brings the face close to the source for extended times. These can include flame retardant chemicals (e.g., PBDEs), stain resistant chemicals (PFAS), dust mites, allergens, and SVOCs that were absorbed from the air by the material covering or foam padding in the furniture. These SVOCs can be released by the warmth provided by the body which shifts the equilibria from the absorbent surface to the air. The thermal properties of the body create an air boundary layer flow, with flow patterns around the body that move upwards since the body is typically warmer than the indoor air temperature. This upwards movement of air contaminants brings them into the breathing zone when they are emitted from lower sections of the front of the body and potentially from furniture being sat upon. Under conditions of low air mixing, these emissions close to the front of the body will impact the breathing zone concentrations (Licina et al. 2015).

Conclusions

Many indoor sources and low air exchange rates contribute to poor indoor air quality. Understanding the major routes of exposure: inhalation, dermal, and non-dietary and indirect ingestion is critical to identifying exposure pathways in the indoor environment to implement steps to reduce exposures and protect public health. As discussed in this chapter, these sources of exposures can originate indoors and near peoples, such as personal care products, building materials, house dust, or penetrate from outdoors or soil, such as radon, ozone, and VOCs. Indoor chemical reactions expose

the general population to additional compounds whose health effects are not completely known. Since people spend the majority of their time indoors during their lifetime, it is important to consider how these factors influence the quality of indoor air and exposures, and subsequently affect health.

Abstract

There is growing evidence that the clothing is an important source of exposure to various chemicals and particles on a daily basis. Emerging knowledge suggests that everyday clothing harbors various contaminants, which if inhaled, ingested, or dermally absorbed, could carry significant health risks. This chapter summarizes the state of the most recent knowledge regarding how clothing, during wear,

influences exposure to molecular chemicals, abiotic particles, and biotic particles, including microbes and allergens. The underlying processes that govern the acquisition, retention, and transmission of clothing-associated contaminants and the consequences of these for subsequent exposures are explored. Chemicals of concern have been identified in clothing, including byproducts of their manufacture and chemicals that adhere to clothing during use and care. Analogously, clothing acts as a reservoir for biotic and abiotic particles acquired from occupational and environmental sources. Evidence suggests that while clothing can be protective by acting as a physical or chemical barrier, clothing-mediated exposures can be substantial in certain circumstances and may have adverse health consequences. This complex process is influenced by the type and history of the clothing, the nature of the contaminant, and by wear, care, and storage practices. This chapter also summarizes the most pressing knowledge gaps that are important for better quantification, prediction, and control of clothing-mediated exposures.

Chemical exposures · Abiotic particles · Biological material · Exposure modelling · Health impacts

Introduction

Clothing harbors diverse chemicals, particles, and microbes. Some are present at the time clothing is purchased, and some are acquired during the care, storage, and use of garments. People spend most of their lives in intimate contact with clothing. They are exposed to the species found on and in their clothing via inhalation, ingestion, and dermal absorption (Fig. 1). More specifically, humans inhale species that desorb or are released from their clothing, ingest clothing-associated chemicals and particles when clothing materials enter their mouths, and acquire species on their skin from the clothing they wear. Clothing-mediated exposures are influenced by factors inherent to clothing, such as fiber type, weave, morphology, dyeing process, color, and chemical treatment (including incorporation of flame retardants, stain repellants, and anti-wrinkle agents). Exposures are also influenced by external factors such as washing, drying, storage, usage patterns, and environmental conditions. Once in the lungs, in the gastrointestinal system or on the skin, chemicals from clothing may be absorbed into the body. This exposure can further contribute to irritation, allergic reactions, and infections as well as risks for adverse health effects as diverse as cancer, birth defects, and heavy-metal poisoning (BfR 2012; KEMI 2014; Rovira and Domingo 2019).

This chapter, largely based on our earlier critical review of the topic (Licina et al. 2019), is organized in the following manner: We first present the role of clothing in exposure to chemicals, then to biotic and abiotic particles. In the part on chemical pollutants, we first present the recent evidence for the influence of clothing-mediated

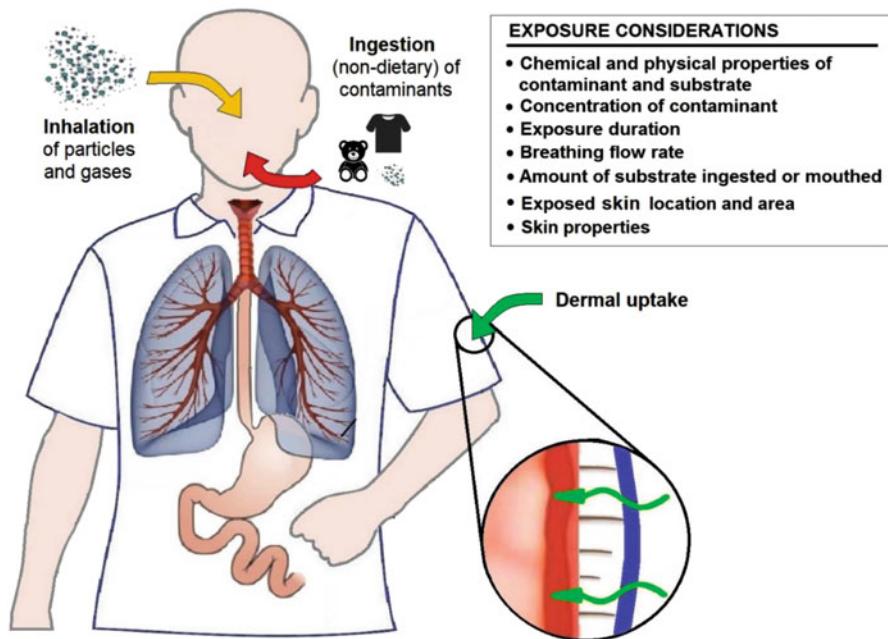

Fig. 1 Non-dietary routes of human exposure for contaminants of concern: Inhalation, ingestion and dermal absorption. (Reprinted with permission from D. Licina, G.C. Morrison, G. Beko, C.J. Weschler and W.W. Nazaroff, Clothing-mediated exposures to chemicals and particles, Environ. Sci. Technol., 2019, 53, 5559–5575, DOI: <https://doi.org/10.1021/acs.est.9b00272>. Copyright (2021) American Chemical Society)

exposure to chemicals. This is followed by a summary of the evidence of the occurrence and persistence of chemicals in clothing, and by discussion of the mechanisms of accumulation and transfer of chemicals. In the part on particles, we first present evidence for the influence of clothing-mediated exposure to biotic and abiotic particles. We then outline a framework for quantifying clothing-mediated particle exposures, and finally we review factors that influence clothing-associated exposures to particles. The chapter describes situations where the underlying factors influencing chemical and particle exposures are similar, while also recording fundamental ways that they differ. Whereas the potential influence on health risks is the key ultimate reason to improve understanding of clothing-mediated exposures, a detailed examination to quantify clothing-associated health risks is beyond the scope of this chapter. The concluding part examines several knowledge gaps that currently limit the ability to predict or mitigate clothing-related exposures to chemicals and particles. It also suggests some research directions that could reduce these limitations. Overall, the influence of clothing on environmental exposures is often substantial, but additional research efforts are warranted to better quantify, predict, and control clothing-related exposures, and ultimately understand how clothing influences human health and well-being.

Exposures to Chemicals

Evidence of Clothing-Associated Exposure to Chemicals

Clothing-Associated Chemicals in Skin, Blood, and Urine

Human exposure and uptake of organic compounds by means of transfer from treated fabrics has been investigated for several decades. For example, in the late 1970s, Blum et al. (1978) reported finding metabolites of the flame retardant tris (2,3-dibromopropyl)phosphate (tris) in the urine of children who had worn clothing treated with this chemical. Radiolabeled tris in treated and dried cloth was shown to penetrate the clipped skin of rabbits. Other studies showed that moistening the cloth with simulated sweat does not increase absorption. Earlier, Brown (1970) reported instances of infant poisoning attributable to use of phenolic disinfectants in improperly laundered hospital fabrics. More recently, forestry workers wearing permethrin-treated, tick-proof pants were shown to have significantly elevated levels of a permethrin metabolite in their urine (Rossbach et al. 2016). Moreover, absorption of ethylene oxide (a fumigant) and other pollutants such as glyphosate (an herbicide), malathion (an insecticide), and benzothiazole (used as dye, biocide, herbicide, and fungicide) from fabric into skin or a skin-mimicking membrane has been demonstrated in studies using an *in vitro* diffusion cell (Iadaresta et al. 2018).

In another study, measurements of polychlorinated dibenzo-p-dioxins and dibenzofurans (PCDD/F) in the stratum corneum, epidermis, and subcutis of eight volunteers as well as in a variety of new fabric swatches showed that some textiles are contaminated and can be an important source of exposure to these chemicals (Horstmann and McLachlan 1994). The PCDD/F species were shown to diffuse through the stratum corneum into the deeper layers of the skin. Stratum corneum concentrations were substantially higher after wearing contaminated shirts rather than uncontaminated shirts. Skin contamination was heterogeneous, both among individuals and among sites on the same individual. However, when identical, homogeneously contaminated T-shirts were used in a companion study, relatively little spatial and interpersonal variability was observed (Klasmeier et al. 1999). Uptake from polyester was found to be an order-of-magnitude lower than from cotton. Transfer of chemicals was found to increase for fabrics that were previously worn. Residual sweat and lipid compounds may have served as transfer vehicles, or possibly weakened the binding interaction between the fabric and PCDD/F. Heavy perspiration during intense physical activity also increased the migration rate of a textile dye, Dianix®, onto the skin of volunteer subjects, while contact time was found to be less important (Meinke et al. 2009).

As people perform their daily indoor (e.g., working, studying, playing, exercising) and outdoor routines (e.g., driving, cycling, walking), the clothes they wear can act as a means of transporting pollutants from one environment to another. This phenomenon has been studied in the context of health concerns related to “para-occupational” (or “take-home”) exposures. Certain hazardous chemicals, such as lead, beryllium, polychlorinated biphenyls (PCB), and pesticides, can be transferred

from a work site to the worker's home via clothing and thereby contribute to elevated levels in the blood and urine, or even to direct adverse health effects. For example, women who laundered agricultural work clothes had up to 42% higher serum levels of dichlorodiphenyltrichloroethane (DDT) and hexachlorobenzene compared to women who did not (Bradman et al. 2007). Similarly, women living in homes in which agricultural workers wore their work clothes had higher levels of most of the organochlorine pesticides that were being used (Bradman et al. 2007). Multivariate analyses by Park et al. (2015) indicated an association between serum levels of polybrominated diphenyl ethers in California firefighters and the storage and cleaning practices used for protective gear. Park et al. (2015) suggested that these flame retardants can be transported to fire stations via fireborne dust on soiled turnout gear and that good housekeeping practices can reduce subsequent exposure. Instances of para-occupational exposures for toxic and allelopathic particles will be discussed subsequently.

Influence of Clothing on Dermal Uptake of Airborne Chemicals

Until recently, the influence of clothing on dermal uptake of airborne organic compounds received relatively little attention. Initial studies examined a few chemicals, primarily volatile organic compounds in occupational settings. Recent efforts have addressed dermal exposures to semivolatile organic compounds common in everyday indoor settings. For example, Morrison et al. (2016) measured the uptake of two airborne phthalates, diethyl phthalate (DEP), and di-n-butyl phthalate (DnBP), by an individual wearing either clean clothes or clothes previously air-exposed in a chamber with elevated phthalate concentrations. When compared with dermal uptake for bare-skinned individuals under otherwise identical experimental conditions (Weschler et al. 2015), clean clothes decreased transdermal uptake by factors of 3–6, whereas previously exposed clothes increased dermal uptake by factors of 3 and 6 for DEP and DnBP, respectively. The same group of researchers subsequently obtained analogous results for nicotine (Bekö et al. 2018). Figure 2 metaphorically illustrates the role of clothing as either "protector" or "amplifier" of dermal uptake by using a tree and a rainstorm analogy. In another study, three subjects exhibited elevated urinary excretion rates of the UV filter benzophenone-3 (BP-3) and its metabolite benzophenone-1 shortly after donning T-shirts previously exposed to air with elevated BP-3 levels (Morrison et al. 2017a). The authors of that work suggested that dermal uptake of BP-3 from clothing could meaningfully contribute to overall body burdens.

The protective effect of uncontaminated clothing has also been indicated by reduced phthalate concentrations in skin wipe samples taken from body parts covered with clothing compared to uncovered skin (Gong et al. 2016). However, clothing did not provide total protection in these studies. In vitro experiments demonstrated reduced absorption of organophosphates through a cotton shirt as compared to unclothed skin (Moore et al. 2014). However, common clothing is reported to have little effect on dermal exposure to certain gases in hazardous material incidents, such as methyl bromide, sulfuryl fluoride, and chloropicrin (Gaskin et al. 2017).

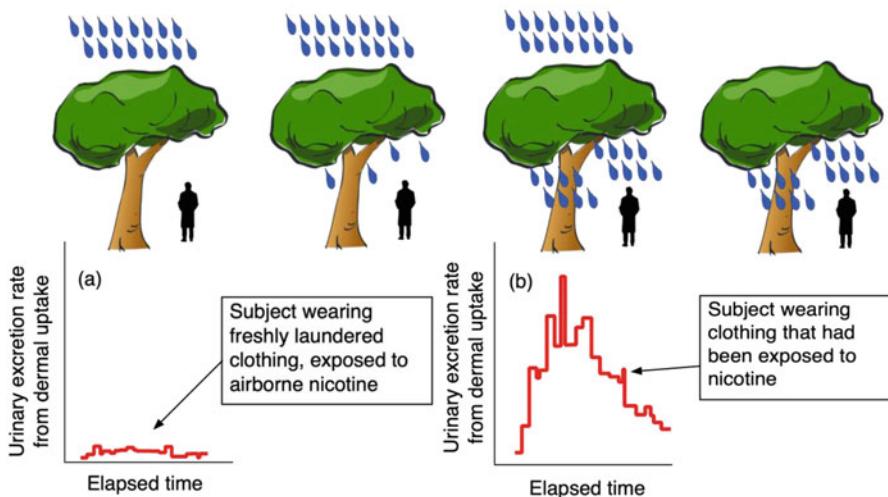

Fig. 2 Dynamic urinary excretion rates due to dermal uptake for nicotine and two urinary metabolites (summed) after exposing participants, who were wearing breathing hoods, to airborne nicotine (Bekö et al. 2018). (a) Freshly laundered clothing, unexposed to nicotine, is protective; this is analogous to a tree at the beginning of a rainstorm that protects a person from getting wet. (b) Clothing that has been previously exposed to airborne nicotine dramatically increases urinary excretion rate for days after wearing the clothing, just as standing under a tree after a long rainstorm is most certain to get the person wet. This exposure occurs while wearing the clothes in the environment containing the contaminant (third tree from left) and can continue after leaving this environment. (Reprinted with permission from D. Licina, G.C. Morrison, G. Beko, C.J. Weschler and W.W. Nazaroff, Clothing-mediated exposures to chemicals and particles, *Environ. Sci. Technol.*, 2019, 53, 5559–5575, <https://doi.org/10.1021/acs.est.9b00272>. Copyright (2021) American Chemical Society)

Numerical analysis of Cao et al. (2018) have shown that the skin-to-clothing contact (direct as opposed to indirect exposure via the air gap between skin and clothing) can significantly affect the skin exposure to chemicals. The effects of clothing on dermal exposure (i.e., accelerating effect of chemical-contaminated clothing and impeding effect of chemical-free clothing) can be stronger with increased skin-to-clothing contact (Liu et al. 2021). As a consequence, skin-to-clothing contact may be the primary pathway for chemicals from clothing to the skin surface. In the model by Cao et al. (2018) applied on the experimental scenarios described by Morrison et al. (2016), 62% and 87% of the total dermal exposure to DEP and DnBP was attributable to skin-to-clothing contact, respectively.

Health Effects as Evidence of Exposure

Studies of health effects related to hazardous substances in textiles further corroborates the significance of clothing-associated exposures. The existing studies have mainly focused on dermatitis caused by textile dyes and finishing resins. A limited literature also exists on carcinogenic, mutagenic, and reprotoxic substances in textile

articles. These effects have been suggested for certain dyes, especially azo dyes and for some antibacterial agents, such as triclosan. Brominated flame retardants, phthalates, and degradation products of highly fluorinated polymeric water repellents and stain repellents, which can be present in textile articles, have been associated with reproductive and developmental toxicity (Jurewicz and Hanke 2011). Evidence of direct health effects of such clothing-related exposures is lacking. Comprehensive reviews of textile-related health studies can be found in the report of the Swedish Chemicals Agency (KEMI 2014) and in the opinion statement of the German Federal Institute for Risk Assessment (BfR 2012).

Occurrence, Persistence, and Accumulation of Chemicals in Clothing

Figure 3 illustrates the typical clothing lifecycle from manufacturing and distribution to everyday use. The contaminants present in clothing are a mix of those present at the time of purchase (e.g., resulting from manufacturing processes; these possibly attenuate with time) and those acquired post-purchase. This mix changes with washing and drying practices, storage, and wear.

Chemicals Present at Time of Purchase

Most of the chemicals that have been measured in clothing at the time of purchase are a consequence of manufacturing processes (e.g., dyeing, bleaching, and finishing) or have been deliberately added and are intended to be retained during the life of the garment. The latter group, referred to as “auxiliaries,” includes antiwrinkling resins, flame retardants, antimicrobial agents, pesticides, surfactants,

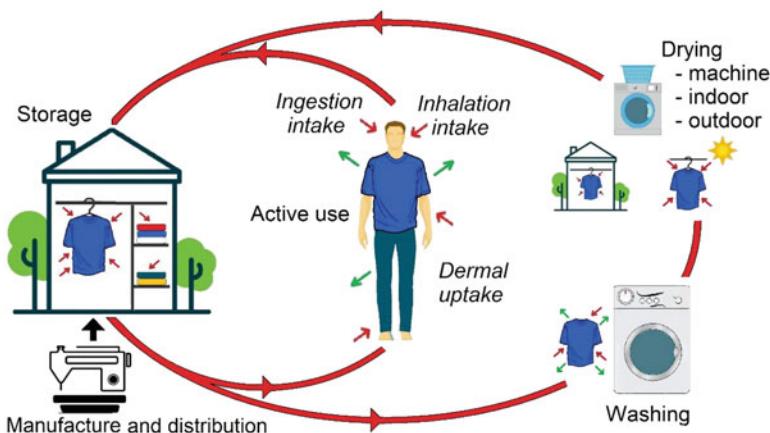

Fig. 3 Stages of clothing lifecycle that determine the rate of acquisition, retention and release of chemicals and particles. (Reprinted with permission from D. Licina, G.C. Morrison, G. Beko, C.J. Weschler and W.W. Nazaroff, Clothing-mediated exposures to chemicals and particles, Environ. Sci. Technol., 2019, 53, 5559–5575, DOI: <https://doi.org/10.1021/acs.est.9b00272>. Copyright (2021) American Chemical Society)

and other coating chemicals. Dyeing involves the largest range of chemicals, with an estimated 800 dyes currently in use (BfR 2012). A move towards more environmentally benign textile dyeing has been further altering the mix of chemicals used in dyeing. Some chemicals in clothing fabrics are present as a consequence of packaging, transport, storage, and other processes that occur between manufacture and purchase.

Chemicals that have been identified on newly purchased clothing include trace elements such as heavy metals (Rovira et al. 2017); residual aromatic amines associated with certain azo dyes (Kawakami et al. 2010); quinoline and substituted quinolines (Antal et al. 2016; Luongo et al. 2016); alkylphenol ethoxylates, alkylphenols, bisphenols, and benzophenones (Xue et al. 2017); benzothiazoles and benzotriazoles (Luongo et al. 2016), dioxins and furans (Horstmann and McLachlan 1994); PCBs, organo-phosphorous flame retardants and pesticides (Zhu et al. 2009); halogenated flame retardants (Blum et al. 1978); fluorinated surfactants (Liu et al. 2014); phthalate ester plasticizers (Schettler 2006); glycol solvents (Laursen et al. 2003); formaldehyde from antiwrinkle resins (De Groot and Maibach 2010); and common petrochemical fuel constituents such as linear and branched C₁₀–C₁₆ alkanes, C₃ alkylbenzenes, and straight-chained C₇–C₁₀ aldehydes (Lentini et al. 2000).

Relatively new chemical analysis techniques are being applied to assess chemicals in clothing. Antal et al. (2016) described the use of direct analysis in real-time (DART) mass spectrometry to measure more than 40 chemicals in 15 clothing items of different materials, types colors and origin. Identified compounds included alkylphenol ethoxylates, phthalate esters, alkyl amines, aniline, pyridine, quinoline, and substituted quinoline. In a recent review, Rovira and Domingo (2019) reported on chemicals that have a high probability of being detected on clothing, with a focus on the health risks posed by these species. These include various flame retardants, trace elements, and organic compounds (quinolines, bisphenol A, etc.). Of special note are extensive government reports from Denmark, Germany, The Netherlands, Sweden, and other countries that review and critically discuss chemicals found in clothing, especially the chemicals that may be present at the time of purchase (Licina et al. 2019).

Chemicals Acquired Post-Purchase

Chemicals present in air, especially indoor air, can also be present on clothing exposed to that air (Cao et al. 2016; Lao et al. 2018; Morrison et al. 2015, 2017b, 2018). A commonly encountered example of chemical uptake from air occurs when clothing is exposed to environmental tobacco smoke (ETS). Up to a milligram of nicotine can be sorbed by a square meter of cotton fabric during just a few hours of exposure (Piadé et al. 1999). Odors derived from ETS constituents can linger on clothing for hours to days. More generally, how much or how little of a chemical is transferred from air to clothing depends on several factors. One key factor is the partition coefficient between clothing and air (K_{ca}) for the fabric in question. As a rule of thumb, the more an airborne chemical resembles the chemical nature of the fabric that constitutes the clothing, the larger is the value of K_{ca} and consequently the

greater is the sorptive partitioning of that chemical to the clothing. The octanol/air partition coefficient (K_{oa}) is a good predictor of K_{ca} for cotton, since cotton is cellulosic, for which octanol is a reasonable surrogate (Morrison et al. 2015, 2018). Values of K_{ca} in relation to vapor pressure for several different fiber types have been reported (Morrison et al. 2018). Still needed are systematic investigations of K_{ca} for an array of environmental chemicals to a range of clothing fibers, including wool, polyester, nylon, rayon, and other synthetics, as well as to blends, to better estimate the sorption of airborne chemicals to these fiber types.

Clothing can also acquire chemicals while in closets, storage containers, and chests. A well-known example is sorption of the chemical agents used as moth repellants: naphthalene, camphor, and *p*-dichlorobenzene (Wang et al. 2011). Similarly, one would anticipate that phthalate esters or alternative plasticizers would be sorbed to clothing stored in polyvinyl chloride (PVC) storage boxes or bags.

Another route for transfer of chemicals to clothing is the contact with various surfaces. Such chemicals can migrate through clothing and become available for dermal uptake. Personal care products and fragrances applied to the skin or hair can also be transferred to clothing via contact. Clothing can retain certain chemicals transferred from personal care products, exposing the wearer, and, in principle, those sharing indoor spaces to such chemicals during storage and during repeat wearings until the item is effectively cleaned.

Laundering and dry-cleaning removes certain chemicals from clothing but can add others. The fraction of a chemical that is removed from clothing during cleaning varies with the nature of the chemical as well as with the cleaning practices, including the detergent or dry-cleaning solvent that is employed. Gong et al. (2016) found that the efficiency with which machine washing removed phthalates from cotton jeans increased with the octanol/water partition coefficient (K_{ow}) of the phthalate. During dry-cleaning, clothing can retain chemicals from cleaning solvents that subsequently contribute to personal exposures. During laundering, clothing may acquire scents (e.g., synthetic musks (BfR 2012)) and other detergent constituents (e.g., alkylphenol ethoxylates). Following the wash cycle, clothing is either air-dried or mechanically dried. When air-dried, the clothing can sorb chemicals from the air in which it is dried. When mechanically dried, some chemicals can be thermally desorbed while other chemicals (e.g., fabric softeners introduced using “dryer sheets”) may be sorbed by the clothing. Laundering also results in chemicals being transferred among the differing items that are washed or dried together. Cross-contamination of fabrics during laundering and storage has been reported for permethrin-treated garments (Faulde et al. 2006).

Chemicals on clothing can be chemically transformed to other species. Of longstanding concern are the abiotic and microbial reduction of azo dyes to carcinogenic aromatic amines such as aniline, benzidine, and 2-naphthylamine. For example, analysis of 86 textile products purchased in Japan detected aromatic amines at low concentrations in socks, undershorts, pants, and other garments (Kawakami et al. 2010). Oxidants can also degrade azo dyes, as shown by reactions initiated by the hydroxy radical, generating benzene and substituted benzenes (Spadaro et al. 1994). Photolytic debromination has been shown to produce low

levels of polybrominated dibenzofurans (Kajiwara et al. 2013) when clothing containing the flame retardant hexabromocyclododecane (HBCD) is dried in the sun.

Another significant source of chemicals in clothing is human skin. During wear for example, clothing acquires skin oils, whose constituents can be altered via microbial activity. Different fiber types promote the growth of different microbes, influencing malodor generation from microbial metabolism of apocrine and sebaceous secretions (Callewaert et al. 2014). Squalene, a major constituent of skin oil, has been shown to react with ozone on clothes generating products with a range of volatilities. The less volatile products remain on the apparel item, exposing the wearer to species such as C₂₇-pentaenal, C₂₂-tetraenal, C₁₇-trienal, and their carboxylic acid counterparts (Wisthaler and Weschler 2010). Squalene also reacts with HOCl, the active ingredient in chlorine bleach, to generate chlorinated squalene products. Three to four chlorine atoms become covalently incorporated into the squalene molecule during a 1-h exposure to 1 ppb HOCl (Schwartz-Narbonne et al. 2018). Such species may not be fully removed from clothing during washing. More generally, bleach oxidizes chemicals on clothing, increasing the water solubility of the contaminants but perhaps leaving behind oxidized and chlorinated residues. Numerous low volatility oxidation products, starting with primary carbonyls and carboxylic acids and evolving to products with high O to C ratios, result when ozone reacts with terpenes or sesquiterpenes transferred to clothing from personal care products. Other examples of chemicals generated via reactions that occur on clothing include nonylphenol, a known endocrine disruptor, from the degradation of nonylphenol ethoxylate detergent residues (Antal et al. 2016) and formaldehyde from urea-formaldehyde and melamine/formaldehyde resins used as antiwrinkling agents (De Groot and Maibach 2010). The potential for chemical transformations to occur on clothing is commonly overlooked during assessments of exposures to environmental chemicals.

Mechanisms, Quantification, and Prediction of Exposure and Transfer of Chemicals

Clothing influences chemical exposure by a variety of mechanisms, including some that are complex and poorly characterized. Organizations such as the US Environmental Protection Agency, the World Health Organization, and the European Chemicals Agency provide guidance on estimating exposure from consumer articles; however, such recommendations are based on a far-from-complete understanding and are therefore of limited utility in accurately characterizing complex chemical exposures mediated by clothing. Notwithstanding their limitations, these recommendations and models can be combined with stochastic representations of exposure factors and behaviors to estimate population distributions of exposure.

Dermal Transfer and Absorption

Most exposure models of skin contact transfer of chemicals from surfaces are conservative by design, i.e., they account, realistically, for the maximum potential

exposure for risk assessment and risk management purposes. Exposure is derived from factors including the skin area in contact; the concentration of the chemical in the material; the number, frequency, or duration of contact events; the type of contact; and a transfer efficiency. The transfer efficiency is the fraction of the chemical in the material that transfers during contact events. Experimental measurements of the transfer of pesticides and fluorescent tracers from carpet and of permethrin from military uniforms have been used to quantify transfer efficiency of residues from textiles. Some experimental results used to derive residue transfer efficiency are based on low-volatility chemicals directly applied to the side of the textile in contact with the skin. Therefore, the residue transfer model may inaccurately characterize exposure from clothing that has volatile or semivolatile chemicals distributed throughout the fabric. Recognizing that diffusive migration can occur within consumer materials, it has been proposed that a transfer efficiency can be derived from the amount that can diffuse from a thin “contact layer” of the material. The thickness of this layer can be specified for consumer products or can be estimated if diffusion coefficients are known for specific chemical-material combinations. These models generally do not account for the uptake resistance of skin itself.

Models of sweat-mediated transfer of chemicals from clothing also use a transfer efficiency approach. The leachable fraction is derived from experiments using artificial sweat to extract substances such as dyes (Meinke et al. 2009) and trace elements (Rovira et al. 2017). Often, the extracted fraction is assumed to be entirely transferred to the skin. Such an approach is likely to overestimate exposures, since only a fraction of the sweat will return to the skin from clothing. For example, Meinke et al. (2009) extracted fluorescent dyes from a polyester/cotton blend shirt using a sweat simulant and compared the predicted exposure (based on 100% transfer) to that observed in volunteers wearing the shirt during 30 min of exercise or for 12 h of normal activity. In these experiments, less than 1% of the estimated amount of a dye was transferred to volunteers during normal wear or sweating.

Indirect (non-contact) exposure to environmental contaminants can also be influenced by clothing. Clothing has been observed to reduce the transfer of airborne insecticides (Saleh et al. 1998), phthalate esters (Morrison et al. 2016), and organophosphate flame retardants (Moore et al. 2014) to skin. Some existing models of indirect dermal exposure to airborne contaminants have assumed that clothing is fully permeable. Other models assume that clothing is fully impermeable. For example, in estimating dermal uptake of polycyclic aromatic hydrocarbons from barbecue fumes to bare skin, Lao et al. (2018) assumed that areas covered by clothing were fully protected. Between these extremes, a mechanistic modeling approach has been introduced that accounts for the history of clothing, contaminant-transfer between clothing and the environment, sorptive partitioning of chemicals to clothing, diffusive and advective transfer through clothing and to skin lipids, as well as resistance to uptake through skin (Cao et al. 2018; Morrison et al. 2017a). The clothing component of these models is similar to that used to assess clothing for chemical protection and can account for uptake through clothing from air as well as exposure to contaminants present in clothing when donned.

Predictions using mechanistic models agree reasonably well with urinary excretion rate measurements for the limited number of human-subject studies in which adequate information is available to populate the model parameters (Cao et al. 2018; Morrison et al. 2017b). These models indicate that clothing can either reduce or increase dermal uptake relative to bare-skin uptake (Fig. 2). The extent of exposure is predicted to be sensitive to a chemical's partition coefficient between clothing and air (K_{ca}) (Cao et al. 2016; Morrison et al. 2018), the efficiency of chemical removal during laundering (Gong et al. 2016; Luongo et al. 2016), the air-gap between fabric and skin, laundering frequency, and the history of the clothing items prior to wear (Morrison et al. 2017a). Existing models could be further improved by an accurate measurement of the ratio of direct contact area to the total skin area, especially for chemicals with high values of K_{ca} , as well as by accounting for the transport of chemicals through the side openings of clothing. A key advantage of dynamic mechanistic models is that they can predict how clothing accumulates chemicals under non-equilibrium conditions. Such models can be used to derive simpler exposure heuristics for classes of chemicals, types of clothing, and exposure scenarios for risk assessment purposes.

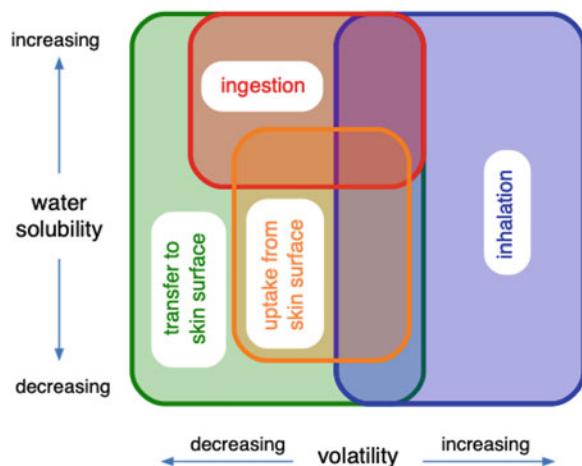

Inhalation

Inhalation exposures for clothing-associated chemicals can be modeled using methods similar to those used to estimate inhalation of chemicals emitted by consumer products. For example, the emission rate of dry-cleaning solvents from clothing hung in a closet can be combined with building air change rates to predict indoor air concentrations, which can then be used to assess inhalation exposures. Inhalation exposure from the emissions that are generated while wearing an article of clothing may be enhanced owing to the “personal cloud” effect, as described later for particles. For gaseous pollutants, personal-cloud type alterations have been illustrated in climate chamber experiments investigating transport and pollutant distribution in the breathing zone (Licina et al. 2015), as well as using computational fluid dynamics to predict breathing zone concentrations of volatile products that result from ozone reactions with the surface of the body and clothing (Rim et al. 2009). For a seated person under typical indoor conditions, inhalation exposure to volatile ozone reaction products with skin oils was predicted to be up to 2.5 times higher than the corresponding value for room-average concentrations. Predicted exposure to ozone itself was estimated to be 0.6 to 0.9 times the corresponding condition for room-average concentrations (Rim et al. 2009). Simulations are currently limited to simple scenarios, such as stationary seated or standing individuals. Experimental validation of personal cloud effects for clothing-associated chemical exposures are lacking.

Ingestion

Ingestion by mouthing of fabrics can be a significant exposure pathway, especially for young children. Exposure estimation requires information on the extractability of compounds in saliva, the frequency of mouthing clothing and the area of the fabric mouthed. Various studies quantified extractability using a broader set of

Fig. 4 The relative importance of clothing-associated exposure pathways based on a chemical's volatility and water solubility. (Reprinted with permission from D. Licina, G.C. Morrison, G. Beko, C.J. Weschler and W.W. Nazaroff, Clothing-mediated exposures to chemicals and particles, Environ. Sci. Technol., 2019, 53, 5559–5575, DOI: <https://doi.org/10.1021/acs.est.9b00272>. Copyright (2021) American Chemical Society)

in vitro bioavailability methods, which have been applied to determine extractability in saliva simulants of azo dyes and for silver from nanoparticles. For highly water-soluble species, upper bounds on exposure can be established by assuming that the chemical is completely extractable. In an evaluation of indirect exposure to environmental airborne methamphetamine in former residential methamphetamine labs, mouthing of cotton fabric by toddlers was predicted to generate intakes approximately 10 times greater than all other exposure pathways combined (Morrison et al. 2015).

A diagrammatic summary of these exposure pathways as influenced by physical-chemical properties is qualitatively shown in Fig. 4. Excepting particles and particle-associated chemicals, inhalation requires a chemical to be volatile enough to become airborne. Ingestion is important for more water-soluble chemicals. Most species can be transferred to skin by contact or transfer through the clothing-skin air gap. For both ingestion and transfer to the skin surface, the chemical must be of lower volatility to be present in clothing at meaningful concentrations. Transdermal uptake from the skin surface tends to be highest for chemicals with intermediate volatilities and relatively low water-solubilities.

Exposures to Particles

Clothing-Associated Exposures to Biotic and Abiotic Particles

A large number of environmental and occupational exposure studies indicate that clothing can act as an important source of particle-borne agents that contribute to human exposures. Clothing-associated exposures have been observed for biotic and abiotic particles, with varied acquisition, retention and release mechanisms,

exposure routes, and potential health outcomes. This subsection summarizes evidence from relevant empirical and field studies to provide an overview of exposure to biotic and abiotic particles associated with clothing.

Allergens

A substantial body of research related to clothing-associated exposures to particles has focused on the risk of allergenic exposures. Studies examining exposure to allergenic biological particles from clothing include cat allergen (*Fel d 1*), dog allergen (*Can d 1*), dust-mite allergen (*Der p1*, *Der f1*), and pollens including pollen fragments. Tovey et al. (1995) were among the first to identify clothing as a significant source of inhalable allergens. They showed that allergenic dust particles can become released into the air directly from clothing by body movement and can travel to the wearer's breathing zone by means of the buoyancy-driven thermal plume, thus causing increased allergenic exposures. Other researchers found that exposures to mite and cat allergens were strongly related to the quantity of particle-bound allergen found on wearer's clothing, suggesting that personal clothing could be an important factor influencing both mite and cat allergen exposure (D'Amato et al. 1997). Evidence of allergen exposure also has been reported for people that are not in direct contact or proximity to any allergenic source (D'Amato et al. 1997). These studies identified clothing as an important indirect exposure vector, transporting particle-borne allergens from one space to another.

Many studies investigating clothing-mediated exposures to pet allergens have focused on school environments. They have found that allergens can be transported on children's clothing from homes to schools, including both the cat allergen, *Fel d 1* (D'Amato et al. 1997), and the dog allergen, *Can f 1* (Berge et al. 1998). Several studies evidenced that children without pets can also acquire allergens while in school and subsequently bring them back to their homes and potentially expose their family members. A study focusing on exposure interventions found that the level of airborne cat allergens in schools could be effectively mitigated either by pet ownership prohibition or by using school uniforms (Karlsson et al. 2004). Additional evidence has shown that clothing can be a transport vector for the mite allergens, *Der f 1* and *Der p 1* (Berge et al. 1998), and for allergenic pollen (Jantunen and Saarinen 2011). In summary, this body of research persuasively documents that clothing can be an important secondary source of allergenic exposures in buildings. These exposures can also occur in environments in which there are no direct sources of allergens.

Pathogenic Microbes

Another category of clothing-related biological particles is pathogenic microorganisms that pose threats for the transmission of infectious diseases. Most research about clothing-associated pathogens has focused on health-care settings, owing to concern about hospital-acquired infections. Studies have identified pathogenic bacteria on physicians' white coats (Wiener-Well et al. 2011), on neckties (Lopez et al. 2009), on gloves (Snyder et al. 2008), on nurses' uniforms (Perry et al. 2001), and on the coats of medical students (Scott et al. 2015). A commonly detected pathogen on

health-care apparel is methicillin-resistant *Staphylococcus aureus* (MRSA) (Perry et al. 2001; Snyder et al. 2008; Wiener-Well et al. 2011). Other pathogenic bacteria found on healthcare workers' uniforms have included *Clostridium difficile* (Perry et al. 2001) and vancomycin-resistant *Enterococcus* (VRE) (Perry et al. 2001; Snyder et al. 2008; Wiener-Well et al. 2011). In addition to bacterial pathogens, analysis of clothing samples worn by caregivers and visitors has revealed the presence of respiratory syncytial virus, a major cause of respiratory infections among premature infants (Homaira et al. 2016).

Other studies have provided evidence that links bacterial occurrence in clothing with subsequent exposure. The direct dispersal of *Staphylococcus aureus* and other bacteria from clothing into air has been identified in operating theatres (Doig 1972), in isolation wards (Hambræus 1973), and in hospital storage rooms (Handorean et al. 2015). Early research indicates that pathogen liberation from clothing into air can occur by human movement that induces frictional interactions between clothing fibers and skin (Doig 1972; Duguid and Wallace 1948; Hill et al. 1974). A seminal study by Duguid and Wallace (1948) found that clothing can liberate pathogenic microbes by promoting skin shedding. That same study also showed that sterile, dust-proof fabrics can act as a barrier to the release of skin-associated microbes.

Nanomaterials Associated with Clothing Additives

During the past few decades, embedded nanomaterials have emerged as a class of technological innovations for improving certain features of clothing fabrics, such as reducing microbial growth and survival, protecting against ultraviolet radiation, and improving water repellency. To achieve specific targeted functions, prevalent nanostructured clothing additives have included titanium dioxide (TiO_2), silver, zinc oxide (ZnO), gold, copper, carbon nanotubes, and nanoclays (Dastjerdi and Montazer 2010). An emerging consensus indicates that excessive exposure to nanomaterials can contribute to detrimental health outcomes, including pulmonary inflammation, carcinogenicity, genotoxicity, and circulatory effects (Savolainen et al. 2010). However, the effects of nanomaterial additives in clothing on human exposure and consequent health effects remain a subject of debate. Such materials have the potential to be released from clothing fabrics and contribute to exposures of their wearers and others. The mechanisms of release from clothing are different for nanomaterials as compared with biological particles. For example, in addition to mechanical abrasion, nanoparticles can potentially be released from clothing by migrating into human sweat and saliva.

Majority of exposure-related studies performed to date have focused on the migration of silver nanoparticles from clothing into human sweat, their release during laundering, and their antimicrobial properties. Dermal exposure to clothing-embedded nanoparticles has not been rigorously investigated. One group of studies reported that TiO_2 and ZnO nanoparticles do not penetrate deeply into the skin (Nohynek et al. 2007). To the contrary, there is evidence of the increase of the ^{68}Zn isotope in the blood of a healthy adult after exposure to ^{68}ZnO nanoparticles in a sunscreen formulation (Gulson et al. 2012). One study reported that healthy skin is a more effective barrier for silver nanoparticles than damaged skin (Filon et al. 2015).

In summary, there is a need for more research to characterize the influence of antimicrobial agents, including nanoparticles, on microbial diversity in clothing, and on the development of microbial resistance over time. Whether the presence of nanomaterials on fabrics in contact with the skin could alter the local skin microbiota remains a key open question.

Para-occupational Exposures

Studies have reported instances of para-occupational (or “take-home”) exposures to hazardous particles encountered in workplaces. Most such studies have focused on asbestos. As reviewed by Donovan et al. (2012) and Goswami et al. (2013), there is abundant evidence for increased risks of mesothelioma and lung cancer owing to para-occupational exposure to asbestos fibers and asbestos-containing dust on workers’ clothing. However, relatively little research provides quantitative evidence that mechanistically links workplace encounters with subsequent household exposures. Sahmel et al. (2014) found that handling clothes contaminated with chrysotile asbestos resuspends 0.2–1.4% of the material. Similar to scenarios with allergenic exposures, other studies demonstrated that healthcare uniforms can act as a vector for pathogen transmission outside of hospitals. The recent COVID-19 pandemic has raised additional concern over this route of transmission of biological aerosols. Therefore, the take-home effect for particles and microbial exposure via clothing seems to be a plausible route of transmission worthy of increased attention.

Personal Cloud

Owing to proximity between clothing and breathing zone of a wearer, an enhancement of inhalation exposure to particles beyond the room-average levels may occur for clothing-associated particle emissions. This feature, defined as the “personal cloud,” was introduced previously for clothing-mediated chemical exposures.

There are multiple factors influencing the personal cloud effect associated with particle release from clothing. Key determinants involve size-dependent emission rates of particles from clothing, proximity of clothing to the breathing zone, and local air movement in relation to personal activities. Increasing evidence from controlled and field studies suggest that direct shedding from clothing surfaces may be a noteworthy source of coarse-mode particles and bioaerosols indoors (Bhangar et al. 2016; Licina et al. 2016; Yang et al. 2021; Zhou et al. 2017). However, none of these studies quantified clothing-associated contributions to the personal-cloud effect. A recent study by Licina et al. (2017) reported that clothing movement can release coarse particles into the perihuman space of a seated person, which can then be transported upwards by means of the buoyancy-induced human thermal plume. In that study, the contribution of such releases to the personal cloud was substantial – from 2 to 13 $\mu\text{g}/\text{m}^3$ in the particle diameter range 1–10 μm . The contribution of clothing-associated particle release to a personal cloud effect was observed only for seated occupants. During walking, occupants would strongly mix the room air and break away the thermal plume, which resulted in the absence of the personal cloud effect. The study suggests that the personal cloud is contingent on physical activities and that manipulating the metabolic thermal plume could alter exposure to

clothing-released particles. Additionally, during more intensive clothing manipulations, such as putting on and taking off a shirt, or folding and unfolding a shirt, sharp peaks in the breathing zone PM₁₀ mass concentration were detected, at times exceeding 40 µg/m³. Overall, the emerging evidence regarding the personal cloud combined with evidence that clothing can harbor allergens, potentially pathogenic microorganisms, and other harmful substances suggest that clothing surfaces may be an underappreciated factor influencing particle exposure, possibly with public-health relevance.

Toward Quantifying Clothing-Mediated Particle Exposures

The previous section summarized evidence that clothing-mediated exposures to biotic and abiotic particles are potentially meaningful in different circumstances. It is important to characterize exposures quantitatively and – in as far as it is possible – mechanistically, so that one is able to extract generalizable findings from relatively limited experimental evidence. This section outlines a framework that could guide and support systematic knowledge acquisition for better understanding how clothing influences inhalation exposures to biotic and abiotic particles.

The central element in this framework is the determination of size-resolved and composition-specific emission rates of particles associated with clothing. Such emission rates can be expressed in terms of particle mass per time (relevant to coarse particles) or particle number per time (relevant to submicron particles). Particle composition is another important characteristic in relation to health outcomes of concern: allergenic particles, infectious microbes, and abiotic particles each contribute to increased yet distinct adverse health risks.

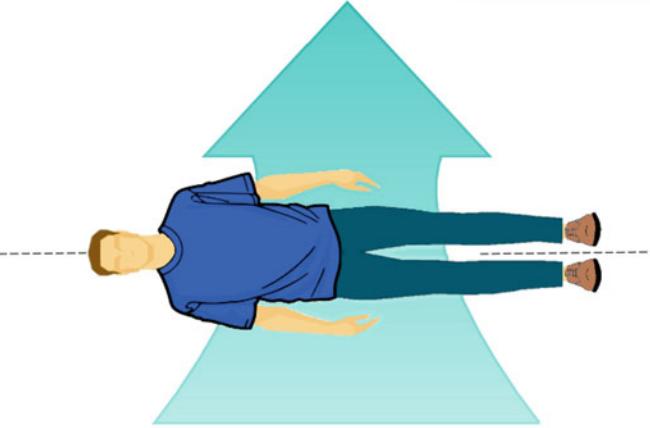

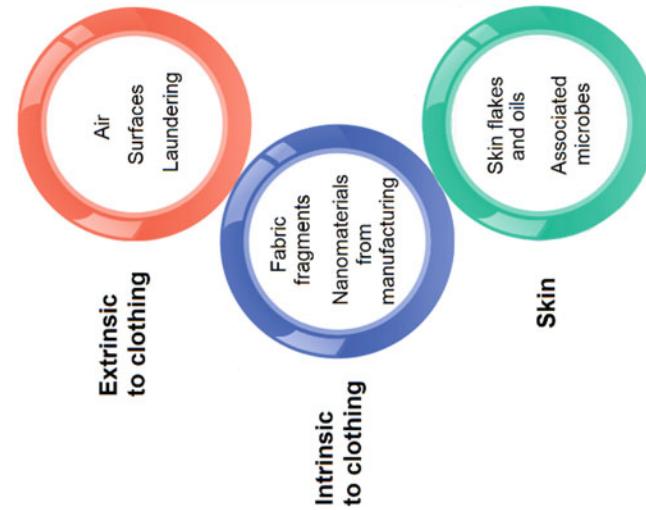

For known clothing-associated particle emission rates, contributions to exposures can be assessed. For example, particle emission rates from clothing can be incorporated into a single- or multi-compartment material balance model to estimate the component of exposure associated with increased indoor air concentrations. Alternatively, the intake fraction approach can be applied to estimate mass or particle number inhalation increments directly from emission rate information. Additional contributions to exposure from the personal-cloud effect can be assessed based on experimental evidence (Licina et al. 2017).

It is reasonable to expect that particle exposures associated with clothing occur mainly indoors. As with other indoor particle sources, emission rates can be inferred from measuring time- and size-resolved particle concentrations in chamber experiments with controlled environmental conditions (e.g., known ventilation rate, low particle backgrounds, and minimization of particle resuspension from flooring surfaces) and simulated activities (Bhangar et al. 2016; Licina et al. 2017; Yang et al. 2021). It is also plausible to infer emission rates from field observations; however, doing so for clothing-associated particle emissions poses the challenge of separately accounting for resuspension from flooring, commonly an important source of coarse particles indoors (Qian et al. 2014).

In assessing clothing-associated emissions, it is worthwhile to differentiate broadly among three particle source categories. As presented in Fig. 5, one category

PARTICLE SOURCE

PARTICLE RELEASE

Shedding - release of endogenous particles including skin flakes and associated microbes, and intrinsic fabric materials (clothing fragments and particles from manufacturing), as the result of skin-clothing frictional interactions

Resuspension - release and transport of exogenous particles that have previously settled onto clothing surfaces as the result of physical activity of a wearer or owing to a direct contact between clothing and other surfaces

Formation - release of ultrafine and nanocluster aerosols from ozone-skin oils chemistry
Migration - release of nanoparticles into human sweat and saliva

Resuspension characteristics

Dominant particle size mode:

- 3-5 μm diameter

Emission rate (skin-clothing frictional interactions):
 - 0.17 mg/h per sitting person (size range 1-10 μm)

- 0.45 mg/h per walking person (size range 1-10 μm)
 Clothing transport vector:
 - 0.3-3% of previous deposit (size range 1-10 μm)

Fig. 5 Particle source categories associated with clothing (left); and mechanisms of size dependent particle release and resuspension characteristics (right). Corresponding references: dominant particle size mode reported by Bhanger et al. (2016); size-resolved emission rates from sitting and walking person reported by Licina et al. (2017); release of previously deposited particles from clothing (transport vector effect) reported by Licina and Nazaroff (2018). (Reprinted with permission from D. Licina, G.C. Morrison, G. Beko, C.J. Weseloh and W.W. Nazaroff, Clothing-mediated exposures to chemicals and particles, Environ. Sci. Technol., 2019, 53, 5559–5575, DOI: <https://doi.org/10.1021/acs.est.9b00272>. Copyright (2021) American Chemical Society)

includes material that exists on human skin. For example, skin flakes (known as squames) are aerosolized through complex frictional interactions between clothing and skin. These squames consist of skin fragments with associated microbes, especially bacteria. Additionally, constituents of skin oils deposited on clothing (e.g., squalene, which is commonly present on clothing surfaces) rapidly react with ozone, producing ultrafine (Rai et al. 2013) and nanocluster aerosols (Bekö et al. 2020). A second category would be particles endogenous to the clothing fabric, such as fabric fragments and nanoparticle additives. These are typically acquired during manufacturing processes. A third category, the broadest, is exogenous particles that become associated with clothing articles by means of environmental transfer indoors and outdoors. The first category has been studied most carefully in connection with concerns about hospital-acquired infections. Knowledge on ultrafine and nanoparticle emissions generated by clothing surface chemistry is just beginning to emerge. Concern about the second category is increasing, in part due to the emerging use of nanoparticle fabric treatments. The third category would be relevant for concerns as diverse as allergen exposure, para-occupational exposure, and general enhancements of airborne particles via the personal cloud.

For squame emissions associated with clothing, key factors would include the state of the skin surface (dryness, for example), the nature and intensity of frictional interaction between fabric and skin, and the tightness of the weave. Variability in the emissions of skin-associated *Staphylococcus aureus* among individuals has been demonstrated to be large, and systematically higher for men than for women (Hill et al. 1974). Notwithstanding a long history of studies, the issue of what should be worn by medical staff in the operating theatre to minimize surgical site infections remains a subject of debate. For endogenous particle emissions (e.g., nanoparticle additives), one expects that important factors affecting emissions would include initial particle loading of the fabric, ability to remove particles by laundering, the nature of particle bonding with fibers, the nature and intensity of movement generating frictional forces, and the overall wear of the fabric.

For emissions of exogenous particles, one might envision clothing articles as environmental reservoirs and aim to account for the net movement of particles between these reservoirs and the surroundings. Consider an article of clothing, such as a T-shirt, passing through a cycle starting with laundering. The washing cycle might effectively remove previously deposited particles, but could conceivably add particles from dissolved salts in the wash water and from detergent residue. A tumble-dry cycle could effectively add some airborne exogenous particles filtered by the clothing items from the drying air that passes through the drum. The clothing article might then lose some of these particles, and contribute an increment of exposure, during the post-laundry handling of folding and placing in storage. When worn, the T-shirt can acquire exogenous particles by deposition from the air and by direct contact with particle-laden surfaces including the skin. Exogenous particles may also be acquired during storage intervals, especially if exposed in a manner that would be influenced by settling dust. The accumulation of particles during these processes could be quantified through deposition assessments, for example, through the multiplicative combination of exposure concentrations of

particles, a suitable deposition velocity, and duration of exposure. Knowing the size-resolved and composition-specific quantities of exogenous particles on a clothing article, one could assess the emission rate through the use of loss-rate coefficients. An analogous approach has been used to systematically investigate particle resuspension from walking (Qian et al. 2014).

Factors Affecting Clothing-Mediated Particle Exposures

The previous section outlined an approach that could be used to systematically assess clothing-associated exposures to particles. Specific information about relevant factors and processes is sparse. This section describes what is known from prior experimental investigations about the major factors that influence the size-dependent emissions of particles associated with clothing, emphasizing the relationship to inhalation exposures.

Early studies revealed important findings about clothing-skin surface interaction as a means of liberating bacteria-laden skin flakes (Doig 1972; Duguid and Wallace 1948; Hill et al. 1974). Recent advances in DNA-based measurements have enabled rapid progress in characterizing the human microbiome, including detailed descriptions of diverse communities of bacteria and fungi present on human skin. Different studies analyzed biological material from clothing surface samples or air exposed to clothing. They identified populations of pathogenic bacteria, respiratory syncytial virus, fungi, dust-mite and cat allergens, endotoxins, and allergenic pollen. Some quantitative evidence exists documenting microbial transfer to clothing from skin and by hands, although more studies are needed to quantify this phenomenon and to better characterize the process mechanistically.

Available evidence suggests that the rate of particle release from clothing fibers is influenced by a combination of three main factors: properties of clothing, environmental conditions, and human factors. A dominant factor influencing particle release from clothing is the intensity of movement. Up to an order of magnitude higher emission rates have been observed during vigorous bodily movement compared to slight activity, presumably owing to increased frictional interactions between clothing fibers and skin (Bhangar et al. 2016; Duguid and Wallace 1948; Licina et al. 2017; You et al. 2012). Men have been found to release significantly more particles compared to women (Hill et al. 1974). Another study found that application of skin lotion has been linked to reduced dispersal rate of biotic particles (Hall et al. 1986; Zhou et al. 2017). Some studies (Speers Jr et al. 1965), but not all (Hall et al. 1986), have found that the emission rate of biotic particles from clothing-skin interactions increases within an hour after showering. Transport of particles through clothing surfaces and subsequent dispersal can be reduced by wearing tightly-woven and non-woven fabrics (Whyte and Hejab 2007).

A few recent studies have applied a material-balance approach to infer size-resolved biotic particle emission rates associated with human occupancy. Qian et al. (2012) used quantitative PCR to infer that a single university classroom occupant contributes effective emissions of 37 million bacterial genomes per hour,

with a modal aerodynamic diameter of 3–5 µm. However, that study could not differentiate between emissions associated with clothing and those from other sources such as resuspension from a carpeted floor. Bhaggar et al. (2014) applied a laser-induced fluorescence technique to quantify the per person emission rate of fluorescent biological aerosol particles (FBAP) in the size range 1–15 µm diameter in an uncarpeted university classroom. Their work, which again did not isolate the contribution of clothing, yielded an average emission rate of 2 million FBAP per hour with modal diameters of 3–4 µm. In a subsequent chamber study, Bhaggar et al. (2016) found that at least 60–70% of occupancy-associated FBAP emissions originated from the floor. However, they also found that “*clothing, or its frictional interaction with human skin, was . . . a source of coarse particles, and especially of the highly fluorescent fraction.*” That study also revealed a dominant size mode for FBAP of 3–5 µm diameter. In another recent chamber study, Yang et al. (2021) found that occupants who wore long-sleeve shirts and pants produced 40% more fluorescent aerosol particles relative to occupants that wore t-shirts and shorts. The study found that the total and fluorescent particle emissions from young adults and teenagers were 50% higher compared to elderly people. This difference could be attributed to differences in skin conditions, as elderly replace their epidermis slower compared to younger people, which may result in lower particle shedding rate. Additional influencing factors could be increased skin roughness and wrinkle area of elderly, which may trap particles and reduce the physical contact with clothing.

When considering the specific issue of infectious disease transmission in relation to clothing, the persistence and survival of infectious agents on fabrics needs to be considered. Variation in building environmental conditions and properties of clothing fabrics produce various effects on microbial persistence and survival. Longitudinal assessment of bacteria survival across different studies showed a remarkably high persistence – from several days up to more than 90 days for isolates of VRE and MRSA (Neely and Maley 2000). Several studies suggest that survival and persistence of viruses and fungi on clothing fabrics has similar days- to months-long time scales (Neely and Orloff 2001). Among different factors influencing survival and persistence, relative humidity and fabric material have been explored. Increased relative humidity (from 35% to 78%) has been linked to reduced stability of both bacterial and viral strains in clothing (Sidwell et al. 1966). Survival and persistence of bacteria, virus, and fungi is higher on commonly used polyester and wool fabrics compared to cotton materials (Neely and Orloff 2001).

Another common theme in the literature concerning clothing-mediated exposure to pathogenic microbes considers the effectiveness of laundering practices such as washing, drying, and ironing. Mechanical removal includes fabric agitation assisted by surfactant properties of detergents, while inactivation processes can occur as a consequence of elevated water temperature combined with laundry additives such as sodium hypochlorite. Among relevant studies, Callewaert et al. (2015) documented microbial exchanges among clothing articles during washing. Nordstrom et al. (2012) found that home-washed hospital scrubs had increased prevalence of bacterial species compared to those laundered in hospitals, presumably due to low temperature washing. A 7-log reduction in bacterial load can be achieved by

10-min of washing with 60 °C water (Lakdawala et al. 2011). Adding sodium hypochlorite to a detergent is an effective way to eliminate bacteria and inactivate enteric and respiratory viruses (Gerba and Kennedy 2007); however, it might also lead to increases in the abundance of chlorinated organic compounds on clothing (Schwartz-Narbonne et al. 2018). Detergents free of bleach can reduce the prevalence of *Staphylococcus aureus* (Vikke and Giebner 2015), while adding bleach-enriched detergents completely eliminates the same. Recent adjustments in laundering procedures include addition of enzymes, reduced water use, lower water temperature, and bleach-free detergents.

Both biotic and abiotic material can be deposited onto clothing surfaces from various environmental sources including outdoor air and grassland (Jantunen and Saarinen 2011), residential air (Noble 2000), and public transport microenvironments (Liljegren et al. 2016). Physical contact with various indoor and outdoor surfaces and during the storage can be another pathway of particle acquisition (Clarke et al. 2015). The rate of deposition from air to clothing can be described using the deposition velocity concept. Studies have found that particle size and local air movement are dominant influencing factors (Liljegren et al. 2016).

Research has clearly documented that previously deposited material can be released into air from clothing (Licina and Nazaroff 2018; McDonagh and Byrne 2014b; Sahmel et al. 2014). For example, using a controlled chamber study approach, Licina and Nazaroff (2018) found that 0.3–3% of particles (size range 1–10 µm) deposited through settling could be released via fabric motion. In that work, the release fraction monotonically increased with particle size. Not surprisingly, they also found that the particle release fraction increased with the intensity of movement and with the amount of dust deposited onto the clothing fabrics. It was found that the majority of particle release from clothing occurs shortly after the onset of the movement.

The degree of particle binding to clothing fibers and the rate of resuspension may arise from a combined influence of different forces acting upon the fibers. The forces governing the release of clothing-embedded particles are abrasive actions between clothing surfaces – a consequence of physical activity of a wearer (Duguid and Wallace 1948; Hill et al. 1974). Forces influencing release are strongly linked to particle size. Because detachment forces increase more strongly with particle diameter than do adhesion forces, clothing-associated emissions are more discernible among coarse-mode than fine-mode particles (Bhangar et al. 2016; Licina et al. 2016, 2017; Yang et al. 2021; Zhou et al. 2017).

Common clothing fibers are wool, cotton, and polyester. Wool has been reported to have particle release rates up to 10 times higher than the other two materials (Yoon and Brimblecombe 2000); cotton exhibits higher emissions than polyester (You et al. 2012). The higher particle emissions from wool garments could be linked to different surface roughness and weave pattern (McDonagh and Byrne 2014a), but also to less frequent laundering as compared to cotton and polyester fabrics (Yoon and Brimblecombe 2000). Other clothing conditions found to increase particle release rate include increased clothing age (Cohen and Positano 1986) and reduced cleanliness (Yoon and Brimblecombe 2000). While it is generally understood that

adhesion forces acting on particles increase with relative humidity, we know of only three studies that have examined its effect on clothing-associated emissions. Yoon and Brimblecombe (2000) found an association between low relative humidity and increased particle emission rate. Similarly, particle emissions decreased by 30–60% when relative humidity increased from 34% to 62% (Yang et al. 2021). On the other hand, Zhou et al. (2017) reported an insignificant influence of relative humidity on particle emissions from clothing.

Conclusions

There is ample evidence that clothing influences human exposure to chemicals and particles. Yet, only a few studies have quantified clothing-mediated exposure by means of direct measurements (Bekö et al. 2018; Blum et al. 1978; Horstmann and McLachlan 1994; Licina et al. 2017; Morrison et al. 2016, 2017b; Rossbach et al. 2016).

We know surprisingly little about the occurrence of contaminants acquired by everyday clothing after purchase. For a relatively low cost, we could learn a large amount from simply assessing the occurrence, concentrations, and extractability (e.g., by sweat and saliva) of chemicals and particles in everyday clothing. Cross-sectional exposure studies would greatly benefit from the addition of clothing analyses, potentially identifying direct connections between clothing-associated exposure and health.

The diversity of clothing, environmental and human factors make predicting exposures challenging. Therefore, it will be important to reduce the many variables to those that are most influential. Progress can be achieved through models, laboratory, and field investigations of human exposure and uptake. In addition to chemical properties, important factors affecting exposures may include textile materials, weave, thickness, and permeability; wear, care, and storage practices; environmental conditions (e.g., relative humidity, ozone); intensity and types of activities; skin-oil transfer to clothing and its aging; human physiology (skin integrity, lipid generation, sweating) and personal hygiene habits. Simulated exposures with human subjects also should consider pollutant transfer from textiles other than clothing (e.g., pillows, quilts, bed linen). The sleeping environment is potentially of great importance in this matter given the large proportion of time spent in bed.

Predicting and controlling exposure rely on adequate understanding of underlying mechanisms. A robust literature describes transport mechanisms for chemicals among environmental reservoirs. Reasonable approaches have been proposed for assessing risk and exposure to chemicals in clothing. However, we have limited *in vivo* evaluations of such assessments. Compared with chemical transport, mechanisms of particle uptake and subsequent release from clothing are even less well understood. Further quantitative investigations of factors that drive acquisition, retention, and transmission of biotic and abiotic particles in clothing are needed to better link such processes to clothing associated exposures. In addition, enhancement of chemical and particle concentrations in the breathing zone compared to bulk air concentrations (“personal cloud” effect) should be taken into account when

considering emissions from clothing. We also need to better understand the extent to which clothing plays a role in the spread of infectious disease. Considerable research has focused on textile innovations and personal protective clothing designed to limit the spread of infectious agents in hospital environments. Researchers could usefully build upon lessons learned and consider the potential utility of incorporating such innovations in everyday clothing.

One should anticipate that future changes in clothing will influence exposure. The useful lifetime of some clothing has become shorter. High turnover (short ownership time) might yield greater exposure to chemicals that are present in newly purchased clothing, with proportionately less exposure to environmental chemicals that require a long period to equilibrate (e.g., high molecular weight phthalates). Similarly, increased use of antimicrobial agents as coatings on clothing articles may increase uptake of nanoparticles by the human body and lead to altered toxicological effects. Worth noting is that people in Western countries commonly have closets full of clothes that are rarely worn. These articles may have sufficient time to equilibrate with the chemicals present in their storage environment. Worldwide, demand for synthetic fabrics is increasing. Synthetics have chemical partitioning behaviors and moisture holding capacities that differ from those of natural fibers, altering the capacity to be reservoirs of contaminants. Advances in materials and adjustments in laundering procedures may also influence how clothing is cared for and how chemicals and particles are acquired and retained in clothing. Increased recycling and re-use of clothing can influence tertiary exposures.

It is also important to recognize that the new regulations for substances in clothing are beginning to emerge. As of November 2020, new EU-wide legislations were put in place, as amendment to the REACH regulation, to limit the use of 33 substances that are classified as carcinogenic, mutagenic, or toxic for reproduction (European Commission 2018). This regulation specifies maximum concentration limits for the use of the following group of substances in clothing and textiles: cadmium, chromium, arsenic, and lead compounds; chlorinated aromatic hydrocarbons; benzene and polycyclic aromatic hydrocarbons (PAHs); phthalates; formaldehyde; polar aprotic solvents; azo-dyes and acrylamides; and quinoline. Clothing products on the EU market that exceed these limits are banned. Moving forward, we need robust policies on a global level to eliminate hazardous substances and their anticipated replacements from clothing manufacturing processes. Together with requirements for manufacturers to fully disclose the material content and chemical makeup of clothing, these efforts could result in improved exposure management.

People spend nearly their entire lives in intimate contact with clothing and other textiles. The evidence reviewed in this chapter supports a view that this environmental compartment plays important roles in exposure and health risk. Consequently, clothing as a mediator of chemical and particle exposure deserves substantial attention from the environmental science research and regulatory communities.

Acknowledgments The authors acknowledge the substantial contribution of Glenn C. Morrison, Charles J. Weschler and William W Nazaroff to this chapter.

Abstract

Time-activity pattern refers to the time and behavior of people at different locations. The knowledge of time-activity pattern is essential for indoor air pollution exposure assessment when direct personal exposure monitoring cannot be conducted. This chapter systematically reviewed the survey method of time-activity patterns and related large-scale surveys conducted in typical countries

worldwide. The survey method included both traditional and emerging survey methods, including questionnaire method, global positioning system method, videotaping method, sensors method, and mobile phone method. New technologies have great demand for data mining and analysis, so the data analysis technology is a great challenge and the focus of future research. Many countries like China, America, Canada, and Korea all carried out their national wide survey. Due to the discrepancy in culture, habits, and economical level, human time-activity patterns differed greatly among countries. Current surveys mainly adopt questionnaire survey method, with the development of exposure science, more accurate and detailed information, including location, time, duration, and activity patterns using new technologies that are necessary for future indoor air-related exposure assessment.

Keywords

Time-activity patterns · Human exposure · Exposure assessment · Survey method · Population survey

Introduction

Time-activity pattern refers to the time spent and behavior of people at different locations. It consists of three basic elements: location, duration, and activity. People may have different exposures to indoor air pollutant when they are in different indoor environments or engaged in different activities. There are differences in the concentrations of air pollutants in different indoor microenvironments. For instance, the concentrations of volatile organic compounds in gas stations and dry cleaners are higher than that in other indoor places (Cankaya et al. 2020). Additionally, individuals' inhalation rates vary under different activities, with the greater the activity intensity, the greater the inhalation rate. Time-activity patterns vary among individuals depending on culture, ethnicity, hobbies, location, sex, age, socioeconomic characteristics, and personal preferences (Duan et al. 2014). Therefore, the knowledge of time-activity patterns is essential for indoor air pollution exposure assessment when direct personal exposure monitoring cannot be conducted.

There are direct and indirect methods for assessing exposure to air pollution. Direct methods include in personal exposure monitoring and intraindividual exposure monitoring, i.e., exposure biomarker monitoring. Personal exposure monitoring requires the respondent to carry the monitoring instrument, with the implementation process complicated and costly, so it is not suitable for large-scale population. Additionally, instruments for monitoring some air pollutants with high sensitivity, portability, and sufficient time resolution are still lacking. In addition, since most air pollutants lack specific exposure markers, the applications of intraindividual exposure monitoring are very limited. The indirect assessment method assesses air pollutant exposure levels by integrating concentration monitoring data for air pollutants in different microenvironments and human time-activity pattern data using

time-weighted method. This method comprehensively considers the concentration of pollutants in various microenvironments and the duration and activity pattern of the subjects in different microenvironments, which could more comprehensively reflect the real situation of individual exposure. In addition, this method has the advantage of low cost and strong operability, and can be applied to exposure assessments for both small-scale fixed populations and a wide range of populations.

The use of indirect assessment methods to assess the exposure level to an air pollutant is generally calculated according to the formula (1):

$$\text{Exposure} = \sum C_i \times IR_j \times t_{ij} \quad (1)$$

Exposure – exposure dose to an air pollutant through inhalation route

C_i – concentration of an air pollutant in microenvironment i

IR_j – subject's inhalation rate under activity condition j

t_{ij} – subject's duration under activity condition j in microenvironment i

It can be observed that it is necessary to obtain the activity pattern and duration of the subject in different microenvironments in addition to the concentration of air pollutants in different microenvironments. Therefore, the time-activity pattern information of the subject is a key parameter to determine the accuracy of air pollutant exposure assessment. In the assessment of indoor air pollutant exposure, microenvironment classification can be divided into residential indoors, workplace indoors, school indoors, restaurants, shopping malls, bars, etc., but in many cases, more detailed classification is needed, such as residential interiors, subdivided into bedrooms, bathrooms, kitchens, garages, basements, laundry rooms, etc. In addition to directly using the time-activity pattern as an exposure parameter in the exposure assessment model, the specific activity itself can also indirectly reflect the exposure, such as whether it has been to a gas station or dry cleaner (volatile organic compound); whether it is with a smoker in the same room (environmental tobacco smoke) is a good indicator of the exposure to specific air pollutions for the respondents.

Survey Method

Time-activity data are generally obtained using recall questionnaires and diaries to record the person's activities in microenvironments. Other methods include the use of videotaping, global positioning system technology, and so on to provide information on individuals' locations.

Questionnaire Method

The questionnaire survey method collects time-activity pattern information of respondents by filling in a time-activity diary or questionnaire. This type of method

is currently most widely used, which is relatively simple, low cost, and can directly obtain the detailed activity information. However, it has the shortcomings of response error (recall bias), low temporal and spatial resolution, and large report burden of participants.

The questionnaire survey method can be divided into two categories according to the method of obtaining time-activity information, real-time diary recording method, and retrospective questionnaire survey method. The former requires the respondent to record the time, place, behavioral activities, and surrounding environment conditions of various microenvironments in real time, while the latter is to obtain the above information from the past (usually 24 h) or special time points through the investigation object. Although the method of real-time logging is relatively more accurate, the respondents are more burdened and usually only apply to small-sample individual monitoring studies, while retrospective survey methods are often used in large-scale population surveys.

In general, the questionnaire or the diary should include the cover of the questionnaire, the foreword of the questionnaire, and the content of the questionnaire.

- (a) The cover of the questionnaire should include the title of the questionnaire, the code of the questionnaire, the area of the respondent, and the information of the investigator.
 - 1. Questionnaire code: It is a unique identifier that distinguishes the questionnaire. It is generally composed of numbers and is located at the top right of the cover of the questionnaire.
 - 2. Questionnaire title: Used by respondents to understand the subject of the survey.
 - 3. Investigator information: Used to clarify the responsibilities and facilitate the inquiry and verification. It should include the name of the investigator, the date of the investigation, the name of the quality controller, the date of the quality control, and the length of the questionnaire.
- (b) Foreword to the questionnaire: Informed consent for obtaining the respondent should include the purpose and significance of the investigation, the commitment to confidentiality, the requirements for completing the questionnaire for the respondent, and the personal identity and organization name of the investigator.
- (c) Questionnaire content: It is the main body of the questionnaire, and should include test questions, answer methods, and instructions for answering.

The survey method includes telephone surveys, face-to-face surveys, and web surveys. Dialing by telephone is one of the most commonly used survey methods. For example, the National Human Activity Pattern Survey (NHAPS) was conducted by the US Environmental Protection Agency (EPA) in 1992–1994 to collect nationwide population exposures-related time-activity pattern information. University of Maryland Survey Center Computer-assisted telephone interview equipment was conducted to survey 9386 people in 48 states (Klepeis et al. 1996). The questionnaires used were divided into timetable for recording 24 h activity status and supplementary questionnaire. The former is the core of the questionnaire, and the

respondents were required to report all activities of the previous day in chronological order, the start and end time, detailed position (83 position codes), behavior (91 types), and whether someone is smoking.

In addition to the above telephone survey, face-to-face surveys was employed in a study on environmental exposure-related human activities patterns survey in the Chinese population, in which a multistage stratified cluster random sampling is used, and the respondents were investigated through a face-to-face questionnaire survey (Ministry of Ecology and Environment the People's Republic of China (MEE) 2013b, 2017c).

Global Positioning System Method

The global navigation satellite system (GNSS) refers broadly to all satellite navigation systems, such as GPS from the USA, Glonass from Russia, Galileo from the Europe, and BeiDou from China, that enables precise positioning of ground points. The methodology continuously records other information such as time, location, speed, and activity status of respondents in real time by wearing positioning devices, sometimes combined with accelerometers or other devices, and then parses the time-activity pattern status of respondents using tools such as geographic information systems (GIS) and specialized statistical packages. Among them, GNSS technology is increasingly used for time-activity pattern surveys, which have the advantages of good record continuity, high temporal resolution, and reduced subject burden compared to traditional time-activity survey methods (e.g., self-reported paper diaries and telephone interviews). However, barriers exist for accurately extracting time-activity patterns for human subjects from raw GNSS data because they are not consistently reliable due to errors caused by satellite or receiver issues, atmospheric and ionosphere disturbances, multiparty signal reflection, or signal loss or blocking. The multiparty problem occurs mainly in urban areas where tall buildings and structures reflect satellite signals many times before they reach a GNSS device, leading to GNSS coordinates errors.

In fact, few air pollution epidemiological studies have effectively used GNSS data to classify temporal activity patterns, possibly due to issues, including GNSS data quality, human subject compliance, and lack of reliable methods for mining raw GNSS data. GNSS data classification techniques have been largely documented in the field of travel behavior and physical activity research. Travel mode, activity location, and end-of-trip detections are the main applications of GNSS classification algorithms. Several studies have developed methods to classify travel activities using GNSS data or GNSS combined with body-worn sensors. Ellis et al. (2014) used body-worn sensors, such as accelerometers and SenseCam cameras, to classify physical activity into five modes (cycling, riding, sitting, standing, and walking/running) using a random forest classification model. Kohla et al. (2014) predicted eight modes of transportation based on a multivariate logistic regression model using GNSS and acceleration data. Combining GNSS, GIS, and accelerometer data, Brondeel et al. (2016) developed a trip-level traffic mode prediction model based

on a random forest approach and obtained a 90% correct prediction rate. However, the reliability of accelerometer data can be negatively affected by external factors, such as clothing and weather changes. Spatial data (e.g., roads and building roofs) have also been used to improve the accuracy of temporal activity classification. Nethery et al. (2014) manually mapped the boundaries of participants' homes and school buildings to help detect specific locations.

A tool that can be used to investigate time-activity patterns is presented here, MicroTrac, a model that uses global positioning system (GPS) data to estimate the time and duration people spend in different microenvironments (e.g., indoors and outdoors, work, and school) (USEPA). The model takes into account the time spent by individuals in specific locations and can improve air pollution exposure assessment for health research and risk assessment. MicroTrac addresses the limitations of time-activity diaries, including participant burden, diary returns, and inaccuracies due to reporting errors. MicroTrac is an automated classification model for estimating the time and duration spent by individuals in eight microenvironments (home, work, school, and car; other locations, indoors and outdoors). MicroTrac's inputs include GPS time course data (location, speed, and signal quality) and geocoded boundaries of respondents' homes, workplaces, and school building roofs. It has several novel features to classify GPS samples. First, MicroTrac uses a spatial buffer of building boundaries to account for spatial GPS inaccuracies. Second, MicroTrac uses a temporal buffer of GPS data to account for spatial errors that occur near structures that reflect GPS signals (e.g., high-rise buildings and dense tree cover). In addition, temporal filtering of GPS velocity samples is used to reduce misclassification within slow-moving or stopped vehicles (e.g., traffic congestion and traffic signals.) The performance characteristics of the MicroTrac model were evaluated in detail in a pilot study in central North Carolina by Breen et al. (2014).

Videotaping Method

Videotaping is a method in which trained videographers tape the subject's activities and subsequently extract the pertinent data manually or with computer software. Stanford's unique method of capturing children's microlevel activity time series (MLATS) lies in the use of a computer-based video extraction technique to extract children's activities from video footage. Results of this video-translation for a given subject yield the American Standard Code for Information Interchange (ASCII) files containing records of the following fields: an exposure boundary (e.g., left hand, right hand, and mouth), microenvironment (e.g., kitchen, garden, and bedroom), microactivity (e.g., playing, resting, repetitive action, and continuous action), object contacted (e.g., hard floor, upholstered furniture, soil, vegetation, and clothing), and duration in seconds. Each recorded line in the file corresponds to a unique time sequence of activity-related events (i.e., amount of time that body part spent touching that object in that microenvironment while performing that activity).

The process of collecting MLATS is labor-intensive. It requires the development of step-by-step methodologies suitable for the specific exposure scenarios as defined

by the needs of a particular project, and then the implementation of the methodologies to recruit and videotape subjects, train personnel, translate the videotaped activities into usable text files, and interpret the activity patterns. During the videotaping and video-translation process, steps must also be taken to ensure that quality MLATS data are collected and the data remains organized and protected.

Videotaping human activity for exposure assessment has become a more common practice over the past decade. In 1994, Stanford University's Exposure Research Group (ERG) conducted its first pilot study to collect MLATS data for young children. The pilot study involved videotaping four children of farmworkers in the Salinas Valley of California and converting their videotaped activities to valuable text files of contact behavior using video-translation techniques.

Sensors Method

The application of sensors has not been used for large-scale time-activity surveys. It has good application potential in the study of time-activity patterns. Currently, sensor-based time-activity research focuses on wireless sensor-based indoor positioning (Guo et al. 2017; Huang et al. 2019) and wearable device sensor-based activity recognition (Sprint et al. 2017).

In the past 10 years, due to the increasing demand for indoor positioning, the indoor positioning system (IPS) has been developed rapidly. Indoor positioning systems based on technologies such as LTE, WiFi, Bluetooth, wireless sensor network (WSN), or ultrawide band (UWB) have emerged. Such systems are often capable of (i) providing accurate location estimates to meet demand; (ii) facilitating the expansion; and (iii) inexpensive infrastructure inputs (Correa et al. 2017).

Another application for investigating time-activity patterns is to use sensor data to accurately identify the wearer's activity classification. Human activity recognition has become one of the hot topics in the field of artificial intelligence (AI) research in recent years, and many activity recognition methods have been proposed. Lukun Wang proposed continuous automatic encoder (CAE) as a new stochastic neural network model to improve the ability of model continuous data for wearable sensors to identify human activities (Wang 2016). Mary E. Rosenberger et al. compared the accuracy of the nine sensors in the 24 h activity measurement and found that no device was able to accurately capture the activity data for the entire 24 h workday. However, the future of activity measurement should aim at accurate 24 h measurements, and researchers should continue to select measurement devices based on the primary outcomes of the research objectives (Rosenberger et al. 2016). People have different breathing rates under different activities (such as sleeping, sitting, walking, etc.), so accurately identifying the active state helps to achieve reliable air pollution exposure assessment.

At present, sensor data mining methods are still one of the research hotspots because they cannot only provide accurate and continuous information on time activities, but also provide information on the physical activity of subjects, which has a very good application prospect in the investigation of exposure-related

activities. However, the mining and analysis of sensor data require some algorithm support. Ellis K et al. based on data obtained from 3D accelerators used a random forest model to predict five categories of physical activity (biking, cycling, sitting, standing, and walking/running) and hip accelerometers to predict four categories of physical activity (walking, and running); the average accuracy rate reached 92.3% (Ellis et al. 2014). When the accelerometer is combined with GPS data, the data can be analyzed to obtain the active activity of the wearer more related to environmental exposure.

Sensor methods typically require investigation and analysis to process measurement information from a subject's sensor rather than directly. A combination of multiple types of sensors or a comprehensive sensor-based survey framework with the ability to capture information such as location, time, duration, and activity patterns is used. The application of this sensor combination application in the study of time-activity patterns may be more desirable.

Mobile Phone Method

As the location-aware technologies grew and developed, scientists paid more and more attention to the feasibility of using them to observe urban mobility. Among these technologies, cellphone networks stand out as a more promising way of collecting data. Cellphone networks have a built-in capability of recording the location of their subscriber's cellphone without the need of any additional infrastructure. Massive and passive data such as cell phone traces provide samples of the whereabouts and movements of individuals. A method to reveal activity patterns is to emerge from cell phone data by analyzing relational signatures of activity time, duration, and land use.

There are some advantages for using cellphone data: advantages such as higher accuracy in comparison to traditional methods, all-daylong coverage of cellphone networks, reachability of data in all sorts of weather conditions, etc. Cellphone networks are capable of tracking a large portion of citizens for as long a period as required and for as many times as needed. The location updates are passive and the subscribers do not take any actions to make it happen. When we use the data obtained by cellphone networks to represent citizens movements the participant is unaware of being in the sample which increases the reliability of the data. On the other hand, some issues arise when we try to elicit traffic-related information from cellphones spatiotemporal data. The main challenge is that phone traces have low spatial precision and are sparsely sampled in time, which requires a precise set of techniques for mining hidden valuable information they contain.

Some people studied the trajectory of mining activity patterns and distributed activities in different parts of the network (Allahviranloo and Recker 2015). Although their data comes from GPS, the methods they propose can also be used for cell phone data. They attempted to infer the types of activities each person is engaged in at different locations by characteristics such as length of stay and distance from home. Later, they used the Markov chain of the conditional random field to

discover the relationship between the socioeconomic attributes of the individual and the sequence of activities and the temporal and spatial trajectories of the activity. Peter Widhalm and others worked to find patterns of urban activity in mobile phone data (Widhalm et al. 2015). To do this, they developed a dual approach. In the first phase, they detect stays and extract geocoded timestamps that form the travel chain. In the second phase, they combined the stay data with the land use data to cluster the activities. They model dependencies, activity types, trip scheduling, and land use types through a relational Markov network. They tested their approach using the Boston City CDR dataset and claimed that the results were consistent with the city survey. Yang Xu et al. tried to understand aggregate human mobility patters using passive mobile phone location dataset from Shenzhen, China (Xu et al. 2015). Their study presented a home-based approach to find human movements patterns that considered homes of individuals as anchor points and references to analyze those individuals' activities. Then they categorized people based on their approximate home locations to obtain aggregate mobility patterns for each BTS. Finally, they used a multilevel hierarchical clustering algorithm to classify regions that show similar mobility patterns.

Some study proposed a new method to distinguishing stays and activity locations from on-move points by considering factors other than duration of stop it is possible to robustly detect a stay (Zahedi and Shafahi 2016). Here are two conditions that if any of them is met, the point under consideration is highly likely to be a stay.

1. If a cellphone connects to a tower (or remains within a cluster of ping-ponging towers) for more than 20 min it can surely be stated that the user of that cellphone is purposefully staying near that tower, because the configuration of the city and the BTSs inside it are in a way that a moving cellphone is not likely to connect to one tower (or remains within the cluster of the towers with ping-pong handover) for more than 20 min. In other words, four consecutive repetitions of the same location in the time-stamped sequence indicates a stay.
2. For the points with two or three consecutive repetitions of the same location, if the cover range of the tower or towers representing that location is fairly small it can be assumed that the user has stopped in that location to perform some activity.

The general development of smartphones in recent years has provided convenient conditions for the monitoring of behavioral patterns. Smartphones mainly monitor behavior patterns based on GPS and motion sensors. The relevant working mechanisms and principles of GPS and sensors have been described in the above description. Activity recognition based on smartphone sensors is becoming an area of extensive research. Smartphones can collect important data from sensors. These sensors include acceleration sensors, position sensors, vision sensors, audio sensors, temperature sensors, and direction sensors. In addition, many applications are developed on smartphones using GPS and sensors. GPS and motion sensor-embedded smartphones provide a new platform for activity reasoning. Originally used for mobile phone enhancements, these sensors are now available for a variety of applications. Providing mobile phone users with information about their own

physical activity in an understandable format can enable users to make smarter and healthier lifestyle choices.

The National University of Science and Technology of Pakistan has developed an app (Arjum and Ilyas 2013). In this work, they built a smartphone app that tracks the user's physical activity and provides feedback, and in daily operations, the user is not required to lose the app to report estimates of calories burned by physical activity. This application differs from previous activity recognition work in that it: 1) it does not require user interaction settings, 2) it does not require additional sensing hardware, it only relies on the physical sensors of the low-end smartphone standard, 3) it does not require calibration, 4) it supports the detection of seven different physical activities, including walking, running, climbing stairs, going down the stairs, cycling, driving, and staying inactive, and 5) the decision tree classifier used by the activity diary app is accurate. Researchers are currently testing the "Activity Diary" application in the field and are working to open it to the public through the Google Android market. In 2018, Pratool B proposed a new system called "HuMAN" that fills this gap by identifying and classifying human complex family activities with wearable sensors (Bharti et al. 2018). Specifically, HuMAN achieves this classification by leveraging a selective multimodal sensor suite on wearable devices and enhances activity classification by carefully utilizing the placement of wearable devices in multiple locations on the human body. According to the richness of the perceived information, HuMAN's system consists of: (a) extracting a set of useful features from a selected multimodal sensor set; (b) a new two-level structure classification algorithm that uses multiple body position sensors to improve accuracy; and (c) improves the classification of complex activities with minimal external infrastructure support (for example, only a few Bluetooth beacons are used for location context). In a real home environment, the system was evaluated with ten users. The experimental results show that the system can detect 21 complex family activities with high precision. For the same user evaluation strategy, the average classification accuracy of all 21 activities was as high as 95%. Health Mate is also an application that can be used on Android and iOS systems to track human behavior and identify activities. It can manually record 30 different activities and automatically detect running, walking, and swimming. However, there is currently no relevant literature supporting the accuracy of this application.

On activities type recognition, Esfahani et al. introduced a new dataset, called position-aware multisensor (PAMS) (Esfahani and Malazi 2018). The dataset contains both accelerometer and gyroscope data. The gyroscope data boosts the accuracy of activity recognition methods as well as enables them to detect a wider range of activities. We also take the user information into account. Based on the biometric attributes of the participants, a separate learned model is generated to analyze their activities. We concentrate on several major activities, including sitting, standing, walking, running, ascending/descending stairs, and cycling.

In addition to the molded application, there is also a dataset on the smartphone for activity identification, among a group of 30 volunteers between the ages of 19 and 48 ongoing (Anguita et al. 2012). Everyone wears a smartphone on the waist (Samsung Galaxy S II) for six activities (walking, upstairs, downstairs, standing,

sitting, and laying). Using its embedded accelerometer and gyroscope, we capture three-axis acceleration and three-axis angular velocity at a constant rate of 50 Hz. Data has been manually tagged by video recording experiments. The obtained datasets were randomly divided into two groups, of which 70% of the volunteers were selected to generate training data and 30% of test data. The sensor signals (accelerometer and gyroscope) were preprocessed by applying a noise filter and then sampled in a fixed-width sliding window (128 readings/window) of 2.56 s and 50% overlap. The sensor acceleration signal has a gravity and body motion component that is separated into body acceleration and gravity using a Butterworth low pass filter. It is assumed that gravity has only a low-frequency component, so a filter having a cutoff frequency of 0.3 Hz is used. From each window, the feature vector is obtained by calculating variables from the time domain and the frequency domain.

Time-Activity Patterns Survey

China

Adults

The first Chinese Environmental Exposure-Related Human Activity Patterns Survey for adults (CEERHAPS-A) was carried out among 91,527 permanent residents aged 18 years and above in 159 counties/districts, 636 streets, and 1908 villages committees of 31 provinces, autonomous regions, and municipalities directly under the Central Government (excluding Hong Kong, Macao Special Administrative Region and Taiwan) in the People's Republic of China in 2011–2012. The multistage cluster random sampling method was used in this survey, with demographic characteristics, rural/urban status, and gender as stratified factors. Table 1 represents the distribution of interviewees by selected factors (Duan et al. 2014).

Face-to-face interviews were conducted to ask each interviewee about their basic information and time-activity patterns. All of the surveyors were trained to ensure they have the same understanding of each question. The contents of the survey included the basic situation of the respondents, the exposure characteristics related to environmental media, the exposure characteristics related to pollution sources, and the exposure behavior characteristics related to environmental health risk factors. Time-activity factors related to indoor air pollutant exposure mainly include time indoors. The mean and 5th ~ 95th percentile data of time indoor by gender, age, urban/rural, and region group are presented in Table 2.

Statistical analysis was completed using SAS. All results were weighted and adjusted as follows: first, the obtained data were weighted using factors calculated from the probabilities for adults in the household, resident groups in the village/community, village/community numbers in the town, and towns in the investigated site; the weighted results were then adjusted using poststratification weight analysis to normalize the population distributions of gender and age in our results with those in the Sixth China National Census (Ministry of Ecology and Environment the People's Republic of China (MEE) 2013a).

	Southeast	1148	846	1030	1174	1290

The exchange of subjects in the sampling roll with other subjects was strictly monitored; less than a 5% exchange rate was allowed for each field site. To ensure uniformity, all surveyors were trained, tested, and deemed qualified, in their understanding of the questionnaire content and possible responses. Parallel questionnaires were performed among 5% of the participants. The subject response was 95% and the recovery rate of valid questionnaires was 99.6%. Ultimately, 91,121 households located in 9108 villages, 636 towns, and 159 counties were used in the analysis (Ministry of Ecology and Environment the People's Republic of China (MEE) 2013b).

Children

The Chinese Environmental Exposure-Related Human Activity Patterns Survey for Children (CEERHAPS-C) was the first national-scale survey of children's exposure factors conducted by Chinese Research Academy of Environmental Sciences from 2013–2014. It investigated the exposure characteristics of children under different conditions. In order to ensure the nationwide representativeness of the survey samples, the multistage stratified cluster random sampling design was adopted for the survey, with regions, rural/urban status, gender, and ages as stratified factors. The subjects in this survey included 75,519 children aged 0–17 years (children under 6 months need to be born in the place of investigation and other subjects need to live

in the place of investigation for more than 6 months) from 55 counties/districts, 165 townships/streets, and 316 schools in 30 provinces (districts and municipalities) of the People's Republic of China. The distribution of the survey respondents is presented in Table 3 (Ministry of Ecology and Environment the People's Republic of China (MEE) 2017a).

The field survey adopted the method of combining questionnaire survey and field measurement (semi-quantitative and quantitative). The questionnaire was designed by the self-designed questionnaire, which was conducted by one-to-one and face-to-face questionnaires by trained investigators. Children under 9 years old were answered by their caregivers; children over 9 years old were answered by the children themselves. The contents of the survey included the basic situation of the respondents, the exposure characteristics related to environmental media, the exposure characteristics related to pollution sources, and the exposure characteristics related to environmental health risk factors. Time-activity factors in this survey associated with exposure to indoor air pollutants mainly included time indoors, time exposure to cooking fumes, time exposure to secondhand smoke, and type of fuels used for cooking or heating in children's living indoor environment (Ministry of Ecology and Environment the People's Republic of China (MEE) 2017b).

Weighting of the survey data produced estimates representative of the Chinese child population. CEERHAPS-C sample weighting was carried out in two steps. The first step involved the computation of sampling weights of each stage, including district, school, and class. In the second step, the sample weights were poststratified by district, urbanicity, gender, and age to the 2010 Chinese child population. The final weight was the product of the base sample weight and the poststratification weight (Ministry of Ecology and Environment the People's Republic of China (MEE) 2017c). The recommended values of time indoors (min/day) are presented in Table 4.

The average time exposure to cooking fumes of children is presented in Table 5. The average daily exposure time of Chinese children to cooking oil fume was 11 min. In terms of age distribution, children aged 5 years had the shortest exposure time to cooking fume, which was 2 min/day, while children over 15 years old had the longest exposure time, which was 18 min/day. From the urban and rural distribution, children in rural areas had the highest exposure time to cooking fume than children in urban areas; from the regional distribution, children in Southwest China had the highest exposure time to cooking fume, while children in East China had the lowest exposure time.

The average time exposure to secondhand smoke of children is presented in Table 6. The average exposure time of children to secondhand smoke in China is 6 min per day. There was no significant difference in the age and sex distribution of children's exposure time to secondhand smoke. From the urban and rural distribution, rural children's exposure time to secondhand smoke was slightly higher than that of urban children; from the regional distribution, in general, children in Northeast China had the longest exposure time to secondhand smoke and the shortest exposure time in East China.

The proportion of children exposure to indoor environment with cooking or heating using solid fuels (%) is presented in Table 7. In China, 26.8% of children were exposed to indoor environments where solid fuels are used for cooking or heating, which was higher in rural areas than in urban areas. In terms of regional distribution, the number of children exposed in Northwest China was the highest, while the number of children exposed in East China was the lowest.

USA

California Activity Pattern Survey (1987–1988)

In California, 1762 residents aged 12 and older living in households containing a telephone were selected to participate in this survey. Interviews were conducted between 1987 and 1988 over four study periods by season: October–December, January–March, April–June, and July–September. The distribution of the sample by age and season of interview (October–December, January–March, April–June, and July–September) is shown in Table 8 (Wiley et al. 1991a).

During this research, interviewers collected some of the information related to four categories: a) personal background of the respondents, including age, education, area of residence, household income, and presence of children in the household; b) description of the respondent's living quarters, work conditions, and smoking behavior; c) a time diary of activities and locations, time spent outdoor and specific location like living room or kitchens in the home, or in automobiles or buses, as well as time spent in various activities such as cooking or playing sports; and d) time spent on one or more associated facets of daily activities that have implications for air pollution exposure (e.g., presence of smokers, cooking equipment, use of solvents, etc.).

Questionnaires and time diaries were conducted through computer-managed auxiliary telephone survey access (CATI) technology developed at the University of California at Berkeley. Interviewers asked respondents some time diary questions, with activities recorded in chronological order, along with the time each activity ended, where the activity occurred, and whether or not smokers were present during the activity. When respondents completed the diary, they were asked whether they spent time in potential exposures and other similar questions.

Indoor Activity Time of Various Microenvironments

Of the time spent indoors, 85% (1226 min per day) was spent in indoor location, and more than two-thirds (893 min per day) was inside the respondent's home, with the bedroom (524 min) and living room (196 min) being the main rooms of the house where time was spent. At the same time, of the time spent indoors away from home, about one-third of time was spent at places of work and other people's homes.

It could be seen that the most time-consuming activity was sleeping, namely the bedroom (524 min). About 328 min more time was spent there each day than in the next most time-intensive place, the living room (196 min). And almost three times as much time was spent in the living room as in the kitchen, the third most frequently

used room in the house (74 min). In general, less than half an hour per day on average was spent in the next set of at-home location – bathrooms, dining rooms, and “other” rooms. Garages, basements, utility rooms, and pool/spa areas took up less than 10 min per day when aggregated across the entire sample. The detailed data is shown in Table 9, 10, 11, 12, and 13.

Smoking and Secondhand Smoke Contact Time

Among the adult portion of the sample, about a fifth (22%) reported having smoking at least one cigarette on the diary, with about half of these smokers having smoked

more than ten cigarettes, and cigarette smoking was significantly higher among men. Smoking of cigars and pipes was highest among men aged 65 and over (6%), as well as men aged 45–54 (4%), but was almost nonexistent among younger men and among women of all age groups. According to the data, the place with the most smoking is at home. And other locations with the highest percentage of episodes with the presence of other smoking were bars and nightclubs (78%), restaurants (42%), plant/factories (37%), and other indoors (33%). Based on weighted data, about 62% of adults and adolescents of Californians would inhale secondhand smoke during the diary day. For such persons, the average duration of all activities with others smoking was 286 min per day. Over longer durations, say a week or more, the population prevalence of some degree of passive exposure to tobacco smoke must be quite high.

Kitchen Smoke Contact Time

Average time spent cooking was 38 min per day, with half of the sample (51%) engaging in some cooking activity on the diary day. Average cooking time per participant was 75 min, with one respondent reporting a high of 465 min cooking on the diary day. From the perspective of gender, women spent more time in cooking, and nonemployed women spent up to half again as much time as employed women in cooking. From the perspective of region, cooking time is the lowest in the South Coast Region. And from the perspective of season, time spent cooking was high in the spring.

Other Smoke Contact Time

In the research of CAPS, about 26% of respondents said they were at a gas station, parking garage, or auto repair shop, with 16% of all adult respondents saying they had pumped or poured gasoline. Also, 62% of the adult sample reported having an attached garage or carport at their dwelling unit. Some 37% reported that a motor vehicle had been parked in that attached garage or carport at their home. From the data point of view, men and employed persons reported being at auto repair shops/gas station/parking garage or pumping or pouring gas than women and unemployed persons, while differences in proximity to operating gas ovens and stoves were not significant across gender or employment status. From the perspective of age, spending time at auto repair shops/gas station/parking garage was higher among younger people, and the figures for pumping or pouring gasoline were also higher among younger people. From the perspective of region, having an attached garage was 11% higher in the San Francisco Bay area (70%) than in the South Coast region and other areas of the state (59%); however, the prevalence of being at auto repair shops/gas station/parking garages “yesterday” was higher in the South Coast region than in the other two areas of the state.

Heating Time

About 30% respondents reported that they were in a room heated by a gas furnace and the use of gas furnaces or any heat source was lower than average in the South Coast region. From the perspective of season, gas heat was the highest in winter

(52%) and the lowest in summer (2%), and the home heating reaches a peak in the winter months at 76% daily use and was only 4% during the summer months.

California Children's Activity Patterns Survey (1989–1990)

The California Children's Activity Patterns Survey (Wiley et al. 1991b) provided estimates of the time children spent in various activities and locations on a typical day. The target population for the children's survey consists of children 11 years old and younger living in California households at the time the survey was conducted. Households with no telephones were excluded, as were households in which there were no English-speaking adults.

The sample was stratified by region to provide a sufficient number of interviews to make comparisons among three major areas of the state: the Southern Coast (including Los Angeles, Orange, and Riverside counties and parts of San Bernardino and San Diego counties); the SF Bay area (including San Francisco, Alameda, Contra Costa, San Mateo, Napa, and parts of Solano, Sonoma, and Santa Clara counties); and counties not included above, i.e., "The Rest of State."

The questionnaire instrument for the California Children's Activity Patterns Survey was divided into three main parts: the adult sections, the children's section, and the daily time diary. When the randomly selected child was eight years old or less, the preferred respondent for all sections of the questionnaire was the parent or guardian who spent the most time with the child on the diary day. In most cases the preferred adult respondent was also the actual respondent. Approximately 92% the adult respondents were the parent or guardian who spent the most time with the selected child on the diary day. Nearly 98% of the adult respondents were either father, mother, step-father, or step-mother to the selected child. In fact, over three-quarters of the adult respondents were the children's mothers. When the selected child was 9–11 years old, he or she was the preferred respondent for the children's and diary sections of the questionnaire. This occurred in about 85% (269 of a total of 316) of such cases. The diary and children's sections were completed by the adult informant in 931 of the 1200 interviews. Most (about 58%) of these proxy interviews were conducted with adults who had spent at least eight waking hours with the child on the diary day. Less than 1% of the proxy interviews were with adults who had spent less than one waking hour with the child on the diary day.

The questionnaire was developed by staff of the Survey Research Center in consultation with the staff of the California Air Resources Board and a panel of scientific advisors. The content of the questionnaire is similar to that used for the 1987–1988 California survey of the activity patterns of adults and children aged 12–17 years (Wiley et al. 1991a). The majority of the substantive content of the questionnaire consists of three kinds of questions: a) direct questions about potential exposures to sources of air pollution on the diary day; b) the daily diary, an inventory of the child's activities and locations on the diary day, which includes beginning and ending times (i.e., durations in minutes); whether or not tobacco smoke was present, and a classification of each activity with respect to whether it occurred in an indoor or outdoor location; c) sociodemographic characteristics of the selected child (age, gender, race-ethnicity, and grade in school) and the adult respondent (marital

status, employment status, years of schooling, and household annual income). The direct questions about potential exposures were generally included the same as those used in the adult survey and items dealing with proximity to the following sources of air pollution, mainly on the diary day (i.e., the day before the interview): gasoline fumes from vehicles parked in attached garages or parking areas (on diary day), use of mothballs in the home (in general), use of toilet bowl deodorizers (in general), use of scented room fresheners (in general), gas heat on (on diary day) open windows (on diary day), use of a fan for ventilation (on diary day), use of air conditioners (on diary day), working vacuum cleaner (in general), child on floor and/or outside surface (on diary day), child around a humidifier or vaporizer (on diary day), child at gas station or auto repair shop (on diary day), child in room with gas oven on (on diary day), and potential exposure to paint products, solvents, pesticides, soaps or detergents, household cleaning agents, personal care aerosols, and hot showers or baths (all on diary day).

The questionnaires and the time diaries were administered via a computer-assisted telephone interviewing technology. The telephone interviews were conducted during April 1989 to February 1990 over four seasons: spring (April–June 1989), summer (July–September 1989), fall (October–December 1989), and winter (January–February 1990).

The data obtained from the survey interviews results in ten major activity categories (113 detailed activity code) and six major categories of locations (63 detailed code). The time respondents under 12 years of age spent in ten activity categories and six location categories are present in Table 14. For each of the categories, this table presents the mean duration for all survey participants. The activity category with the highest time expenditure was personal needs and care, with a mean of 794 min/day. Night sleep was the detailed activity that had the highest mean duration in that activity category. For all respondents, the largest mean amount of time spent was at home, with a mean of 1086 min/day. Table 15 shows the average time children spent in proximity to gasoline fumes and gas oven fumes. In general, the sampled children spent more time closer to gasoline fumes than to gas oven fumes.

Table 16 shows the mean time children under 12 years of age spent indoors by age and sex. Activities performed indoors were assumed to include household work, child care, personal needs and care, education, and communication/passive leisure. The average times spent in these indoor activities and half the time spent in each activity which could have occurred either indoors or outdoors (i.e., work related, goods/services, organizational activities, entertainment/social, do not know/not coded) were summed.

The National Human Activity Pattern Survey

The National Human Activity Pattern Survey (NHAPS), the first nationwide study, is a two-year nationwide telephone survey (9386 samples). The survey, supported by the US Environmental Protection Agency (EPA), aims to gather information about exposure patterns in human activity patterns.

The survey was conducted from late September 1992 to October 1993, and was followed up by the University of Maryland Research and Research Center using the

computer-assisted telephone follow-up system (CATI). Each survey time unit of the study consisted of independent, randomly sampled families. The NHAPS surveyed all of the families with telephone in 48 neighboring states, using a standard two-stage random digit dial (RDD) sample design to select the family.

In an adult-only family (e.g., respondents aged 18 or older), an adult is randomly selected. In families consisting of adults and children (respondents aged 17 or under), 60% of children are randomly selected from all children. Another 40% of adults are randomly selected from all adult residents. All data for adults is collected directly from selected respondents. For children under the age of 10, the family adult who knows the best about children's activities have completed an agent interview with the child. For children aged 10–17, adult respondents answered general family and demographic questions. Then, children between the ages of 10 and 17 answered questions about the time diary and diary of their own activities. Weekly and working day samples were sampled separately in the time unit of each sample collection. The study completed a survey of 9386 samples, and the statistical distribution of respondents is shown in Table 17.

During the survey, the interview time for each sample was controlled below 25 min. The questionnaire was set up in two different editions: Questionnaire A and Questionnaire B, both of which included demographic issues, a 24 h diary and a series of supplementary exposure issues. Among them, Questionnaire A emphasizes the exposure of potential pollutants in household air. NHAPS follows the method of past time diary research, which particularly enhances the accuracy of time estimates in microenvironment calls. The 24 h diary contains five main locations: own house, friends/other houses, travel, other indoors, and other outdoor locations. There are a total of 83 more specific location options, such as bedroom, kitchen, bars, restaurants, stadiums, shops, offices, trains, planes, etc. Fig. 1 shows a reported result of

Klepis et al. (1996)

time location associated with exposure to indoor air pollutants. Six of ten microenvironments and their respective durations are associated with exposure to indoor air pollution.

There are 91 different activity codes in the 24-h diary section of NHAPS, which are considered to be related to human exposure. The original NHAPS category was reclassified into eight categories, each of which contained multiple incidents such as cooking, laundry, housekeeping, bathing, sports, and more. Besides, whether or not someone else smokes in each microenvironment (excluding their own smoking) is also part of a diary that involves exposing specific activities. The content of the survey is related to the exposure level of indoor air pollution. The following two figures (Figs. 2 and 3) show that some of the findings from NHAPS were exposure-related activities and ETS exposure, respectively.

Human activity patterns are critical for identifying and determining human exposure to environmental contaminants, including of course indoor air pollutants exposure. The NHAPS survey covers a wide range of microenvironmental

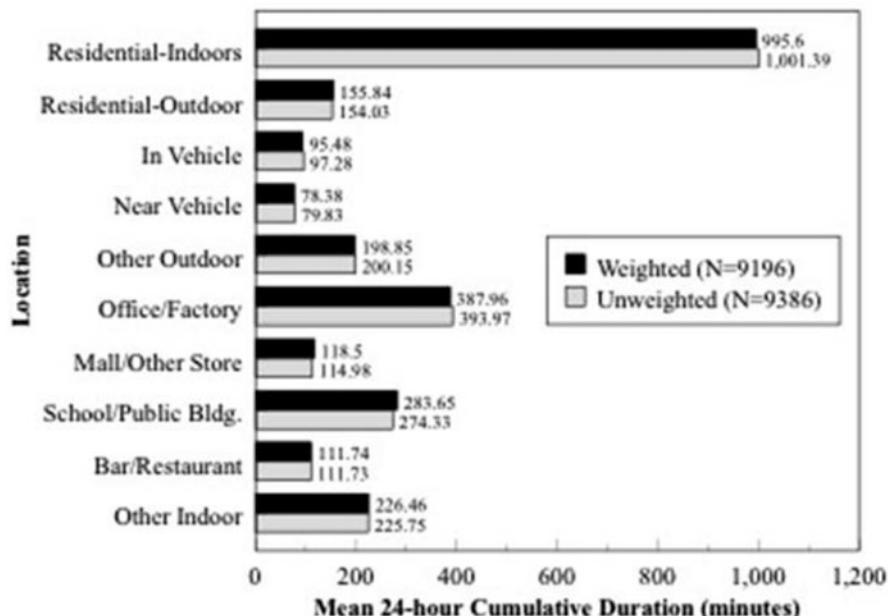

Fig. 1 The overall weighted and unweighted mean 24 h cumulative durations in each location. In the weighted analyses, 190 respondents with missing age or gender values were excluded (Kleppeis et al. 1996)

information related to human time-activity patterns. The NHAPS may provide useful information to indoor air pollution, but also provide experience and reference for the later investigation (Tables 18, 19, 20, and 21).

Canada

The Canadian Human Activity Pattern Survey II (CHAPS II) is the latest national time-activity pattern survey conducted in Canada from 2010–2011 to collect information on the time activities of Canadians of all ages. The survey was carried out taking into account the earlier Canadian Human Activity Model Survey (CHAPS I) conducted in 1994–1995 for the past 15 years, and changes in human activity patterns may have changed as the social situation changed. Moreover, the new survey compensates for some of the potential determinants of time-activity patterns that are not well captured in CHAPS I.

The target population for CHAPS II is the telephone resident who lived in the core area of the census metropolitan areas of: Vancouver, British Columbia; Edmonton, Alberta; Toronto, Ontario; Montreal, Quebec; and, Halifax, Nova Scotia, as well as those who lived in the rural portions of the Census Divisions of: Haldimand-Norfolk, Ontario, and Annapolis Valley-Kings County, Nova Scotia. The surveyed

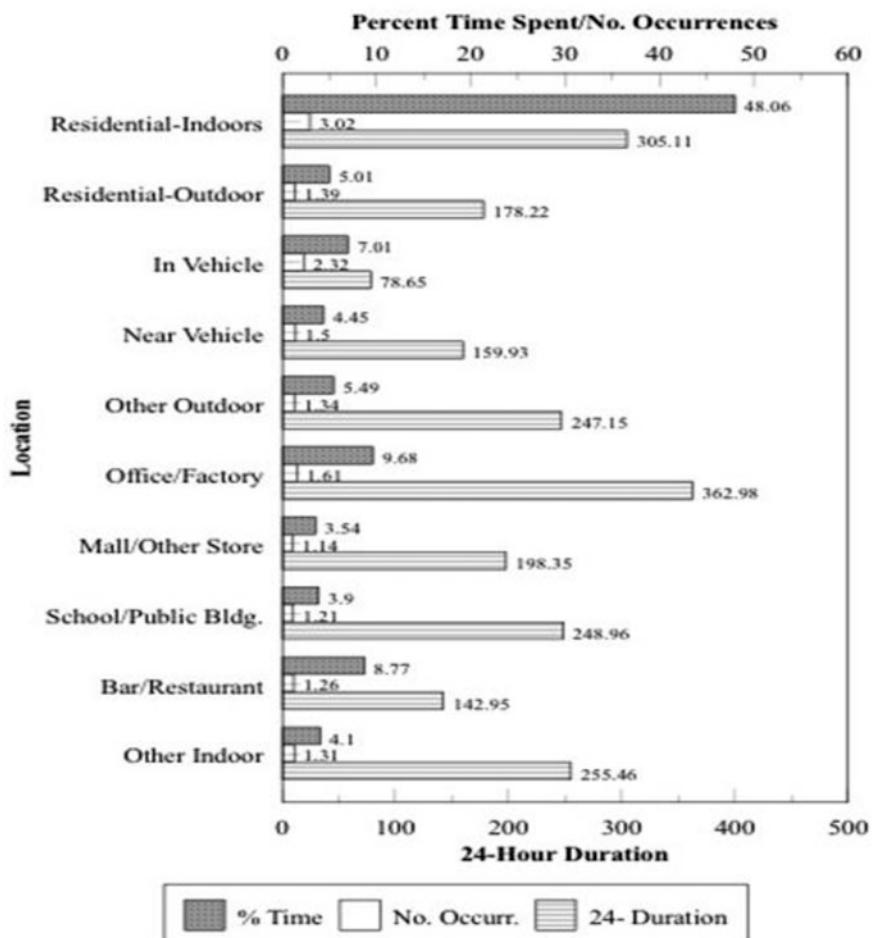

Fig. 2 The overall weighted ($N = 9196$) and unweighted ($N = 9386$) mean 24 h cumulative durations in each exposure activity. In the weighted analyses, 190 respondents with missing age or gender values were excluded (Klepeis et al. 1996)

areas include urban centers who account for 35% of Canada's total population, and two rural areas with more than 100,000 people. The residents in the survey included French residents, while CHAPS1 only English residents. The sample frame is divided into two sampling subframes for infants and noninfants.

CHAPS II included two survey periods from July to September 2010 (summer sampling) and January to January 2011 (season sampling). The survey conducted at each location is based on the sampling framework for the latest phone book listing information provided by ASDE Survey Sampler Inc and supplemented with random digit dialing (RDD) technology. The investigator obtains the zip code obtained from

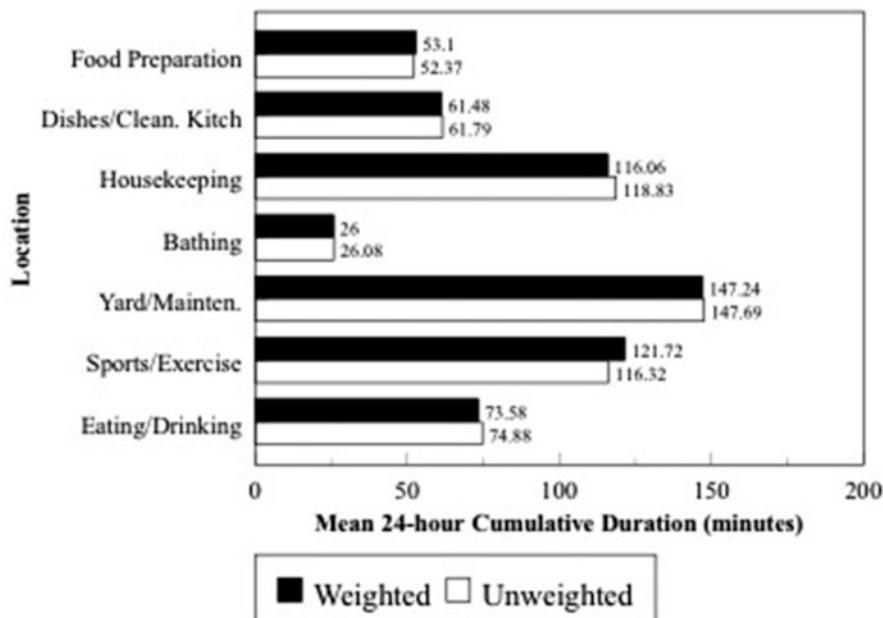

Fig. 3 The overall weighted percentage of time spent, mean number of occurrences, and mean 24 h cumulative durations (in minutes) of ETS exposure in each location (Klepeis et al. 1996)

the respondent and verifies the survey area of the respondent. In addition, different telephone number samples were drawn separately for noninfant and infant surveys as well as summer and winter sampling. The weighting includes several steps: initial calculation of basic weights; adjustment of nonresponse; adjustment of multiple telephone lines within the family; adjustment of over sampling of individuals under 18 years of age; deletion of records that are out of scope; and ensure that the population estimate is consistent with the region of the Canadian Census population-age-gender total.

The telephone survey consists of three main components: questions about the characteristics of the respondent and family composition; a 24 h memory diary; and a supplementary questionnaire on activities that are potentially exposed to specific pollutants, residential characteristics, and socioeconomic factors. Among the 24 h diaries, respondents were asked to describe what they did yesterday, from midnight the previous day to midnight last night, capturing the time, location, and amount of activity for each continuous event within 24 h. CHAPS II's main microenvironment survey was set under the two scenarios "At Home" (includes: indoors, outdoors, and indoors awake) and "Away from Home" (includes: indoors or in vehicle, outdoors, and other outdoor activities). The survey obtained possible potential factors affecting the time-activity pattern such as the age (Table 22), season, and urban-rural. Obviously, "Indoor Awake" is an important information that can be used for indoor air

Table 18 Time spent (min/day) in various rooms at home and in all rooms combined, doers only (Klepeis et al. 1996)

pollution exposure assessment applications and extraction, which is inseparable from the exposure time-activity pattern of indoor air pollution.

Korea

The Time Use Survey

The Time Use Survey was conducted by the Korean National Statistical Office to calculate people’s time spent on various activities (Jang et al. 2014; Kim et al. 2006). The subjects were randomly sampled after designing a sample proportional to the population of 16 metropolitan cities across the nation, stratified by gender and age as of the autumn of 2007. Diaries were distributed to participants who volunteered to participate in advance so that they could record their time spent in various places every 10 min between 6:00 in the morning and 6:00 in the morning the next day. They wrote down their places of activity and how much time they spent in each

Table 21 NHAPS minutes spent with a smoker on the diary day for California (NHAPS – CA) versus the entire nation

Location with a smoker	n	Overall mean (min)	Doer%	Doer	Doer mean (min)
NHAPS-nation (17% of respondents reported being cigarette smokers; weighted)					
All locations	9196	163	43.8	3949	372
In a residence	9196	78	25.6	2331	305
Office – factory	9196	16	4.3	394	363
Bar – restaurant	9196	14	10	951	143
Other indoor	9196	19	7.6	725	247
In an enclosed vehicle	9196	11	14.5	1340	79
Outdoors	9196	24	11.4	1038	213
NHAPS-CA (14% of respondents reported being cigarette smokers; weighted)					
All locations	930	114	36.9	332	309
In a residence	930	45	16.5	164	270
Office – factory	930	9	3.4	26	280
Bar – restaurant	930	13	8	82	168
Other indoor	930	19	7.4	58	252
In an enclosed vehicle	930	5	8.3	82	58
Outdoors	930	23	11	108	209

Means and percentages have been calculated using sample weights, whereas the sample sizes n and doer n are raw counts. The time spent with a smoker does not include one's own smoking (Klepis et al. 1996).

throughout their 24 h routine, after which they entered the records into a web-based survey, which was designed to avoid repetition and overlapping of answers. The survey took place in the spring (March 21) and summer (July 4) of 2007 to reflect seasonal factors. The final number of participants was 2073 with 1001 in the spring survey and 1072 in the summer survey. After excluding the answers of 67 spring and 27 summer participants (who had clearly not recorded accurate information or had not responded to follow-up calls), data from 1980 respondents were used in the final analysis.

Locations were classified into the categories of indoor, outdoor, and transportation. Indoor locations were then further subdivided into homes and locations outside of the home. Outdoor locations were subdivided into the home, locations outside of the home, and movement, as well as various sub-subcategories for each of these three subcategories. Transportation was classified into the subcategories of the bus, taxi, subway, passenger car, truck, high-speed train, and airplane.

In order to estimate the amount of exposure to pollutants through the environment medium in the life of the individual, it is necessary to provide information about how much time has been active in some places. In particular, information on the ratio between indoor and outdoor activities and the time spent at home is an important variable in assessing exposure. In this handbook, it was proposed to separate the time and place by the location of the indoor and outdoor places, and transportation. In the development of the next-generation environmental technology development project, the Korean exposure index, and the cloud system, the research was conducted to

Table 22 Daily time spent in major locations by age group of the CHAPS II

Age Group	Location	Mean		Median		95th percentile	
		% of day	h: min	% of day	h: min	% of day	h: min

	Other indoor locations	12.5	2: 59	8	1: 55	40.6	9: 44

Matz et al. (2014)

evaluate the time spent in each activity's place for the purpose of exposure assessment. Indoor time is included in the interior of the house, offices, department stores, etc., where the respondent is home.

The time spent indoors during the day of the Korean adult is 1281.0 min (about 21 h and 30 min), which showed that most of the time were spent indoors. The outdoor travel time was 76.2 min and the transportation hours were 82.8 min.

The time of the day indoors was 1281.0 min. The women spent 1306.7 min indoor, higher than that of men with 1256.4 min. It tended to decrease in the time spent indoor, for example, the people aged 65 or older spent 1254.3 min indoor and was about 32 min shorter than that of people aged from 18 to 24 years old, who spent 1286.3 min indoor. Seasonal differences were shorter in the summer and about 8 min in the summer time compared to spring. From the time spent indoors, the longest detail place of the day was 440.0 min into the bedroom (about 7 h 20 min), the office 253.9 min, the living room/hallway 138.3 min. It was spent in the room for 8 h and 30 min except for bedtimes, which was for more than one-third of the day. The recommended values for indoor time are shown in Table 23.

Children's Time-Activity Patterns Survey

A study was conducted on 2080 male and female children under 9 years old in Korea (I) (2013) and (II) (2014) time-activity patterns. The selection of survey subjects was based on stratified sampling according to the square root proportional distribution for the whole country and based on the estimated population in 2013. The ratio of male to female was approximately 50:50, and 500 persons were surveyed by season (spring, summer, autumn, and winter). A time-activity logbook was developed to measure and investigate the time activities of children under the age of nine. The time unit of the time-activity logbook was 30 min, and the room was divided into indoor, school (kindergarten, day care, and elementary school) indoor, and other building indoor. The means of transportation were divided into walking, bicycle, taxi (or passenger car), bus, and train (or subway). Be sure to include the main act (study, play, watch TV, etc.) at the beginning, respectively. If there were more than two places during the time unit (30 min), all records were made and counted. The time-activity logbook allows one child's parents to record on behalf of the child.

The National Statistical Office Life Time Survey is an example of representative samples from all Koreans and is recorded 24 h a day at intervals of 10 min. Therefore, this data can be used as representative and reliable data for the time spent by the activities of the Korean people (10–18 years old). However, since this data is not the data that was examined for the purpose of exposure assessment, it does not provide information on the specific place where each activity occurred, and it does not distinguish whether the place is indoor or outdoor. Therefore, the National Statistical Office's Life Time Survey data was used to calculate the time required for specific activities among time-activity variables. Since the National Statistical Office (NSO) survey was not developed or classified according to the purpose of exposure assessment, the original data were reclassified and reworked according to the purpose of the exposure assessment.

The main exposure variables related to time activities are the time required by location, the time required by activity, and time spent on transportation. Among these exposure variables, the time required for each activity was from 0 to 9 years old, and the data from 10 years to 18 years old were reclassified and reanalyzed.

The indoor environment is divided into indoor, school, or kindergarten (day care center) indoor and other indoor. In Korea, only 16.86 h on weekdays, and 5.13 h on weekdays during daytime for children aged 0–9 years, and most of the time spent indoors. The average time spent living in a house during a day of a 10- to 18-year-old child was 12.11 h on a weekday, 9.84 h in school and other indoor environments (school, etc.), and 1.43 h on transportation (vehicle). The recommended values for indoor time are showed in Tables 24, 25, 26, and 27.

Europe

The EXPOLIS (Air Pollution Exposure Distributions of Adult Urban Populations in Europe) Study used uniform questionnaires and time-activity diaries in conjunction with personal monitoring of pollutant concentrations in several countries in Europe

(Hänninen et al. 2004). Within the framework of the EXPOLIS study, TMA (Time Microenvironment Activity) data of 1447 subjects in seven cities (Helsinki, Athens, Basel, Grenoble, Milan, Prague, and Oxford) had been collected between 1996 and 2000. In total, 543 subjects completed a diary during the period of personal exposure measurement, whereas 904 participated in a less demanding diary-only study (Schweizer et al. 2006).

The TMA diary was collected during working days only, for example, from Monday morning to Wednesday morning (from 06:00 to 06:00) or from Wednesday evening to Friday evening (from 18:00 to 18:00) for 48 h. Subjects were asked to record in the TMA diary every 15 min of the day in the appropriate microenvironment–activity category. Multiple entries were allowed for each 15 min segment (mE). We then calculated for each participant how much time he/she spent in each mE (each 15 min segment was divided evenly between all entries). They distinguish two aspects of an individual's TMA pattern during the sampling period: (1) whether the person enters a specific microenvironment at least once and therefore becomes what they call a “habitue” of the corresponding microenvironment (Graham and Mccurdy 2004; Mccurdy and Graham 2003), and (2) the total duration of time spent in specific microenvironments. To investigate TMA patterns across subgroups and cities, they present four criteria: (1) the percentage of people (habitue's) entering in each microenvironment, (2) the duration of participation by these habitues, (3) the determinants for becoming a habitue, and (4) the determinants for the duration of time spent in each microenvironment by the corresponding habitues (Eurostat 2010).

Table 28 presents the distribution of time spent in indoor locations (home, work, and other) by city. It only includes data of habitues. Home indoor dominated time spent in indoor locations with 100% habitues in all seven cities and with averages ranging from 13.5 h/day in Milan to 15.8 h/day in Oxford, or 56–66% of a day. The coefficient of variation was low with values between 19% in Milan and 28% in Grenoble.

Africa

Between January and June 2007, South Durban conducted a survey of 381 adults. The questionnaire included a set of questions on demographics, potential air pollution exposure sources, and a time-activity diary. The diary was divided into three microenvironments, namely indoor, outdoor, and in-vehicle. The first two microenvironments were subdivided into indoor at home, indoor other and indoor at work, and outdoor at home, outdoor other and outdoor at work, respectively (Matooane et al. 2011).

According to the results, data cleaning process resulted in 291 complete questionnaires which were analyzed using STATA 10. Robust regression with Huber-M estimation was used to determine drivers for time spent in microenvironments by the study population. Due to the limited number of weekend days, as a result of data

collection constraints on weekend days, the analysis was confined to weekdays. On average participants spent approximately 21.2 ± 1.51 h/day in indoor environments, the home indoor microenvironment accounted for a large portion (82.5%) of time spent indoors. Table 29 indicates that significant gender, employment, educational, and family type differences in the distributions of the time spent in microenvironments were confined largely to “indoor at home” and “outdoor at home” microenvironments.

The statistically significant drivers for time spent indoors at home on weekdays were gender, occupational status, and temperature (Table 30). Time indoors at home increased significantly with being male and when temperatures were high. However, being employed resulted in participants spending significantly less time indoors at home. Only employment status remained a significant driver for time spent indoors at other locations. Of the many drivers for time spent in various microenvironments, our study found employment status, gender, and temperature to be the main drivers of time spent in various microenvironments in south Durban.

In Durban, South Africa studies have shown that more than seven out of ten households in low-income metropolitan areas rely on kerosene for domestic purposes, leading to widespread problems of poor indoor air quality (Muller et al. 2003). According to Statistics South Africa (SSA 2000), there are approximately five million households in South Africa currently using fossil fuels for domestic purposes. Of these, a fairly high proportion rely on kerosene, with 21% using it for cooking, 14% for heating, and 13% for lighting. And the residents of Cato Crest tend to live in smaller dwellings, often comprising only one room, which serves as a

multipurpose room in which most people slept and in which cooking was undertaken.

Air quality monitoring in 69 households took place over a 9-day period from 5 to 15 September 2000. This survey used the form of a questionnaire, and the questionnaire consisted of 48 closed-ended questions related to personal details, fuel use, building structure, cooking habits, and time-activity patterns. A multistage sampling method was used, in which the initial population was divided according to the eight recognized areas of Cato Crest. Within each area, transects were marked on aerial photographs along pathways that provided vehicular access at either end of a transect. The transects were also selected to ensure an even allocation of houses within areas. Thereafter, sampling along each transect was random, although certain difficulties were encountered. The haphazard and unplanned nature of the informal settlement made strict adherence to the sampling procedure difficult. In such cases the nearest dwelling to that designated on the aerial photograph was selected.

Women were targeted in the questionnaire as they were generally the only household members involved in cooking and other domestic activities. The questionnaires were administered by a group of ten trained students. All interviewers were fluent in isiZulu and English and conducted the interview in the language in which the respondent was most comfortable. The questionnaires were completed by the interviewers in English.

Of the 69 interviews conducted, 66 interviews were with female respondents. The average age of the interviewees was 34 years. Only ten respondents were employed full time, with 39 unemployed respondents. Two respondents were students.

In response to questions on the average time taken to cook meals, 45 respondents reported that it took between 1 and 2 h. Fifty respondents reported that there were people in their household that slept in the same room as the cooking was done in. Forty of these households had between 1 and 3 people sleeping in the “kitchen.” Table 31 shows the average number of hours spent conducting several different daily activities in summer and winter months.

Conclusion

So far, due to the advantages of simplicity of the method as well as low cost and direct access to detailed activity information, large-scale time-activity pattern surveys mainly adopt questionnaire survey method. However, the questionnaire survey method has the disadvantage of recall bias and low temporal and spatial resolution. In recent years, with the development of related technology, the application of GPS method is more and more popular. Compared with the traditional questionnaire

survey method, GPS method has the advantage of continuous recording, high spatial and temporal resolution, and less reporting burden of respondents. Meanwhile, with the development of wireless sensor technology, wearable sensor devices can accurately identify the activity state of the human body, and can be used to identify fine activity patterns in conjunction with GPS and other positioning devices. In addition, the widespread development of smart phones, mainly based on GPS and motion sensors, also provides convenience for monitoring time-activity patterns. However, the time-activity monitoring technology based on GPS, sensors, and smart phones has a great demand for data mining and analysis. In general, the data analysis technology of the new technology is a great challenge and the focus of future research. With the requirement of refined time-activity patterns information, new challenges are presented to the survey methods.

At present, the investigation of the time-activity pattern related to air exposure mainly focuses on the indoor and outdoor time. However, affected by various factors such as building decoration materials, HVAC systems, electronic office supplies, kitchen combustion products, and human activities (such as smoking), different microenvironment led to great differences in the types and intensity of air pollutants. Nowadays, with the development of air pollutant exposure assessment models, it is necessary to accurately match the air pollutants concentrations and human time-activity pattern both in time and space in the future. In addition to the survey of total indoor and outdoor time, more accurate and detailed time information is also needed to improve the precision of exposure assessment. In addition, previous time-activity pattern surveys paid less attention to activity intensity of the people, which could directly affect people's inhalation rate and indirectly affect their air pollution exposure levels. Therefore, collecting more accurate and detailed information, including location, time, duration, and activity patterns, is necessary.

Abstract

A framework to predict human exposure to chemicals present in indoor environments is described with a focus on semivolatile organic compounds (SVOCs). The framework consists of six mechanistically consistent source emission categories (SECs), i.e., solid, soft, frequent contact, applied, sprayed, and high-temperature sources. Environmental compartments include the gas phase, airborne particles, settled dust, indoor surfaces, and clothing. Exposure may occur via contact with a source or via compartmentally mediated chemical uptake. To illustrate how the framework can be used to derive exposure estimates that can be used for rapid risk prioritization, two examples are described in detail. The first example focuses on

di-n-butyl phthalate (DnBP) present in a vinyl flooring material, leading to mediated exposure to DnBP via different pathways. In the context of this example, the special role of clothing is also discussed. The second example explores contact exposure to tris(2-chloroethyl) phosphate (TCEP) in a smartphone casing. The two examples allow the identification of knowledge gaps, and fruitful directions for further research. In addition, next steps for further development and implementation of the framework as a community modeling tool are discussed.

Introduction

One of the primary reasons to improve indoor air quality is to reduce exposure to potentially harmful chemicals present in various forms in the indoor environment. To effectively achieve this goal, exposure assessment strategies that focus on rapidly prioritizing sources of exposure and exposure pathways are needed. Furthermore, it is necessary to integrate our current understanding of the fundamental mechanisms that govern chemical emission and transport in these exposure assessments. For this purpose, Eichler et al. (2021) proposed a modular mechanistic modeling framework to assess human exposure to semivolatile organic compounds (SVOCs), which are introduced into indoor environments in materials, products, and articles. The focus of their work was on SVOCs because of the multimedia behavior of these chemicals, but the framework is designed to enable the integration of other volatile organic compounds (Liu et al. 2013; Salthammer et al. 2018; Zhang et al. 2016), as well as inorganic chemicals and airborne particles. Overall, the framework intends to provide an initial structure and guiding roadmap on which current and future exposure modeling efforts can build.

The framework currently integrates more than 15 years of research focusing on SVOCs (Bennett and Furtaw 2004; Li et al. 2018; Liang et al. 2019; Little et al. 2012; Weschler and Nazaroff 2008; Weschler et al. 2008; Xu and Little 2006) and is based on 16 points of consensus achieved among the international scientific community involved in the research (Eichler et al. 2021). One critical aspect is the focus on mechanistic (i.e., process-based) emission and transport models. Mechanistic models are robust, can be applied to different chemicals, and rely on well-established physicochemical processes such as diffusion, sorption, and equilibrium partitioning. Compared to empirical models, mechanistic models can be more easily scaled in complexity for different modeling purposes. However, mechanistic models may not yet be available for all relevant emission and transport processes, and in those cases, machine learning or statistical models (Wei et al. 2019) as well as expert opinion may need to be used.

Many of the models that this framework aims to integrate are discussed in detail in this handbook, in particular in ► Chap. 23, “Source/Sink Characteristics of SVOCs.”

This chapter therefore focuses on showing how the framework may be applied to assess exposure to chemicals, in particular SVOCs, in consumer products. Specifically, the objectives are to (1) briefly summarize the underlying principles of the modular mechanistic framework, (2) describe two exposure examples in detail, and (3) discuss current limitations, knowledge gaps, and next steps.

A Modular Mechanistic Framework for Rapid Modeling of Indoor Exposure

General Description of the Framework

The description of this framework is based on Eichler et al. (2021), who proposed it as a strategy to rapidly model indoor exposure to SVOCs. The framework can be expanded to assess exposure to other chemical classes, but the examples given here focus on SVOCs.

As shown in Fig. 1, the framework consists of three major elements. These are emission of a chemical from a source into an indoor compartment, transport of the chemical among compartments and any associated chemical transformations, and exposure of occupants to the chemical via contact or compartmentally mediated pathways. Any consumer product, article, or building material that contains the

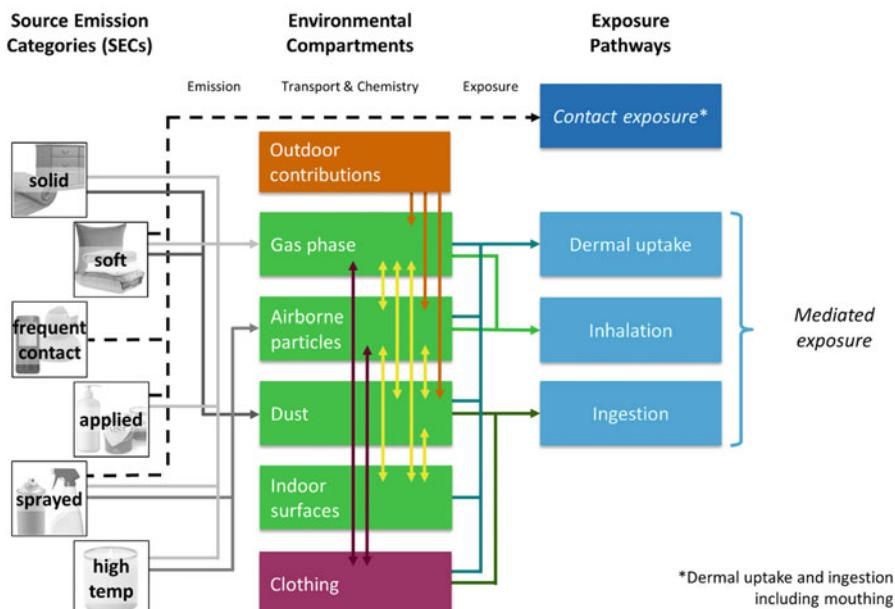

Fig. 1 The modular mechanistic framework for modeling indoor chemical emission, transport, chemistry, and exposure, as presented by Eichler et al. (2021) for SVOCs. (Reprinted with permission from Eichler et al. (2021). Copyright 2021 American Chemical Society)

chemical of interest, or a mixture of chemicals, and is present indoors can be considered as a source. To evaluate chemical emission into the compartments, each source is placed in mechanistically consistent source emission categories (SECs) that are potentially relevant for this particular type of chemical. For SVOCs such as phthalates and organophosphorus flame retardants (OPFRs), the following six SECs have been identified: solid sources, soft sources, applied liquid sources, sprayed liquid sources, high-temperature sources, and frequent contact sources. Exposure to a chemical in a source can be described for each SEC by mechanistically consistent models corresponding to a specific emission, transport, or exposure pathways. However, there is a continuum of sources present in indoor environments, and some sources cannot be clearly placed into one SEC. Instead, multiple SECs may be relevant, and in this case, all possible emission scenarios should be evaluated depending on the purpose of the assessment and the regulatory context.

From the source, emission occurs into different indoor compartments driven by the prevailing chemical activity (or fugacity) gradient. Key compartments in which a chemical can be present are the gas phase, airborne particles, settled dust, and indoor surfaces. Additionally, outdoor contributions and clothing are compartments that have to be considered separately. From sources categorized that are solid or soft, chemicals are emitted into the gas phase and also to dust settled onto the surface of the source, without entering the bulk gas phase. From applied sources, such as creams or paint, emission to the gas phase occurs. Sprayed (e.g., deodorants or air freshener) and high-temperature (e.g., candles or incense) sources emit chemicals into the gas phase and also into the airborne particles compartment. Once a chemical enters the indoor environment, transport among those compartments occurs to some extent for all chemicals. However, all compartments are not equally important for the various classes of chemicals, depending on their properties. Furthermore, chemical processing may occur in all compartments, depending on the chemical properties and the availability of reactants. Parameterizing models describing indoor chemistry remains challenging, but the potential relevance of these processes should be addressed at least qualitatively. Other chemical removal processes, e.g., microbial degradation and occupant activities such as cleaning, may have to be considered.

Some chemicals of interest indoors may also be present outdoors (e.g., polycyclic aromatic hydrocarbons (PAHs)) and may therefore contribute to the indoor mass balance. These chemicals can enter indoor environments with infiltrating air (gas and particle phase) and as dirt and dust carried in by occupants and pets. Chemicals present in the gas phase may partition from there to other compartments, which over time may become reservoirs from where a chemical can be reemitted, if the chemical activity gradient is reversed. Deposited airborne particles that accumulate in settled or resuspended dust may enter the airborne particle phase. Airborne particles and dust, and associated chemicals, also contribute to the potential buildup of organic films on indoor surfaces. Here, surfaces include all readily accessible interfacial regions (air-substrate interface and bulk substrate near the interface) of materials such as wood, painted walls, furnishings, glass, nonclothing fabrics, and upholstery. Uptake of chemicals by surfaces is strongly influenced by the presence of the thin organic films that develop on nearly all indoor surfaces over time.

For sources categorized as soft, applied, or sprayed, and especially for sources identified as frequent contact, contact exposure may play an important role. During contact exposure, the chemical in the source is in direct contact with the exposed individual by dermal uptake, ingestion of the source, or by mouthing of the source, instead of first entering an environmental compartment. The mediated exposure pathways are: (1) dermal uptake from air (gas and particle phases), dust, surfaces, and clothing; (2) inhalation of air (gas and particle phases); and (3) oral exposure, i.e., ingestion of dust or mouthing of clothing and other sink materials.

Figure 1 shows the generic mechanistic modeling framework developed by Eichler et al. (2021) for SVOCs. To adapt the framework for other classes of chemicals, such as volatile organic compounds (VOCs) or per- and polyfluoroalkyl substances (PFAS), additional SECs and indoor environmental compartments may have to be added. For example, some chemicals are present in food and beverages as additives or because of manufacturing, therefore the SEC “food contact materials (FCMs)” may be a useful addition in these cases. The corresponding indoor environmental compartment may then be “food and beverages,” from where additional ingestion exposure can occur. Currently, exposure to chemicals present in FCMs and partitioning into foodstuff is not considered in the framework. However, many FCMs (e.g., packaging, storage containers, and cookware) are often present indoors, and contact with food and other environmental compartments may increase exposure to some chemicals. It is an important task to expand the framework to include other, mechanistically consistent SECs and compartments that allow comprehensive exposure assessments of multiple classes of chemicals.

Assumptions

Emission, transport, chemistry, and exposure occurring in indoor environments are fundamentally dynamic processes. However, to simplify models, the following assumptions can be made in some cases.

1. *Equilibrium between environmental compartments.* Compartments with a large capacity for a chemical, e.g., due to a large available surface area, will take longer to reach equilibrium with other compartments. In this case, the assumption of equilibrium may no longer be applicable.
2. *Well-mixed indoor air.* Exceptions may apply for poorly ventilated spaces.
3. *Negligible outdoor contributions.* Not all chemicals found indoors have outdoor sources.

For SVOCs, it can usually be assumed that emission is externally controlled. The material-phase SVOC concentration C_0 is usually constant because source depletion occurs over a very long time period. These assumptions are not appropriate for VOCs, for which emissions are usually governed by diffusion within the material and depletion may occur within days to weeks (Xu and Little 2006; Liang and Xu 2014a).

Usually, normal conditions (i.e., a temperature of 20 °C and a pressure of 101.325 kPa) are implicitly assumed. Because many of the processes and their associated model parameters are temperature dependent, the parameter values must be appropriate for the assumed conditions. If parameters are available at other conditions (e.g., vapor pressure is often measured at 25 °C), they need to be adjusted.

Modeling and Parameterization

The arrows shown in Fig. 1 represent specific mechanistic models or submodels that can be used individually or combined to described the path of a chemical from a source via the indoor environment to an exposed individual. Many, but not all, models are available based on the current state of science. Many of those models are described within this handbook and can also be found in Eichler et al. (2021). The models used in the examples described below will be discussed in more detail, but different models may be applicable for other scenarios, depending on the goal of the assessment. Uncertainty and problems related to parameterization will be discussed as part of the examples and at the end of this chapter.

Example 1: Di-n-Butyl Phthalate (DnBP) in Vinyl Flooring

Source: For the first example, we estimate exposure of a young child to di-n-butyl phthalate (DnBP) emitted from vinyl flooring covering a room, for example, a kitchen. The initial step of any assessment using the framework is the characterization of the source, i.e., the identification of the relevant SEC (or SECs) and description of the chemical of interest in the source. DnBP is a plasticizer and an SVOC, thus we focus on the six SECs described for SVOCs in Eichler et al. (2021): solid, soft, frequent contact, applied, sprayed, and high temperature. For vinyl flooring, the SEC “solid” is most appropriate, because of the large emitting surface area and infrequent direct contact of the occupants with the source. This means that contact exposure is not considered and the focus is on mediated exposure.

For this example, it is assumed that the vinyl flooring contains 9 wt% DnBP. Using a density of polyvinyl chloride (PVC), the main component of vinyl flooring, of 1.5 g cm^{-3} (Eichler et al. 2018) corresponds to a C_0 of 0.135 g cm^{-3} . Additional information about DnBP of interest is its saturation vapor pressure p_s of $6.70 \times 10^{-3} \text{ Pa}$ at 25 °C (Wu et al. 2016) and its octanol-air partition coefficient (given as $\log(K_{\text{oa}})$) of 9.8 at 25 °C (Weschler and Nazaroff 2012). For the purpose of this example, we will also assume an indoor temperature of 25 °C, thus no further adjustment of these values will be necessary. The concentration of the chemical of interest is especially critical if the emission parameter y_0 , the gas-phase concentration immediately adjacent to the source material, is not known, because C_0 can be used to estimate y_0 . C_0 has to be either measured experimentally (using extraction procedures and chromatographic methods) or taken from product labels or

manufacturing data. C_0 is also important when evaluating certain contact exposure pathways.

Scenario: Next, the exposure scenario is defined in more detail, including the assumptions used in the model. As mentioned above, the DnBP-containing flooring is present in a kitchen, but for the purpose of this assessment, we estimate the concentrations in the environmental compartments throughout the entire house. The information about the house listed in Table 1 is assumed for this example; however, in many cases it is likely that a user has specific data available instead. The house parameterized here is a roughly standard, single-level US house. Basement, attic, and attached garage are not considered.

The following assumptions are made for modeling emission and transport of DnBP in this scenario:

1. Equilibrium among the indoor compartments has been achieved for DnBP.
2. Outdoor contributions of DnBP are negligible.
3. Interaction of DnBP with clothing is not considered.
4. Chemical and microbial reactions are not considered.
5. The flooring is the only source of DnBP in the house.
6. The concentration of total suspended particles (TSP) in the house is constant with no additional particles generated.
7. Dust removal (e.g., by vacuuming) takes place once per week.

These assumptions lead to a substantial simplification of the model, but they also introduce additional uncertainty.

Model selection: Following the framework (Fig. 1), emission occurs from the flooring into the gas phase, and also to dust settled on the source. Now it depends on the goal of the assessment if the emission rates are calculated independently, followed by modeling of each partitioning mechanism, or if a slightly broader,

Table 1 Parameters describing the indoor exposure scenario

Parameter	Symbol	Value	Reference
Total floor area of a US house	$A_{\text{floor},\text{total}}$	250 m ²	census.gov (2020)
Source surface area (kitchen)	A_{source}	19 m ²	Manuja et al. (2019)
Ceiling height of a US house	H_{ceiling}	2.4 m	Manuja et al. (2019)
Total volume of the house	$V_{\text{house},\text{total}}$	600 m ³	based on $A_{\text{floor},\text{total}}$ and H_{ceiling}
Surface area to volume ratio, with contents	S^*/V^*	3.2 m ⁻¹	Manuja et al. (2019)
Total surface area of the house	$A_{\text{house},\text{total}}$	1920 m ²	calculated, based on $V_{\text{house},\text{total}}$ and S^*/V^*
Air change rate	λ	0.4 h ⁻¹	Jaycock and Havics (2018)
Air flow rate through the house	Q	240 m ³ h ⁻¹	calculated, based on $V_{\text{house},\text{total}}$ and λ
Total suspended particle concentration	TSP	20 µg m ⁻³	Little et al. (2012)

mass balance–based approach is used that combines the relevant processes. Therefore, model selection is the next step. For this example, the mass balance approach is chosen to evaluate the concentrations of DnBP in the different environmental compartments after certain time periods. The mass balance reveals which additional parameters are needed. As described in Eichler et al. (2021), the general mass balance for describing transport of SVOCs in indoor environments is:

$$\begin{aligned} V \frac{dy}{dt} + V \frac{dF}{dt} = & Q \cdot (y_{\text{out}} + F_{\text{out}}) - Q \cdot (y + F) + h_m \cdot A_{\text{source}} \cdot (y_0 - y) \\ & - h_{m,s} \cdot A_{\text{sink}} \cdot (y - y_s) - v_d \cdot F \cdot (A_{\text{source}} + A_{\text{sink}}) + R_p \cdot M \cdot P_{\text{dust}} \cdot A_{\text{source}} \\ & + R_p \cdot M_s \cdot P_{\text{dust},s} \cdot A_{\text{sink}} \end{aligned} \quad (1)$$

where V is the volume of the indoor environment, y is the gas-phase SVOC concentration in the indoor environment, F is the particle-phase SVOC concentration in the indoor environment, t is time, Q is the air flow rate, y_{out} is the gas-phase SVOC concentration entering from outdoors, F_{out} is the particle-phase SVOC concentration entering from outdoors, h_m is the mass transfer coefficient for a source surface, A_{source} is the surface area of the source, y_0 is the gas-phase SVOC concentration in the boundary layer immediately adjacent to the source, $h_{m,s}$ is the mass transfer coefficient for a sink surface, A_{sink} is the sink surface area, y_s is the gas-phase SVOC concentration in the boundary layer immediately adjacent to the sink surface, v_d is the size-dependent particle deposition velocity, R_p is the size-dependent particle resuspension rate, M is the mass loading of settled dust on the source surface, P_{dust} is the concentration of SVOC in the dust settled on the source surface, M_s is the mass loading of settled dust on the sink surface, and $P_{\text{dust},s}$ is the concentration of SVOC in the dust settled on the sink surface.

Based on the first assumption, steady state has been achieved and the mass balance in Eq. 1 can be set equal to zero, thus eliminating the accumulation terms:

$$V \frac{dy}{dt} + V \frac{dF}{dt} = 0 \quad (2)$$

The first assumption also means that the gas-phase SVOC concentration in the boundary layer adjacent to the sink surfaces equals the bulk gas-phase concentration, i.e., no further loss to the surfaces occurs because equilibrium has been reached:

$$y_s = y \quad (3)$$

The second assumption yields:

$$Q \cdot (y_{\text{out}} + F_{\text{out}}) = 0 \quad (4)$$

F can be calculated as:

$$F = K_p \cdot TSP \cdot y \quad (5)$$

where K_p is the gas-particle partition coefficient. Similarly, P_{dust} and $P_{\text{dust},s}$ can be calculated using:

$$P_{\text{dust}} = K_{\text{dust}} \cdot y_0 \quad (6)$$

$$P_{\text{dust},s} = K_{\text{dust}} \cdot y_s \text{ (here : } P_{\text{dust},s} = K_{\text{dust}} \cdot y, \text{ see Eq. 3)} \quad (7)$$

where K_{dust} is the dust-gas partition coefficient.

Additional simplifications are made by assuming that $h_{m,s} = h_m$ and $M_s = M$. However, if measured data on mass transfer coefficients or mass loadings are available, they should be used. To explicitly calculate h_m or $h_{m,s}$, the correlation by Axley (1991) can be used, but see also Huang et al. (2004). Together with Eqs. 2–7, the simplifications result in the following mass balance, which can be rearranged to solve for y :

$$y = \frac{y_0 \cdot A_{\text{source}} \cdot (h_m + R_p \cdot M \cdot K_{\text{dust}})}{Q + Q \cdot TSP \cdot K_p + \nu_d \cdot TSP \cdot K_p \cdot (A_{\text{source}} + A_{\text{sink}}) - R_p \cdot M \cdot K_{\text{dust}} \cdot A_{\text{sink}}} \quad (8)$$

Having calculated y and further assuming solid sink surfaces with negligible porous surface area, the concentration of DnBP on the sink surfaces, C_s , at equilibrium can be calculated as:

$$C_s = K_s \cdot y_s \quad (9)$$

where K_s is the surface-gas partition coefficient. As stated in Eq. 3, we assume that $y_s = y$ for this scenario. K_s is specific to a material and a chemical, but has not been measured for many such combinations. If directly measured data cannot be used, K_s can be estimated based on different types of regressions established for specific scenarios. For example, Xu et al. (2009) established a regression model to estimate K_s for phthalates and for wooden floors, ceilings, and walls, or:

$$\log(K_s) = -0.779 \cdot \log(p_s) - 1.93 \quad (10)$$

where the vapor pressure p_s is given in mmHg. As this parameter depends directly on p_s and is also only valid for these material types, the resulting DnBP surface concentration is one of the more uncertain values.

K_p can be measured, but in most cases K_p is predicted based on either the K_{oa} of the chemical or on p_s (Salthammer and Goss 2019; Salthammer and Schripp 2015). Here, we will use the approach of Finizio et al. (1997):

$$K_p = \frac{f_{\text{om_part}} \cdot K_{\text{oa}}}{\rho_{\text{part}}} \quad (11)$$

where $f_{\text{om_part}}$ is the fraction of organic matter associated with airborne particles and ρ_{part} is the density of the airborne particles.

K_{dust} is defined as:

$$K_{\text{dust}} = \frac{f_{\text{om_dust}} \cdot K_{\text{oa}}}{\rho_{\text{dust}}} \quad (12)$$

where $f_{\text{om_dust}}$ is the fraction of organic matter in settled dust and ρ_{part} is the density of the settled dust.

To determine M , the following equation is used and solved for $t = 168$ h, based on assumption 7:

$$\frac{dM}{dt} = \nu_d \cdot TSP - R_p \cdot M \quad (13)$$

Parameterization: Now that all relevant equations to model SVOC transport indoors are known, the equations have to be parameterized. Accurately measured data for specific parameters should be used if available. Otherwise, literature values (and the associated uncertainties) have to be applied. For this example, the values shown in Table 2 have been used.

In this example, a measured value for y_0 is available. In many cases though y_0 may not be known. For those situations y_0 can be estimated based on C_0 , as described by Eichler et al. (2018), Liang et al. (2018), and Addington et al. (2020). The particle deposition velocity given here is at the lower bound of the range of deposition velocities for coarse mode particles (Weschler and Nazaroff 2017), which is assumed to make up the largest fraction of particles present in the indoor environment (Shi and Zhao 2012). If a more detailed description of the particle size distribution is

Table 2 Literature values used for parameterization of the transport models, SEC = solid

Parameter	Symbol	Value	Reference
Fraction of organic matter associated with airborne particles	$f_{\text{om_part}}$	0.4	Weschler and Nazaroff (2010)
Density of the airborne particles	ρ_{part}	1 g cm ⁻³	Weschler and Nazaroff (2010)
Fraction of organic matter in settled dust	$f_{\text{om_dust}}$	0.2	Weschler and Nazaroff (2010)
Density of the settled dust	ρ_{dust}	2 g cm ⁻³	Weschler and Nazaroff (2010)
Size-dependent particle deposition velocity	ν_d	4.9 m h ⁻¹	Shi and Zhao (2012) <i>Note:</i> for particle size fraction 2.5–10 µm
Size-dependent particle resuspension rate	R_p	7.2×10^{-5} h ⁻¹	Thatcher and Layton (1995)
Gas-phase concentration of the SVOC in the layer immediately adjacent to the source	y_0	24.7 µg m ⁻³	Liang and Xu (2014b) <i>Note:</i> y_0 measured at 25 °C
Mass transfer coefficient	h_m and $h_{m,s}$	1.44 m h ⁻¹	Xu et al. (2012)

available, the deposition velocity should be adapted accordingly, e.g., by using the size fraction weighted average.

Calculation of concentrations in indoor compartments: Using Eqs. 10–13, K_s , K_p , K_{dust} , and M can be calculated. The results are shown in Table 3. The calculated K_s value is relatively small, indicating that DnBP does not partition strongly to these surfaces. This corresponds with DnBP's relatively high vapor pressure, but the estimate for K_s has to be considered as highly uncertain because it is based on multiple simplifications. Thus, the K_s value reported in Table 3 is likely a lower bound for the given scenario.

Based on all the information gathered so far, F , P_{dust} , $P_{\text{dust,s}}$, y , and C_s can be calculated, as summarized in Table 4.

Exposure calculations: Now that the concentrations in the environmental compartments have been calculated, we can estimate the resulting exposure via the four pathways including dermal uptake from the gas phase, dermal uptake from sink surfaces, inhalation of air (gas and particle phases), and ingestion of dust. Dermal uptake of DnBP from airborne particles or dust is not considered in this example, but one approach to estimate exposure via this pathway is given in Eichler et al. (2021). Here, the following equations will be used to estimate exposure:

$$Ex_{\text{gas_b}} = y \cdot k_{p_s} \cdot A_{\text{exp}} \quad (14)$$

$$Ex_{\text{surf_d}} = C_s \cdot CR_s \cdot f_A \cdot A_{\text{hand}} \quad (15)$$

Table 3 Calculated model parameters, SEC = solid

Parameter	Symbol	Value	Reference
Surface-gas partition coefficient	K_s	26 m	Eq. 10
Gas-particle partition coefficient	K_p	$2.7 \times 10^{-3} \text{ m}^3 \mu\text{g}^{-1}$	Eq. 11
Dust-gas partition coefficient	K_{dust}	$680 \text{ m}^3 \text{ g}^{-1}$	Eq. 12
Mass loading of settled dust on the source and sink surfaces	M and M_s	$1.6 \times 10^4 \mu\text{g m}^{-2}$	Eq. 13

Table 4 Resulting DnBP concentrations in the indoor environmental compartments, SEC = solid

Parameter	Symbol	Value	Reference

DnBP concentration in the dust settled on the source surface	P_{dust}	$16,700 \mu\text{g g}^{-1}$	Eq. 6
DnBP concentration in the dust settled on sink surfaces	$P_{\text{dust,s}}$	$130 \mu\text{g g}^{-1}$	Eq. 7
DnBP concentration in the bulk gas phase	y	$0.19 \mu\text{g m}^{-3}$	Eq. 8
DnBP concentration on sink surfaces	C_s	$5 \mu\text{g m}^{-2}$	Eq. 9

$$Ex_{inh} = (y + F) \cdot IR_{inh} \quad (16)$$

$$Ex_{dust_ing} = P_{dust} \cdot IR_{dust} \quad (17)$$

where Ex_{gas_b} is the transdermal exposure rate from the gas phase to the blood, $k_{p,g}$ is the transdermal permeability coefficient from the gas phase to the blood, A_{exp} is the exposed body surface area, Ex_{surf_d} is the dermal exposure rate for dermal contact with sink surfaces, CR_s is the rate of contact with sink surfaces, f_A is the fraction of chemical accessible for uptake or transfer efficiency, A_{hand} is the surface area of the hands in contact with the sink surface, Ex_{inh} is the inhalation exposure rate, IR_{inh} is the inhalation rate, Ex_{dust_ing} is the dust ingestion rate, and IR_{dust} is the dust intake rate.

The fraction of chemical accessible for uptake f_A , also described as transfer efficiency, has been studied using both chemicals (especially pesticides) and fluorescent tracers, as described in Chapter 7 of the EPA *Exposure Factors Handbook* (USEPA 2011). However, the *Handbook* does not provide explicit recommendations. Cohen Hubal et al. (2008) reported transfer efficiencies ranging from 0.8% to 45.5% for the first contact and 0.6–19.4% for the seventh contact, depending on skin condition (e.g., moist vs. dry skin) and surface loadings, among other factors. Based on the wide possible range, we select a transfer efficiency of 10%, acknowledging the high uncertain of this parameter.

It should be noted that, as given, the exposure rates Ex_{gas_b} and Ex_{surf_d} have different endpoints. Ex_{gas_b} is based on transfer from the gas phase through the skin to the blood stream (i.e., transdermal exposure), while Ex_{surf_d} describes the transfer of a chemical from a sink surface to the skin surface (i.e., dermal exposure). The reason for this inconsistency lies in the history of the equations and both have their relevance. Ex_{surf_d} is particularly relevant if mouthing of hands is considered as an additional exposure pathway, and it also provides an upper bound for the estimation of Ex_{surf_b} , the exposure rate from the skin-surface lipids into the blood stream, under steady state conditions. In this case, it is assumed that no other removal processes take place. In reality, skin permeability may be low and removal by evaporation or mechanical processes may occur, which decreases Ex_{surf_b} in comparison to Ex_{surf_d} . Ex_{surf_b} can be expressed as:

$$Ex_{surf_b} = C_{ssl} \cdot k_{p,ssl} \cdot A_{hand} \quad (18)$$

where C_{ssl} is the concentration of a chemical associated with skin-surface lipids, $k_{p,ssl}$ is the transdermal permeability coefficient from the skin-surface lipids to the blood, and δ_{ssl} is the thickness of the skin-surface lipid layer. C_{ssl} can be measured, e.g., with handwipes, or calculated by:

$$C_{ssl} = \frac{C_s \cdot f_A}{\delta_{ssl}} \quad (19)$$

Eq. 19 gives C_{ssl} after one contact with a sink surface.

Exposure rates can be converted to daily intake rates (DI , in $\mu\text{g kg}^{-1} \text{ day}^{-1}$) by using:

$$DI = Ex \cdot \frac{EF}{BW} \quad (20)$$

where Ex is the respective exposure rate or flux, EF is the exposure frequency in hours per day of a specific exposure route, and BW is the body weight of the exposed individual.

With the exception of $k_{p,g}$, $k_{p,ssl}$, and δ_{ssl} , all parameters needed for the exposure modeling equations can be found in or derived from information provided in the *Exposure Factors Handbook* by the US Environmental Protection Agency (EPA). $k_{p,g}$ is a combined permeability coefficient that describes SVOC transport from the bulk air through several layers of epidermis to the blood (Weschler and Nazaroff 2012). Similarly, $k_{p,ssl}$ describes SVOC transport from the skin lipid layer through the epidermis to the blood (Weschler and Nazaroff 2012). Weschler and Nazaroff (2012) provide an approach for calculating $k_{p,g}$ for different chemicals and give several examples, including for DnBP. $k_{p,g}$ and $k_{p,ssl}$ can vary by several orders of magnitude for different chemicals.

In this scenario, the exposed individual is a young child (2 to <3 years) living in the house. For exposure by dermal uptake from the gas phase, it is assumed that only the child's head, arms, and hands are exposed, while the rest of the body is covered by clean clothing. Here, the clothes that the child is wearing are considered a barrier that protects the clothed skin. As part of the scenario, we further assume that exposure only occurs during the time spent at home. All parameters used as model inputs are summarized in Table 5.

For the purpose of estimating exposure, an average dust concentration throughout the house can be calculated based on the fractions of source and sink floor surface area that is potentially available for a child to come in contact with dust. A child can potentially ingest dust from other locations than the floor, e.g., from a shelf, but it can be assumed that such horizontal surface areas correspond to the floor surface area on which a piece of furniture may be placed. The fractions f_{source} of source (floor) surface area and f_{sink} of sink (floor) surface area can be calculated as:

$$f_{\text{source}} = \frac{A_{\text{source}}}{A_{\text{total}}} \quad (21)$$

$$f_{\text{sink}} = \frac{(A_{\text{total}} - A_{\text{source}})}{A_{\text{total}}} \quad (22)$$

Then, the average DnBP concentration in the dust can be calculated as:

$$P_{\text{dust,avg}} = f_{\text{source}} \cdot P_{\text{dust}} + f_{\text{sink}} \cdot P_{\text{dust,s}} \quad (23)$$

For further calculation of exposure to DnBP by dust ingestion, P_{dust} in Eq. 17 is replaced by $P_{\text{dust,avg}}$. Table 6 summarizes the resulting exposure rates as well as the respective daily intake rates for the example scenario.

Table 6 shows that dermal uptake from sink surfaces and dust ingestion dominate exposure for this particular scenario, while transdermal uptake from the gas phase

Table 5 Parameters for exposure models from the literature

Parameter	Symbol	Value	Reference
Body weight (child, 2 to <3 years)	BW	13.8 kg	USEPA (2011)
Exposed skin surface area (child, 2 to <3 years; head, arms, and hands)	A_{exp}	0.167 m ²	USEPA (2011)
Hand surface area in contact with sink surfaces (child, 2 to <3 years, palms only)	A_{hand}	0.014 m ²	USEPA (2011)
Rate of contact with sink surfaces as indoor hand contact with objects/surfaces (child, 1–6 years)	CR_s	193 contacts h ⁻¹	USEPA (2011)
Fraction of chemical accessible for uptake from sink surfaces or transfer efficiency	f_A	0.1	estimated, see Cohen Hubal et al. (2008) and USEPA (2011)
Inhalation rate (child, 2 to <3 years)	IR_{inh}	8.9 m ³ d ⁻¹ = 0.37 m ³ h ⁻¹	USEPA (2011)
Dust ingestion rate (child, 2 to <6 years)	IR_{dust}	30 mg d ⁻¹ = 0.00125 g h ⁻¹	USEPA (2017)
Exposure frequency or time spent at residency/house (child, 2 to <6 years)	EF	979 min d ⁻¹ = 16.3 h d ⁻¹	USEPA (2011)
Transdermal permeability coefficient from the gas phase to the blood	k_{p_g}	4.8 m h ⁻¹	Weschler and Nazaroff (2012)
Transdermal permeability coefficient from the skin-surface lipids to the blood	k_{p_ssl}	0.095 × 10 ⁻⁶ m h ⁻¹	Weschler and Nazaroff (2012)
Thickness of the skin-surface lipid layer (children's hands)	δ_{ssl}	8.8 × 10 ⁻⁷ m ³ /m ²	Weschler and Nazaroff (2012)

and inhalation exposure are smaller contributors. Overall, the daily intake rate normalized by body weight for this child is 3.94 µg kg⁻¹ BW d⁻¹, excluding Ex_{surf_b} . This result could now be put in further context by comparison with the results for other products and/or chemicals, or by combining this exposure estimate with toxicity information. Another point of comparison is to estimate exposure for an adult under the same conditions, which yields a total daily intake rate of 1.29 µg kg⁻¹ BW d⁻¹, using the appropriate data from the EPA *Exposure Factors Handbook*. As discussed above, Ex_{surf_d} gives an upper bound for the amount of chemical potentially transported through the skin to the blood. Ex_{surf_b} provides a more conservative estimate. In addition, the uncertainty associated with (trans)dermal uptake of DnBP from sink surfaces is relatively high given that (1) K_s had to be estimated based on DnBP's vapor pressure and was averaged for the entire indoor sink surface area, (2) the transfer efficiency from the sink surfaces to the skin was assumed based on a very wide range of reported values, and (3) many other factors affect transdermal uptake that have not been included here. Several chapters of this handbook as well as Licina et al. (2019) provide a detailed discussion of this topic.

Table 6 Calculated exposure and daily intake rates for DnBP for a young child (2 to <3 years), SEC = solid

Parameter	Symbol	Value	Reference
Exposure by transdermal uptake from the gas phase	Ex_{gas_b}	0.15 $\mu\text{g h}^{-1}$	Eq. 14
Exposure by dermal uptake from sink surfaces	Ex_{surf_d}	1.37 $\mu\text{g h}^{-1}$	Eq. 15
Exposure by inhalation of air	Ex_{inh}	0.076 $\mu\text{g h}^{-1}$	Eq. 16
Exposure by ingestion of dust	Ex_{dust_ing}	1.74 $\mu\text{g h}^{-1}$	Eq. 17
Exposure by transdermal uptake from sink surfaces	Ex_{surf_b}	0.15 $\mu\text{g h}^{-1}$	Eq. 18
Daily intake rate via transdermal uptake from the gas phase	DI_{gas_b}	0.18 $\mu\text{g kg}^{-1} \text{BW d}^{-1}$	Eq. 20
Daily intake rate via dermal uptake from sink surfaces	DI_{surf_d}	1.62 $\mu\text{g kg}^{-1} \text{BW d}^{-1}$	Eq. 20
Daily intake rate via inhalation of air	DI_{inh}	0.089 $\mu\text{g kg}^{-1} \text{BW d}^{-1}$	Eq. 20
Daily intake rate via ingestion of dust	DI_{dust_ing}	2.05 $\mu\text{g kg}^{-1} \text{BW d}^{-1}$	Eq. 20
Daily intake rate via transdermal uptake from sink surfaces	DI_{surf_b}	0.17 $\mu\text{g kg}^{-1} \text{BW d}^{-1}$	Eq. 20

Uncertainty: Large uncertainties may have been introduced into the above calculations with the choice of data for the vapor pressure and the octanol-air partition coefficient. Both are important for estimating other parameters, such as the gas-particle partition coefficient. One way to address this problem is to include ranges and distributions into the model, using Monte-Carlo-based approaches. For example, a range of $p_s \pm 0.95 \cdot p_s$ following a normal distribution has been proposed for the vapor pressure (Salthammer and Schripp 2015). The choice of tools to predict chemical properties (e.g., SPARC, EpiSuite, COSMOTHERM, and others) can also influence the outcome of the calculation, and it is recommended to compare predictions and literature values to get a sense for the reliability of the chosen value. It further matters which predictive relationship is used to get certain model parameters, especially for partition coefficients. As discussed in Schossler et al. (2011), it makes a substantial difference if K_p is calculated based on K_{oa} or based on p_s . Furthermore, for compounds of intermediate volatility ($10^{-6} \text{ Pa} < p_s < 10^{-2} \text{ Pa}$) it is very difficult to predict the fraction of the compound present in the particle phase, because small variations in p_s or K_{oa} and in the particle-phase concentration yield substantial variations in the concentration ratio between gas and particle phases (Eichler et al. 2021). Variations of temperature and relative humidity on the parameters are not included in these models, but are expected to have an influence. For higher tier exposure assessments, more information should be included to address these factors, although our ability to include them remains limited. As will become more evident in the next example, gaps in the availability of exposure factors are an additional issue that introduces uncertainty in the exposure estimates.

Extension of Example 1: Considering the Impact of Clothing

The third assumption of the example described above stated that the impact of clothing (as environmental compartment and as mediator of exposure) was not considered. However, it is possible to include clothing based on the previous results. First, we can calculate the concentration of DnBP in the clothing material C_{cloth} that has equilibrated with the gas phase. The following equation can be applied if steady state has been reached:

$$K_{ca} = \frac{C_{\text{cloth}}}{y} \quad (24)$$

where K_{ca} is the clothing-air partition coefficient (either unitless or normalized by clothing mass or volume) and C_{cloth} is the concentration of a chemical in the cloth. For DnBP, K_{ca} has been determined experimentally by Morrison et al. (2015) for different types of cotton clothing. Here, we use the average values for K_{ca} and for the cloth density δ_{cloth} determined from those measurements (see Table 7). If K_{ca} is not known, $\log(K_{ca})$ can be roughly estimated based on $\log(K_{oa})$ (Morrison et al. 2018). For the calculation of the exposure estimate, both $C_{\text{cloth,vol}}$ and $C_{\text{cloth,area}}$ can be used, as discussed below.

Based on the cloth density, the mass fraction of the chemical in the clothing w_{cloth} can be determined:

$$w_{\text{cloth}} = \frac{C_{\text{cloth,vol}}}{\rho_{\text{cloth}}} \quad (25)$$

w_{cloth} is necessary to estimate exposure by mouthing, while in this example a simplified model based on the gas-phase concentration y is used to estimate exposure by transdermal uptake from the clothing material (Eq. 26).

The exposure calculations can now be expanded by considering transdermal uptake of DnBP from clothing worn by the child and mouthing of clothing that has accumulated DnBP. A simplified mechanistic model to estimate transdermal uptake of SVOCs from clothing has been proposed by Morrison (2020):

Table 7 Parameters for modeling clothing-air partitioning and model results, SEC = solid

Parameter	Symbol	Value	Reference
Clothing-air partition coefficient, normalized by volume	$K_{ca,\text{vol}}$	3,900,000	Morrison et al. (2015), average
Clothing-air partition coefficient, normalized by area	$K_{ca,\text{area}}$	4360 m	Morrison et al. (2015), average
Cloth density	ρ_{cloth}	$5.43 \times 10^{11} \mu\text{g m}^{-3}$	Morrison et al. (2015), average
Concentration of DnBP in the clothing, per clothing volume	$C_{\text{cloth,vol}}$	$754,000 \mu\text{g m}^{-3}$	Eq. 24
Concentration of DnBP in the clothing, per clothing surface area	$C_{\text{cloth,area}}$	$840 \mu\text{g m}^{-2}$	Eq. 24
Mass fraction of DnBP in the clothing	w_{cloth}	1.8×10^{-6}	Eq. 25

$$Ex_{cloth_b} = y \cdot \left(\frac{8.3 \cdot k_{p_b}}{8.3 + k_{p_b}} \right) \cdot A_{clothed} \quad (26)$$

where Ex_{cloth_b} is the exposure rate by transdermal uptake from clothing, k_{p_b} is the transdermal permeability coefficient for transport from the skin-surface boundary layer to the blood stream, and $A_{clothed}$ is the clothed body surface area. The factor 8.3 in m h^{-1} equals a normalized daily transdermal uptake of $0.2 \text{ mg m}^{-2} (\mu\text{g m}^{-3})^{-1} \text{ day}^{-1}$ and includes the assumption of a gap between skin and clothing of 2 mm. The factor further reflects clothing that is washed weekly, but removal of SVOCs is incomplete, and that had time to equilibrate with the indoor environment.

Exposure by mouthing of cloth can be estimated using:

$$Ex_{mouth} = w_{cloth} \cdot A_{moutherd} \cdot MR \cdot MF \quad (27)$$

where Ex_{mouth} is the exposure rate by mouthing, $A_{moutherd}$ is the mouthed area (here, of the cloth), MR is the migration rate of the chemical from the object or cloth, and MF is the mouthing frequency. The migration rate depends on the water solubility of the chemical, but also depends on the mass fraction of chemical in the mouthed object. For DnBP in PVC, Wormuth et al. (2006) reported a migration rate for a mass fraction of 11%, much higher than the mass fraction of DnBP in clothing considered here. In their 2014 report on phthalates and phthalate alternatives, the Chronic Hazard Advisory Panel (CHAP) was not able to identify other migration rates for DnBP, and more recent studies could also not be identified. Because of this limitation in the data availability, the following simplified equation is used to estimate exposure by mouthing:

$$Ex_{mouth} = C_{cloth,area} \cdot A_{moutherd} \cdot MF \cdot f_{soluble} \quad (28)$$

where $f_{soluble}$ is the fraction of chemical leached from the cloth during mouthing.

DnBP is not very water soluble ($K_H = 0.183 \text{ Pa m}^3 \text{ mol}^{-1}$ (USEPA 2021)), therefore the migration rates used for this example will be based on the assumption of leaching of 1% and of 100% of DnBP accumulated in the cloth. One percent may be considered the more likely value, while assuming 100% gives an upper bound.

Table 8 shows the parameters used for exposure estimation. To convert Ex_{cloth_b} to DI_{cloth_b} , it is assumed that the child is wearing clothes for 23 h per day. For the conversion of $Ex_{mouthing}$, 14 h per day of mouthing activity are assumed. This exposure frequencies differ from those for the other conversions, which were based on the time spent indoors. Table 9 summarizes the resulting exposure and daily intake rates.

The results show that exposure via mouthing can be an important contributor to the total daily intake rate, if a large fraction of the chemical is leaching from the cloth material. Furthermore, transdermal uptake from clothing can be a source of exposure that should not be neglected in the assessment, especially not for chemicals that have a relatively high skin permeability, such as DnBP.

Table 8 Parameters for modeling exposure mediated by clothing, SEC = solid

Parameter	Symbol	Value	Reference
Transdermal permeability coefficient for transport from the skin-surface boundary layer to the blood stream	k_{p_b}	23 m h ⁻¹	Weschler and Nazaroff (2012)
Body surface area covered by clothing, calculated as the difference between total body surface area (child, 2 to <3 years) and A_{exp}	$A_{clothed}$	0.443 m ²	USEPA (2011)
Mouthing cloth surface area	$A_{mouthed}$	0.001 m ²	CSPC (2014)
Mouthing frequency, mean value for cloth/towel	MF_{cloth}	5.4 contacts h ⁻¹	USEPA (2011)
Fraction of chemical leached during mouthing	$f_{soluble,1}$ $f_{soluble,2}$	0.01 1.0	Estimated
Exposure frequency to clothing	EF_{cloth}	23 h d ⁻¹	Estimated
Exposure frequency mouthing	$EF_{mouthing}$	14 h d ⁻¹	Estimated

Table 9 Estimated exposure and daily intake rates for DnBP for a young child (2 to <3 years), clothing mediated, SEC = solid

Parameter	Symbol	Value	Reference
Exposure by transdermal uptake from clothing	Ex_{cloth_b}	0.52 µg h ⁻¹	Eq. 26
Exposure by mouthing of cloth, based on 1% and 100% leaching of chemical	$Ex_{mouth,1}$ $Ex_{mouth,2}$	4.6 × 10 ⁻² µg h ⁻¹ 4.6 µg h ⁻¹	Eq. 28
Daily intake rate via transdermal uptake from clothing	DI_{cloth_b}	0.87 µg kg ⁻¹ BW d ⁻¹	Eq. 20
Daily intake rate via mouthing of cloth, based on 1% and 100% leaching of chemical	$DI_{mouth,1}$ $DI_{mouth,2}$	4.6 × 10 ⁻² µg kg ⁻¹ BW d ⁻¹ 4.6 µg kg ⁻¹ BW d ⁻¹	Eq. 20

As discussed above, substantial uncertainty is introduced into these calculations because of missing information to fully and robustly parameterize the exposure models. In addition, assuming that clothing does not contribute to overall exposure may lead to significant underestimation of total daily exposure. Further measurements are needed to provide more information on clothing-air partitioning and on the role of clothing in reducing or enhancing exposure.

Example 2: Tris(2-Chloroethyl) Phosphate (TCEP) in Smartphone Casing

Source: For this example, we assume a cell phone containing 5 wt% of tris (2-chloroethyl) phosphate (TCEP) in its casing. As in the first example, the initial step is to determine the applicable SEC. Here, the object has a small emitting surface area but is handled frequently, thus it can be considered a frequent contact source.

For frequent contact sources, the following contact exposure pathways may be of importance: (1) dermal uptake by direct contact with the source, (2) ingestion of the source, and (3) mouthing of the source. Here, the first and third pathway are likely to occur.

To further describe the source, information about the vapor pressure, K_{oa} , and the molecular weight of TCEP is needed. TCEP is an organophosphorus flame retardant (OPFR) and plasticizer that has been measured in a range of products and in indoor environments (see, for example, Liu et al. (2016), Liagkouridis et al. (2017), Vykoukalová et al. (2017)), and is considered an SVOC. Yang et al. (2019) determined concentrations of TCEP and other OPFRs in surface wipes of different products, including cell phones. This information is very useful, and the following calculations of exposure estimates could be based on these data (Table 10). Here, another approach is described to illustrate how the concentration of TCEP on the surface of the phone can be determined in a mechanistically sound way.

The relationship between C_0 and y_0 for SVOCs is based on a compound's vapor pressure and an activity coefficient (Eichler et al. 2018). Liang et al. (2018) investigated emission parameters of OPFRs and determined a relationship between C_0 and y_0 based on their findings and literature values for OPFRs and phthalates, where w_0 is the mass fraction based on C_0 :

$$\frac{y_0}{p_s} = 3.40 \cdot w_0 \quad (29)$$

Note that for use with Eq. 29, p_s has to be converted to $\mu\text{g m}^{-3}$, using the ideal gas law. Here, a temperature of 25 °C (298 K) was used for the conversion. Eq. 29 allows to calculate y_0 based on C_0 , if p_s is known. As shown in Table 10, the vapor pressure of TCEP has a relatively high uncertainty, because the values available in the literature span several orders of magnitude. Because Eq. 29 is based on the work by Liang et al. (2018), we are also using 0.00114 Pa in our calculations. However, as additional, more reliable measurements of p_s become available, Eq. 29 may have to be revised.

Scenario and model selection: Smartphones are often touched and likely to have developed a thin organic film on their surface. Here, we assume that the TCEP emitted from the phone casing is present in this film, and that the film has equilibrated with y_0 , i.e., the gas-phase concentration of TCEP immediately adjacent to the source material surface. To describe partitioning between y_0 and the concentration of TCEP in the film $C_{s,film}$, we assume that the surface film consists of predominantly organic material, and that K_{oa} can be used as partition coefficient (Weschler and Nazaroff 2017). Based on these considerations, Eq. 30 can be used to determine the TCEP concentration in the surface film on the phone:

$$C_{s,film} = y_0 \cdot K_{oa} \cdot \delta_{film} \quad (30)$$

where δ_{film} is the thickness of the organic surface film.

Table 10 Parameters used for estimating exposure to TCEP. If multiple values for a parameter were found, those printed in bold were selected for calculations. SEC = frequent contact

Parameter	Symbol	Value	Reference
Molecular weight of TCEP	MW_{TCEP}	285.48 g mol ⁻¹	USEPA (2021)
Vapor pressure of TCEP @ 25 °C	$p_{s,TCEP}$	0.00114 Pa 0.056 Pa 8.15 Pa	ECHA (2008), used in Liang et al. (2018) Okeme et al. (2020) USEPA (2021), experimental average
Octanol-air partition coefficient of TCEP @ 25 °C	$\log(K_{oa,TCEP})$	7.6 7.85 8.41	Yang et al. (2019) Okeme et al. (2020) USEPA (2021), predicted average
TCEP surface wipe concentration, cell phones (n = 31), geometric mean	$C_{s,wipe}$	10.2 µg m ⁻²	Yang et al. (2019)
Mass fraction of TCEP in smartphone casing	$w_{0,TCEP}$	0.05	Assumed for scenario
Thickness of organic film on smartphone	δ_{film}	1·10 ⁻⁹ m	Estimated, based on Weschler and Nazaroff (2017)
Gas-phase concentration of TCEP immediately adjacent to the source material surface	y_0	22.32 µg m ⁻³	Eq. 29
Concentration of TCEP in the organic surface film	$C_{s,film}$	15.80 µg m ⁻²	Eq. 30
Rate of contact with object	CR_{obj}	5 contacts h ⁻¹	Estimated, based on ca. 100 contacts with the phone per day
Transdermal permeability coefficient from the skin-surface lipids to the blood	$k_{p,ssl}$	9.0 × 10 ⁻⁸ m h ⁻¹	Calculated, based on Weschler and Nazaroff (2012) and data from SPARC online calculator
Mouthed object surface area	$A_{mouthed}$	0.001 m ²	CSPC (2014)
Mouthing frequency, mean value for object	MF_{obj}	4 contacts h ⁻¹	Estimated, based on USEPA (2011)
Exposure frequency mouthing and handling object	EF_{phone}	14 h d ⁻¹	Estimated

Exposure calculations: For frequent contact sources, no concentrations in indoor environmental compartments have to be calculated. Instead, for exposure by (trans) dermal uptake from the source and by mouthing, Eqs. 15, 18, and 27 or 28, respectively, can be used. Migration rates from a source to saliva could not be found for TCEP, therefore Eq. 28 will be used to estimate mouthing exposure in a similar way as for DnBP in the first example. Table 10 summarizes all parameters needed to estimate exposure to TCEP by touching and mouthing a frequent contact source. The exposed individual is again a young child (2 to <3 years) and the parameters used in Example 1 apply, unless stated otherwise.

The modeled concentration in the surface film $C_{s,\text{film}}$ is close to the concentration $C_{s,\text{wipe}}$ reported by Yang et al. (2019), giving overall confidence in the assumptions made in the model. However, as can be seen in Table 10, most values needed for the calculation of the exposure estimates had to be estimated because directly applicable information could not be found. As discussed above, p_s is a highly uncertain parameter in this example, and so is the film thickness δ_{film} , but because $C_{s,\text{film}}$ is supported by direct measurements, at least the order of magnitude of the result can be confirmed. Contact and mouthing frequencies as well as the exposure frequency have been estimated based on review of the EPA *Exposure Factors Handbook*, but may be under- or overestimating, and more observational data would be necessary to reduce uncertainty. The transfer efficiency f_A was assumed to be the same for DnBP and TCEP, which may not be the case, aside from the dependence of this parameter on many other factors. As migration rates of TCEP from an object into saliva were not available, the simplified version of the mouthing exposure model (Eq. 28) has to be used. TCEP is more water soluble than DnBP, but to explore this exposure, a range based on 1% and 100% leached chemical is applied again. These considerations should be kept in mind when evaluating the results (Table 11).

Based on $DI_{\text{surf_d}}$ in combination with $DI_{\text{mouth},1}$ and $DI_{\text{mouth},2}$, the daily intake rate based on contact exposure to this frequent contact source ranges from $0.11 \mu\text{g kg}^{-1} \text{BW d}^{-1}$ to $0.18 \mu\text{g kg}^{-1} \text{BW d}^{-1}$. $DI_{\text{surf_b}} = 0.011 \mu\text{g kg}^{-1} \text{BW d}^{-1}$ provides an additional lower bound. Contact rate (CR), transfer efficiency (f_A), and mouthing frequency (MF) are the most uncertain parameters of the exposure estimate, and variations can lead to a difference of about one order of magnitude. Further evaluation of these important exposure factors is necessary to allow more robust estimates. In addition, more information on migration rates (MR) is urgently needed to assess mouthing exposure more accurately.

Table 11 Estimated exposure and daily intake rates for TCEP for a young child (2 to <3 years), SEC = frequent contact

Parameter	Symbol	Value	Reference
Exposure by dermal contact with source surface	$Ex_{\text{surf_d}}$	$0.11 \mu\text{g h}^{-1}$	Eq. 15
Exposure by transdermal uptake from source surface	$Ex_{\text{surf_b}}$	$0.011 \mu\text{g h}^{-1}$	Eq. 18
Exposure by mouthing of source, based on 1% and 100% leaching of chemical	$Ex_{\text{mouth},1}$ $Ex_{\text{mouth},2}$	$6.3 \times 10^{-4} \mu\text{g h}^{-1}$ $0.063 \mu\text{g h}^{-1}$	Eq. 28
Daily intake rate via dermal contact with source surface	$DI_{\text{surf_d}}$	$0.11 \mu\text{g kg}^{-1} \text{BW d}^{-1}$	Eq. 20
Daily intake rate via transdermal uptake from source surface	$DI_{\text{surf_b}}$	$0.011 \mu\text{g kg}^{-1} \text{BW d}^{-1}$	Eq. 20
Daily intake rate via mouthing of source, based on 1% and 100% leaching of chemical	$DI_{\text{mouth},1}$ $DI_{\text{mouth},2}$	$6.4 \times 10^{-4} \mu\text{g kg}^{-1} \text{BW d}^{-1}$ $0.064 \mu\text{g kg}^{-1} \text{BW d}^{-1}$	Eq. 20

Conclusions

The previous examples were chosen to illustrate the application of the mechanistic framework to rapidly estimate exposure, but also to highlight some of the important considerations and existing gaps that need to be addressed. In addition to the knowledge gaps and sources of uncertainty, it is emphasized that many elements of the current version of the framework do not exist. In particular, the SECs “liquid applied,” “liquid sprayed,” and “high temperature” are missing mechanistically consistent models.

Some other important aspects are not yet included quantitatively in the framework, but should be considered as influencing factors and discussed qualitatively. In particular, these aspects include the influence of indoor chemistry and of occupancy and occupant characteristics on indoor environments and also on the exposure estimates derived using the framework. In general, additional research is necessary to not only improve our understanding of indoor chemistry, but also to include this understanding in the framework in a coherent way. Although these aspects still need to be addressed, the modular structure of the framework should facilitate the inclusion of new and improved knowledge as suitable models become available.

Currently identified compartments include the gas phase, airborne particles, dust, clothing, and surfaces. These compartments are all dynamic over quite different time scales, and this dynamic nature needs to be more completely represented in the framework. We also need to consider other potential SECs, other chemicals, other compartments and other exposure pathways, and whether or not these can all be coherently integrated within the current framework, both mechanistically and computationally. Indoor chemistry has already been mentioned, but we also need to include the effect of occupancy and occupant characteristics, as well as the way in which occupants interact with the various materials, products, and articles over their respective lifetimes in the indoor environment. Finally, in evaluating the generality of the proposed framework, we need to include potential variation of human exposure by location, demographics, and consumer practices.

The current version of the framework has been developed as part of a community, and we anticipate that the development can continue in the form of a community model, an approach which is increasingly being used in a range of knowledge domains (Barker et al. 2012; Byun and Schere 2006; Harri et al. 2009; Hipsey et al. 2019). Also, models organized according to scientific workflows (Jain et al. 2015; Talia 2013) are becoming increasingly popular. For specific decision contexts, including problem-driven and regulatory circumstances, opportunities to leverage extant data, algorithms, and models to analyze and visualize exposures need to be identified. Once the execution order of problem-solving steps to complete exposure analysis is identified, code can be developed as a processing workflow that can link data and computational algorithms published by different organizations. Overall, this would enable us to synthesize curated information and modeling methods to characterize human exposure, potentially fusing mechanistic and data-driven approaches in these scientific workflows. These flexible workflows could be used to analyze information, guide research, and inform decision-makers. Finally, it may be possible

to develop the computational framework as an open-source software platform, but this is not a simple task (see recent article in *Nature*, Nowogrodzki (2019)) and will probably require some form of long-term institutional support.

Abstract

This chapter brings a global clinical perspective to the health consequences of indoor air pollution. Its sections are provided in an order that is defined by exposures and by specific clinical entities. Indoor air pollution exposures discussed in this chapter include secondhand smoke, carbon monoxide, household air pollution, radon, volatile and semi-volatile compounds, bioaerosols, and respiratory infections. Background information is provided for each along with sources and exposures, risks, and mitigation/management. Specific clinical entities related to these exposures are also presented.

Introduction

The health effects of indoor air pollution reflect a broad array of exposures and circumstances that vary by place and that have changed over time, indeed across mankind's history. In higher-income countries, health concerns have varied as housing has changed and building design and maintenance have evolved, and some problems have been recognized and mitigated. In low- and some middle-income countries, indoor combustion of biomass fuels remains a potent source of indoor air pollution. The full health burden caused by indoor air pollution has not been addressed, but estimates from the Global Burden of Disease and the World Health Organization indicate a substantial contribution to morbidity and premature mortality (Table 1). The largest contribution to disease burden from indoor air pollution comes from household air pollution from biomass fuel combustion, reflecting the global and widespread persistence of this source and its potency in causing disease (World Health Organization 2018b).

In addressing the topic of this chapter – the health effects of indoor air pollution – a distinction needs to be made between those diseases that are linked to specific exposures, e.g., hypersensitivity pneumonitis; those multifactorial diseases that reflect the consequences of indoor air pollutants and other exposures; and those syndromic conditions, like multiple chemical sensitivity, that appear to result from a mix of specific and more general exposures. As addressed elsewhere in this volume, researchers using biomarkers have linked various injury processes, including inflammation and carcinogenesis, to indoor air pollution exposure. Plausibility considerations suggest that indoor air pollution could contribute to the causation and exacerbation of multiple acute and chronic diseases.

We spend much of our time indoors and consequently our perception of the quality of the indoor environment is a key contributor to general well-being. Construing health broadly as in the 1948 definition from the World Health

Organization – “Health is a state of complete physical, mental and social well-being and not merely the absence of disease” (World Health Organization 1948) – adverse effects on comfort and well-being from indoor air pollution are also relevant to this chapter. For example, the previous widespread contamination of indoor domestic, transportation, and work environments by tobacco smoke was a source of irritation and annoyance for nonsmokers.

This chapter brings a clinical perspective to the health consequences of indoor air pollution. Its sections are provided in an order that is defined by exposures and by specific clinical entities. Clinicians and other practitioners are not only likely to provide care for patients with specific clinical problems, e.g., multiple chemical sensitivity, but also to address questions related to particular exposures, e.g., secondhand smoke (SHS) or formaldehyde. The specific entities and the exposures, along with their interrelationships, are outlined in Table 2, which provides a matrix linking key clinical outcomes with causal exposures.

While there is a wide range of exposures from indoor air pollution, there are several common underlying mechanisms that lead to symptoms, organ damage, and disease. These include inflammation and irritation, allergic sensitization, chemical sensitization, asphyxiation, and carcinogenesis. As a result, the array of adverse health effects is broad. At the milder end, there may be eye and airway irritation, as with involuntary exposure to secondhand smoke (SHS), while at the more severe end, there may be increased risk for lung cancer, as with indoor radon exposure, and for death, as with acute carbon monoxide poisoning.

Given the length of time spent indoors, the burden of disease from indoor air pollution is substantial. Household air pollution from biomass fuel combustion is prevalent in low- and middle-income countries, leading to an estimated four million premature deaths annually (World Health Organization 2018). Secondhand smoke exposure’s burden of premature deaths is 1.2 million while radon is estimated to cause 84,000 deaths annually from lung cancer worldwide (World Health Organization 2021c). These figures emphasize the significance of indoor air pollution as a public health problem, while indoor air pollution also leads to health conditions and diseases needing attention by the health-care system.

This chapter provides broad, but necessarily incomplete, coverage of the health effects of indoor air pollution. Viewed against the status of the evidence at the time of the first edition of *Indoor Air Pollution: A Health Perspective* (Samet and Spengler 1991), there have been advances, but the fundamental health concerns remain. One exposure, secondhand smoke or SHS, persists, but exposures have been greatly diminished through regulation and a major shift in social norms in much of the world (World Health Organization 2021). For radon exposure and lung cancer, the characterization of risk has become more certain and proven approaches for mitigation of indoor radon are available. For biopathogens, such as molds, scientific methods have advanced providing new tools for research and best practices for their control have been strengthened, but the clinical picture is unchanged. Two multisystem syndromes – sick building

Table 2 Matrix of specific clinical entities and exposures related to indoor air pollution

Hypersensitivity pneumonitis						X
Asthma	X		X		X	
Lung cancer	X		X	X		

syndrome and multiple chemical sensitivity or MCS – emerged across the latter decades of the twentieth century as particularly challenging problems. Sick building syndrome has waned, perhaps reflecting greater attention to building management, while MCS persists and is a focus of ongoing research. Indoor asbestos exposure coming from building materials was of high concern during the last decades of the twentieth century, as asbestos fibers were detected in indoor air from inadequately maintained building materials (Health Effects Institute, Asbestos Research Committee et al. 1991). That concern has largely dropped away as asbestos is no longer used in building construction in the USA and other high-income countries, and in-place materials are maintained or removed under regulation-required protocols (US EPA 2020a). Asbestos-containing cement is still used worldwide, but with declining frequency. Consequently, this chapter does not cover indoor asbestos, a material linked to several cancers and the nonmalignant respiratory disease asbestosis.

As this chapter is written, the pandemic of SARS-CoV-2 and the disease COVID-19 is in its second year, bringing urgent attention to indoor environments as a locus of transmission of viruses and other causes of respiratory infection. Finally, this chapter addresses the global problem of biomass fuel combustion, not included in the first edition.

Indoor Exposures

Secondhand Smoke Exposure

Introduction

Secondhand smoke (SHS), also referred to as environmental tobacco smoke (ETS), is the combination of sidestream smoke produced by a burning cigarette or other combustible tobacco product and the smoke components exhaled by a smoker (US DHHS 1986). Inhalation of SHS is generally termed passive or involuntary smoking. Being derived from the smoke generated by the burning cigarette, SHS contains numerous chemicals, many toxic and cancer-causing. Exposure to SHS is linked to multiple health problems in both children and adults with evidence showing that no level of exposure to SHS can be considered risk free (Centers for Disease Control and Prevention 2021).

Although active cigarette smoking had been established as a major preventable cause of morbidity and mortality in the USA with the publication of the 1964 Surgeon General Report on Smoking and Health (US Department of Health Education and Welfare 1964), SHS exposure was not extensively investigated until the 1970s. By the mid-1980s, the evidence was sufficient to causally associate SHS exposure with lung cancer in never smokers and with adverse effects on children, particularly related to smoking by parents. Since then, the evidence has continued to mount on the adverse effects caused by SHS exposure (Table 3).

Table 3 Increased disease and death associated with secondhand smoke exposure (source)

Disease	Increased risk of disease from SHS exposure	Deaths among nonsmokers per year from disease due to SHS exposure
Heart disease	25–30%	34,000
Stroke	20–30%	8,000
Lung cancer	20–30%	7,300

Sources and Exposure

Tobacco smoke is a complex mixture of gases and particulate matter that contains a myriad of chemicals, perhaps 7,000 or more per the US Centers for Disease Control and Prevention (CDC). Tobacco combustion is a source of many volatile organic compounds (VOCs) and other toxins, including carbon monoxide, benzene, formaldehyde, and hydrogen cyanide, among many others (US Food and Drug Administration 2019). Secondhand smoke exposure occurs when a nonsmoker inhales the combination of both smoke from a burning cigarette (sidestream smoke) and the exhaled smoke from an active smoker. Smoke from other tobacco products and devices, including cigars, pipes, and water pipes, also leads to exposure to tobacco smoke. The scope of sources of exposure has been expanded as nonsmokers may also be exposed to the aerosols generated by the new vaping products, also referred to as electronic cigarettes and electronic nicotine delivery systems or ENDS

(US DHHS 2016). The exposure concentrations vary with the number of people smoking, and the characteristics of the indoor environment, including size and ventilation. Historically, when smoking was allowed without restriction, remarkably high concentrations of particles were measured in indoor environments with heavy smoking in progress (US DHHS 1986).

More recently, the concept of “thirdhand smoke” has been added to that of SHS (Jacob 3rd et al. 2017). Thirdhand smoke or THS refers to the SHS components that are deposited and adsorbed onto surfaces, some components revolatilizing and undergoing further transformations, e.g., through interactions with ozone. Non-smokers can be exposed to THS by contact with contaminated surfaces or inhaling components that have returned to the air. For some volatile components and nicotine specifically, exposure to THS may be a critical pathway. For example, nicotine exposures of infants and toddlers may be driven by contact with nicotine-contaminated surfaces, e.g., rugs and other furnishings, and the clothing of smoking parents.

Exposure to SHS can be assessed by measuring airborne nicotine concentration and also the concentration of smaller particles, particularly PM_{2.5} (particulate matter less than 2.5 microns in aerodynamic diameter), in indoor environments without other prominent sources of small particles (US DHHS 2006). Nicotine concentration has the advantage of being specific to tobacco smoke and it can be measured using passive or active sampling methods. Nicotine and its major metabolite, cotinine, are useful biomarkers for the same reason – specificity. Secondhand smoke exposure can be measured for nonsmokers in a variety of ways. While nicotine has a relatively brief half-life of several hours, cotinine has a half-life of 10–20 h in nonsmokers. Cotinine is used as a biomarker for exposure to tobacco smoke, whether from active or passive smoking, as it is only produced when nicotine is metabolized by the body and it stays in the body longer than nicotine (Baselt 2014). Cotinine concentration can be measured in blood serum, saliva, or urine; the concentration gives a useful internal dose estimate.

Environmental monitoring of SHS, characterized by taking air samples in indoor spaces, like bars or concert venues, is another method for exposure assessment. The approach is useful for documenting the presence of SHS and for providing a quantitative indication of the magnitude of exposure. It is also informative as to the impact of policy measures intended to reduce or eliminate SHS exposure. Finally, SHS exposure can be assessed via self-report on surveys. This method is readily used, although there is the potential for inaccuracy to arise. Nonetheless, self-report has been widely used in epidemiological research and studies using self-report have been critical in establishing the harms of SHS.

As assessed with the biomarker cotinine, SHS exposure has decreased in the USA from a high of 87.9% of nonsmokers having measurable levels of cotinine during 1988–1991 to only 25.2% during 2011–2014 (Tsai et al. 2018). This decline can be attributed to a combination of changing norms and policies, e.g., comprehensive smoke-free laws in public housing, affecting most public spaces, all airplanes, and most workplaces. National and local public health campaigns, e.g., CDC’s Tips from Former Smokers and the Truth Initiative, have contributed and smoking rates have

declined in the general population of the USA and other countries, making the source less widespread. However, globally, an estimated one-fifth of men and one-third of women are still regularly exposed to SHS (Drope et al. 2018), while almost half of the world's children are so exposed (World Health Organization 2021). Exposure to SHS is covered in the Framework Convention on Tobacco Control (FCTC), the World Health Organization's (WHO) treaty addressing tobacco.

While SHS exposure has decreased considerably over the last few decades, disparities in exposure remain in the USA and elsewhere. In the USA, groups with disparate, higher exposure to SHS include non-Hispanic Black Americans, children, people living below the poverty line, people who live in multiunit or public housing, and people who work in blue collar, service, or construction industries (Tsai et al. 2018). During 2011–2014, 50% of non-Hispanic Black Americans were exposed to SHS compared to 25.2% of the general population. Non-Hispanic Black children were also exposed at higher levels than their Hispanic and non-Hispanic counterparts (Walton et al. 2020). Overall, children aged 3–11 are disproportionately exposed to SHS in their homes and in vehicles, and those who live with a smoker or in multiunit housing are significantly more likely to be exposed to SHS (Tsai et al. 2018). Globally, the vast majority of tobacco smokers reside in low- and middle-income countries, placing an undue burden of SHS exposure on these countries' citizens (World Health Organization 2021).

Risk

The disease burden from SHS exposure is substantial in the USA and globally. According to the CDC, 2.5 million adult nonsmokers died from diseases caused by SHS exposure in the USA from the time of the 1964 Surgeon General Report until the 50th anniversary report (U.S. DHHS 2014). Globally, SHS exposure contributes to the deaths of 1.2 million nonsmokers per year (World Health Organization 2021). The burden of tobacco-related disease and mortality is highest in middle- and low-income countries where 80% of the world's smokers reside (World Health Organization 2021).

Exposure to SHS is causally associated with numerous adverse health effects in both children and adults. Infants exposed to secondhand smoke have an increased risk of death from sudden infant death syndrome (SIDS) (US DHHS 2006, 2014). Children have increased risk of asthma and asthma exacerbation, middle ear disease, upper respiratory illnesses, and possibly certain cancers (US DHHS 2006, 2014). Adults exposed to SHS have increased risk of heart attack, stroke, cardiovascular disease, COPD, lung cancer, and asthma as well as increased risk of death from these diseases (US DHHS 2006, 2014). Pregnant women also have an increased risk of fetal loss and having babies with fetal growth defects, and congenital malformations, particularly clefts (US DHHS 2006, 2014).

Infant and Childhood Adverse Health Effects Causally Linked to SHS Exposure

Smoking is estimated to be associated with 1,000 infant deaths per year in the USA as newborns exposed to tobacco in utero via maternal smoking are more likely to have a low birth weight, which increases the risk of health complications (US DHHS 2014). In infancy, those exposed to SHS have a significantly higher risk of sudden infant death syndrome (SIDS) (US DHHS 2006, 2010). When compared to infants

who died from other causes, infants who died from SIDS have higher concentrations of nicotine in their lungs (US DHHS 2006, 2010). It is posited that the chemicals in SHS interfere with the brain's ability to regulate breathing, resulting in the cessation of breathing and, ultimately, death. Secondhand smoke exposure in infancy and childhood is associated with additional health problems such as middle ear disease and increased ear infections, lower respiratory infections such as bronchitis and pneumonia, as well as asthma exacerbation (US DHHS 2006, 2010). Evidence also suggests that SHS is a risk factor for developing asthma as a child (US DHHS 2014).

Adult Adverse Health Effects Causally Linked to SHS Exposure

SHS interferes with normal functioning of the cardiovascular system, leading to increased risk of morbidity or death from cardiovascular diseases such as coronary heart disease and stroke. Even brief exposure to SHS can harm the lining of the blood vessels and make blood more viscous. The CDC estimates 2,194,000 premature deaths from coronary heart disease among nonsmokers exposed to SHS between 1964 and 2014 in the USA (US DHHS 2014). Secondhand smoke contributes to atherosclerosis, narrowing of the arteries by plaque, which restricts blood flow to and from the heart. Approximately 34,000 nonsmokers will die each year from SHS exposure-related heart disease and SHS exposure is associated with a 25–30% increased risk of developing heart disease for nonsmokers (US DHHS 2014). Strokes occur when blood supply to the brain is blocked or a blood vessel bursts in the brain (subarchnoid hemorrhage). Approximately 8,000 nonsmokers will die each year from SHS exposure-related stroke and SHS exposure among nonsmokers is associated with a 20–30% increased risk of suffering a stroke (US DHHS 2014).

Inhaling SHS, particularly over a long period, also damages the lining of the lungs. As the lung tissue is exposed over time, DNA in the cells of the epithelial lining of the lung may mutate irreparably, resulting in uncontrolled cell replication and lung cancer. Despite advances in treatment, lung cancer remains among the deadliest forms of cancer for both men and women. An estimated 7,330 nonsmokers will die each year from lung cancer related to SHS and 10–20% of lung cancer cases in the USA are among nonsmokers – approximately 20–40,000 cases per year (Centers for Disease Control and Prevention 2020, 2021a).

Mitigation/Management

Substantial evidence has supported the authoritative conclusion that no level of exposure to SHS is risk free for nonsmokers (US DHHS 2006, 2010; US Department of Health and Human Services, National Institutes of Health et al. 2014). Thus, the policy goal is to achieve public places and workplaces that are completely smoke free, along with encouraging policies for living spaces, e.g., homes, that limit SHS exposure. Greater exchange of outdoor with indoor air, i.e., ventilation, in areas where smoking is taking place does not assure healthy indoor air. In fact, the American Society of Heating, Refrigerating, and Air-Conditioning Engineers (ASHRAE), which provides guidelines for ventilation of indoor spaces, has concluded that healthy indoor air quality cannot be achieved if smoking is taking place (Samet et al. 2005). Neither increasing air exchange nor air cleaning are sufficient.

Prevention of exposures through government-level smoke-free policies is key to reducing SHS exposure. For example, smoking has long been banned in airplanes and is now banned in public housing by the US Department of Housing and Urban Development (US HUD 2017).

Comprehensive smoke-free policies and laws that prohibit smoking in public places protect the lives of both visitors and workers by reducing public smoking. Workers benefit further from a reduction in tobacco-related health problems when working in a smoke-free environment. Despite the benefits of such policies, only half of US states have laws banning smoking; much of the progress has been driven at the local level (American Nonsmokers' Rights Foundation 2021). While much progress has been made since SHS was determined to cause disease and death in nonsmokers, reduction of exposure has stalled at the US level with many states still not having comprehensive smoke-free laws requiring 100% smoke-free workplaces, restaurants, and bars. In order to reduce exposure to SHS and eliminate the remaining disparities in exposure, comprehensive smoke-free laws are essential.

Children are in a particularly vulnerable situation with regard to SHS exposure as they are typically unable to remove themselves from the offending environment. Children are disproportionately exposed to tobacco smoke in both homes and vehicles (Tsai et al. 2018). Voluntary and sufficiently strict smoke-free policies by parents and caregivers in their homes and vehicles would greatly reduce children's SHS exposure.

The WHO FCTC entered into force for ratifying countries in 2003 in response to the globalization of the tobacco epidemic through multinational tobacco companies. The FCTC's goal is to reduce tobacco smoking globally through establishing smoke-free environments, tobacco packaging, labeling, and education, appropriate taxation, curbs on the industry, as well as communications and public awareness programs (World Health Organization 2003). In the most recent WHO FCTC progress report, 165 of the 180 member countries reported implementing a complete or partial ban on tobacco smoking in indoor workplaces, public transport, indoor public places, and other locations (WHO Framework Convention on Tobacco Control 2018).

Smoke-free environments reduce nonsmokers' exposure to the harmful by-products of tobacco smoke. That understanding has changed social norms around smoking in homes as well. There is the possibility of completely eliminating exposure to SHS through smoke-free policies and changes in norms so that all environments become smoke free. The benefit is clear; communities will see a reduction in disease and death from SHS. The effectiveness of such interventions is well documented through measurements of nicotine in public environments and workplaces, declining biomarker levels, and associated changes in disease occurrence, particularly cardiovascular disease (National Research Council 2010).

Carbon Monoxide

Introduction

Carbon monoxide (CO) is a widespread indoor and outdoor pollutant generated by combustion (US EPA 2010a). It is a well-characterized pollutant as to the mechanism

of its health effects and its link to clinical outcomes, including death. Carbon monoxide has one straightforward mechanism of action in causing adverse health effects, binding firmly to hemoglobin, forming carboxyhemoglobin (COHb) (US EPA 2010a). Its affinity for the receptor molecule for oxygen exceeds that for oxygen, so that CO exposure reduces the oxygen-carrying capacity of the blood.

Carbon monoxide is endogenously produced and functions as a signaling molecule. Typically absent indoor or outdoor exposure to CO, about 1% of the body's hemoglobin is in the form of COHb in people who do not smoke tobacco products (US EPA 2010a). The level of COHb is a well-standardized assay that should be available in most clinical facilities.

Sources and Exposures

There are numerous sources of carbon monoxide in indoor environments, all related to combustion without adequate ventilation. For appliances that are vented by code, such as heating systems, hot water heaters, and stoves, failures of venting systems may result in elevated CO levels. Inappropriate use of unvented combustion sources indoors, e.g., charcoal-burning devices, may lead to very high and even lethal concentrations of CO. An additional source is vehicle emissions coming into a home from an attached garage. Cigarette smokers inhale high concentrations of CO in tobacco smoke and typically have an elevated, albeit generally nontoxic level of COHb. In less-developed countries where biomass fuels are used, carbon monoxide is an unavoidable indoor pollutant.

Risks

The most serious risk is asphyxiation coming from acute exposure to high levels of CO, generally unintentionally, but asphyxiation with CO is a still common cause of suicide. The asphyxiation occurs because the level of COHb reaches such high levels that insufficient oxygen is delivered to the brain and heart (O'Malley and O'Malley 2020). Chronic CO poisoning may also occur from ongoing exposure to elevated levels, coming, for example, from insufficiently ventilated gas-burning appliances, sometimes arising from maintenance failures. Common symptoms include lethargy, headache, difficulty concentrating, shortness of breath, and nausea and vomiting (O'Malley and O'Malley 2020). One characteristic feature of CO poisoning is improvement of the symptoms when away from the place of exposure, typically the home.

Clinically, a careful history is the starting point to making the diagnosis of CO poisoning. The nonspecificity of the clinical picture poses a challenge. Suspicion is needed to explore the timing of symptoms in relation to potential indoor exposure. In the case of acute, high-level exposure, one characteristic finding is a reddish hue to the skin and mucous membranes, often referred to as cherry red. The diagnosis is definitively established by measurement of the COHb level (O'Malley and O'Malley 2020).

Mitigation/Management

Prevention is critical for avoiding CO poisoning. Relatively inexpensive and accurate devices that detect CO and signal risky levels are now available and required by

code in homes in many states in the USA. Strategies for prevention include assuring that appliances are properly functioning and vented to the outside. Public education is needed, along with warnings not to use unvented combustion devices indoors, such as charcoal grills. In Houston, Texas, for example, there were multiple deaths ($N = 11$) during a prolonged electric power outage from carbon monoxide poisoning and more than 1400 visits for emergency care (Masson 2021). The exposure occurred as people sought to stay warm and to cook.

Household Air Pollution

Introduction

Globally, household air pollution (HAP) generated by combustion of biomass and other solid fuels are some of the leading causes of disease and premature mortality, particularly in low- and middle-income countries (LMICs). Approximately three billion people cook and heat by burning solid fuels in inefficient, simple stoves or open fires, routinely exposing themselves and household members to the smoke. For example, approximately one-third of Chinese households report cooking with coal (Duan et al. 2014). Each year, four million people die prematurely of illnesses attributable to HAP. People in low- and middle-income countries experience the overwhelming burden of disease and mortality from this exposure. Emissions from the burning of biomass fuels indoors are significant contributors to outdoor air pollution and also to greenhouse gases. Their control is essential to curbing climate change (Ramanathan 2020).

Sources and Exposure

Inefficient stoves and open fires are used for cooking across the world in millions of homes each day as covered in ► Chap. 6, “Appliances for Cooking, Heating, and Other Energy Services.” Pollutant-producing biomass fuels power these stoves and open fires: kerosene, dung, wood, and coal. These fuels and traditional cooking methods produce PM, methane, carbon monoxide, polycyclic aromatic hydrocarbons (PAHs), and volatile organic compounds (VOCs), all health-damaging pollutants.

Cooking stoves: There are many categories of cooking stoves that produce HAP, some more polluting than others: the three-stone fire, early “Improved Cook Stoves,” fuel-controlled stoves, micro-gasifiers, “fan-jet,” and nonbiomass. The three-stone fire is a traditional, cheap stove, requiring only three stones on which a cooking pot can be placed above a fire (Kshirsagar and Kalamkar 2014). While cheap, these stoves are inefficient, losing heat quickly and burning fuel inefficiently, and having no ventilation. Only one pot can be used at a time, increasing the amount of time that fuel sources are being burned, unventilated, within the home. Accidents are also prevalent ranging from burns to eye damage from flying embers.

Through the 1990s, early “Improved Cook Stoves” were developed to address some of the fuel usage and safety issues of the three-stone fire (Kshirsagar and Kalamkar 2014). These stoves were created using clay, ceramic, and buckets to enclose and insulate fuel combustion, decreasing the amount of fuel needed and

providing protection against children falling into open fires. Fuel-controlled stoves, mainly referred to as rocket stoves, are efficient and particularly hot burning (Kshirsagar and Kalamkar 2014). Small-diameter wood is burned in a combustion chamber with an insulated vertical chimney. Rocket stoves can be produced as portable, stationary (with a chimney), or with a forced air feature. They utilize far less fuel than their open flame counterparts and produce substantially less pollutants. Microgasifier cook stoves convert biomass into gas and are currently the cleanest burning option for solid biomass cooking (Roth 2011). These cook stoves convert biomass into gas and vapor, and provide better heat regulation and less fuel. This “gas burner” produces very little soot and other emissions. “Fan-jet” stoves introduce very strong air currents into the fuel source, significantly increasing the efficiency of combustion (Kshirsagar and Kalamkar 2014). However, these often rely on electricity and are expensive to produce; thus, they are not considered economically sustainable. Finally, there are nonbiomass stoves that utilize non-biomass fuel sources like alcohol, refined fossil fuels, biogas, coal, electricity, and solar power (Kshirsagar and Kalamkar 2014).

Fuel types: Wood fuel is the most commonly used biomass fuel (Kshirsagar and Kalamkar 2014). In many areas, wood fuel is plentiful and requires few tools or specialized knowledge to find and use. Wood can also be processed into pellets for use in certain types of cook stoves, particularly gasifier stoves.

Kerosene is a transparent liquid fossil fuel generated from crude oil refinement. While it is little used in developed countries, kerosene is still widely used as a cooking fuel in low- and middle-income countries (World Health Organization 2014). It is used in urban households where fuels need to be purchased rather than collected and utilities are either unreliable or cost-prohibitive.

Agricultural wastes – for example, rice straw, bagasse, and dried grass – and animal waste, or dung, are widely used fuel sources in low-income regions as they are free and widely accessible (Kshirsagar and Kalamkar 2014). It is primarily used in traditional stoves, such as the three-stone stove. Despite its commonplace use, dung is a particularly inefficient fuel source and produces more ash and smoke than its other biomass counterparts.

Coal is utilized most often in regions where cooking and heating are combined and availability is high, such as China and India, and rarely as a stand-alone cooking fuel (Kshirsagar and Kalamkar 2014). In parts of Eastern Europe, coal is still burned for space heating and is a major contributor to outdoor air pollution (Kshirsagar and Kalamkar 2014). Coal used for cooking and heating vary in composition and form: coal briquettes, coal cakes, coal ball, and raw coal.

Pollutants: HAP-producing cooking methods result in release of PM, methane, carbon monoxide, PAHs (including known carcinogens), and VOCs. Of particular concern is the production of PM by these cookstoves and fuels. Particulate matter from biomass fuel burning comprises a complex mixture of particles that can vary in size, shape, and composition. The health risks of PM have been extensively investigated as has the mechanistic basis by which they cause disease. PM exposure has been linked to eye, nose, and throat irritation; exacerbation of coronary and respiratory disease symptoms; cancer risk; and premature death, particularly in

susceptible people with cardiovascular or respiratory diseases (HEI Household Air Pollution Working Group 2018). Indoor PM levels are affected by many factors: outdoor levels, infiltration, ventilation, and filtration systems present in the home, indoor sources, and human activity (US EPA 2020b). Indoor biomass cooking in particular produces high levels of PM in homes that are well beyond guidelines for outdoor air (World Health Organization 2018b).

Risk

Health Effects Related to HAP

Understanding of the health risks of HAP has advanced greatly over the first two decades of the twenty-first century. Diverse adverse health consequences have been causally associated with HAP (Table 4) (Lee et al. 2020). Each year, an estimated four million people die prematurely of illnesses attributable to HAP with low- and middle-income countries experiencing the overwhelming burden of disease and mortality from this exposure (World Health Organization 2018b). While the global burden of cardiorespiratory, pediatric, and maternal diseases associated with HAP has declined in recent decades, it remains high in the world's poorest regions due to the continued need for and use of biomass fuel combustion for cooking. Women and children experience greater exposure as they assume responsibility for food preparation in these regions (World Health Organization 2018b).

Exposure to HAP increases the risk of acute lower respiratory infections in children, still a leading cause of death in young children (World Health Organization 2018a; Lee et al. 2020). HAP exposure increases risk for the development of pneumonia and other acute respiratory infections and accounts for half of all deaths from pneumonia in children under the age of five worldwide (World Health Organization 2018a; Lee et al. 2020). Evidence links HAP to tuberculosis, still a leading cause of death globally (World Health Organization 2018a; Lee et al. 2020). HAP

Table 4 Health effects attributable to household air pollution, 2017

Health effect	DALYs	Deaths
Communicable respiratory diseases (Acute respiratory infections and pulmonary tuberculosis)	27.4 million	–
Chronic respiratory diseases		
Asthma and COPD	18.4 million	–
Lung cancer	5.5 million	–
Cardiovascular diseases (Ischemic heart disease and cerebrovascular heart disease)	9.5 million	0.3 million
Under 5 mortality	–	0.78 million
Total DALYs	60.9 million	
Total deaths	1.8 million	

Source: Lee et al. (2020)

also increases the risk for development and exacerbation of asthma in children (World Health Organization 2018a; Lee et al. 2020). Finally, reflecting patterns of exposure in households, HAP is associated with increased risk of low birth weight and under age 5 mortality (World Health Organization 2018a; Lee et al. 2020).

Given the inhalation pathway of HAP, risk for chronic respiratory diseases is positively associated with HAP exposure (Lee et al. 2020). Chronic obstructive pulmonary disease (COPD) is a chronic inflammatory lung disease that leads to obstruction of airflow from the lungs. Symptoms include breathing difficulty, cough, mucus production, and wheezing. HAP exposure is possibly the most important risk factor for COPD among nonsmokers. Individuals exposed to HAP, which contains well-documented carcinogens, also have an increased risk of developing lung cancer (World Health Organization 2018b). Lung cancer is the leading cause of cancer death worldwide.

HAP is also associated with increased cardiovascular disease risk, likely through inflammatory mechanisms, possibly from the entry of very small particles into the circulation after translocation through the epithelial lining of the lung. HAP exposure is also linked to increased risk of death from cardiovascular disease and stroke (World Health Organization 2018b).

Finally, HAP is associated with the development of cataracts, the leading cause of blindness in adults in developing countries (World Health Organization 2018b). There is strong evidence linking HAP to cataract formation via inflammation and HAP exposure is estimated to be responsible for up to 25% of the global burden of cataract disease (HEI Household Air Pollution Working Group 2018).

Mitigation/Management

In order to reduce exposure to and disease resulting from HAP, lower emission, modern cookstoves, and fuel sources are needed to replace the open fires and inefficient cookstoves that are so widely used. Substantial improvements in health can be achieved through significant exposure reductions, necessitating the near-exclusive use of the lowest emission stoves and fuels. To be successful, solutions need to fit within cultural norms and practices, address affordability, and be implemented with communication about use and benefits of exclusive clean cooking stoves and fuels, particularly for child health.

These solutions reflect a four-decade story of characterizing the problem and seeking testing solutions. The story begins with the first measurements of PM during cooking with biomass fuels. These measurements were made in India by Kirk Smith, a pioneering researcher and tireless advocate for finding effective solutions for HAP (Smith et al. 1983). Moving from these measurements in the early 1980s, Smith championed further research to characterize HAP exposure and began to seek solutions, including carrying out a clinical trial in Guatemala (Smith et al. 2011). Over time, the global public health community and agencies awakened to the need to address HAP through research and interventions. Now, there is a substantial body of evidence from epidemiological and toxicological studies on HAP and from studies of interventions of lower-emitting stoves and fuels. Globally, a variety of clean cookstove initiatives have been in progress and are making a difference in reducing

the burden of HAP. Early on, emphasis was placed on replacing traditional cookstoves with more efficient low-emission devices. That effort is now complemented by substituting less polluting fuels for biomass fuels.

Thus, current efforts to reduce HAP include both less polluting stoves and fuels. Advanced biomass cookstoves can dramatically reduce HAP exposure. However, many households still employ “rocket stoves,” the design of which is relatively simple but not ideal for reducing HAP enough to reduce risk for adverse health outcomes. Cleaner, more efficient cookstoves are in production in many countries but they are not always easy to use, affordable, and long lasting. Clean fuels such as biogas, liquefied petroleum gas (LPG), ethanol, and solar sources have the potential to virtually eliminate cooking and heating emissions; however, these replacements are relatively costly and need to be implemented in a sustainable fashion.

Improved cookstove development has been attempted since the 1940s with increased scientific development in the 1970s and 1980s. Past initiatives include the Chinese National Improved Stove Program (CNISP) and the National Program on Improved Chulas. The CNISP took place from 1982–1992 and introduced 129 million cookstoves to rural Chinese areas (Smith et al. 1993). The National Program on Improved Chulas took place in India between 1985 and 2002 (Venkataraman et al. 2010). While the program resulted in 35 million units installed, stove quality issues, poor adoption rates due to government subsidy-based delivery mechanisms and lack of provisions for maintenance/repair, and little formal monitoring hampered the programs’ outcomes. These are lessons learned reflected in the initiatives that have followed.

Examples of current cleaner fuel distribution initiatives include Project Surya, the multicountry projects of Envirofit International, and the HAPIN trial, a multicountry research study (Project Surya 2009; Envirofit 2021; Household Air Pollution Intervention Network 2021). Project Surya in India focuses on women and addresses the product life cycle, considering the fuel supply chain, affordability, and maintenance access. The initiative is replacing 5,000 stoves each in pilot areas in the Himalayas, the Indo-Gangetic plain, and South India with solar stoves. Envirofit International is utilizing microloans with 6–8 month payback periods to create a lower entry cost to efficient cookstoves while also supporting cookstove technology innovation. Envirofit International currently serves over five million people with local production and distribution of clean cookstoves in East Africa, West Africa, Latin America, and Asia. The HAPIN Trial is a randomized controlled trial of LPG stoves and fuel distribution in 3200 households in four countries: Guatemala, India, Peru, and Rwanda. Personal exposure data as well as a variety of maternal and child health outcomes are being collected as part of this study to better inform the health benefits from switching to clean cookstoves. The trial’s findings should have global policy impact. These projects are reflective of the substantial scope of the global effort to find solutions to HAP.

Looking forward, the Clean Cooking Alliance and the National Biomass Cookstove Initiative are two major improved cookstove distribution initiatives (Clean Cooking Alliance 2021; Government of India and Energy 2021). The Clean Cooking Alliance has a goal of having 100 million homes adopt clean and efficient

cookstoves. Founded by members including the United Nations, the US Agency for International Development (USAID), the World Health Organization, the US Environmental Protection Agency, Shell, Morgan Stanley, and multiple national governments, this initiative aims to address barriers to uptake and to create local economic opportunities. The National Biomass Cookstove Initiative (India) aims to distribute 15 million clean biomass cookstoves over a decade, helping to reach the goal of 87% of Indian households utilizing the new cookstoves. Through this program, the government of India aims to reduce premature deaths from HAP exposure by 17%.

Adoption of clean cookstoves and fuels is not necessarily a one-step process – there are barriers to both their uptake and long-term use. First, there is often low awareness among low-income populations of the harms related to inefficient, high-emission cookstoves and fuels, and of the benefits of switching to the cleaner, low-/no-emission alternatives (Vigolo et al. 2018). Experience shows that successful introduction of these health-harming cookstoves requires consideration of cultural norms and practices. For instance, some culturally significant foods are traditionally made over three-stone fireplaces. A cleaner cookstove or fuel source may alter the resulting dish, changing traditional foods in unacceptable ways. There are also potential cost barriers to clean stoves and fuel (Vigolo et al. 2018). Populations using inefficient, health-damaging cookstoves are relatively poor and consequently purchasing a cleaner stove may be financially impossible. While some countries and organizations have established programs to address this issue, cost remains a barrier to uptake. In addition to initial cost barriers, there are also long-term cost barriers (Vigolo et al. 2018). Traditional biomass fuels are relatively cheap and, in some cases, free if available for gathering. Alternative, low-/no-emission fuels are more expensive, particularly for poor populations. While clean cookstove programs may initially cover these costs, long-term use of these cleaner fuels is dependent on affordability. Thus, in order to successfully transition populations to the cleanest cookstoves and fuels available, awareness of benefits and harms must be raised, cultural norms and practices must be considered and addressed, and both the initial and long-term costs must be managed.

Radon

Introduction

The gas radon is a ubiquitous indoor air pollutant that decays into a series of radioactive solid progeny, two emitting alpha particles that cause cancer-producing mutations in cells of the respiratory epithelium (National Research Council. Committee on Health Risks of Exposure to Radon 1999). Based on studies of radon-exposed underground miners and supporting mechanistic research, radon is a long-established occupational carcinogen, causing lung cancer. Epidemiological studies of multiple cohorts of miners show that risk increases with exposure and varies in a complex fashion with attained age, time since exposure, and smoking. Risk models have been developed for policy purposes that reflect these complexities and that provide risk estimates for establishing standards for occupational exposures and

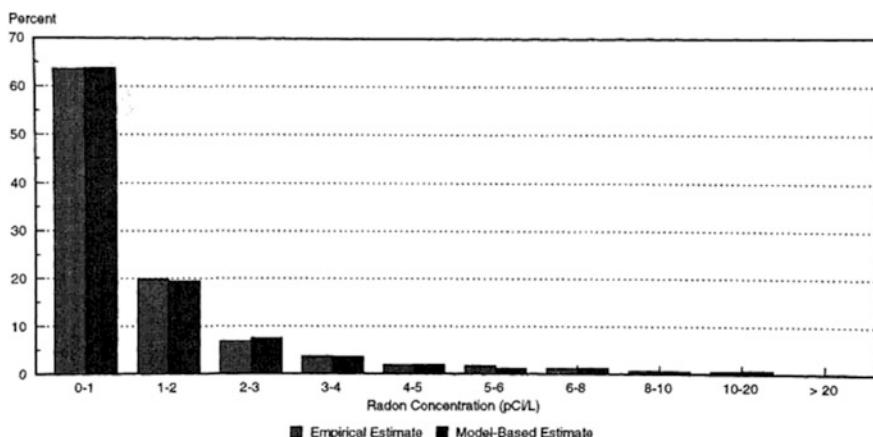

guidelines for exposures in homes and other indoor spaces. The most recent risk model, based on 11 epidemiological studies of underground miners, was developed by the Biological Effects of Ionizing Radiation (BEIR) VI Committee of the US National Research Council (National Research Council. Committee on Health Risks of Exposure to Radon 1999). Although the risk model dates to 1998, it continues to support policy (US EPA 2021c). With regard to the scientific basis for policy formulation, based on dosimetric considerations and mechanistic understanding, the BEIR VI Committee concluded that risk of lung cancer follows a no-threshold linear relationship at typical indoor exposures. This relationship implies that any exposure increases risk for lung cancer and that a no-risk level of radon indoors cannot be achieved. Hence, from the policy perspective, radon guidelines are aimed at achieving an acceptable level of risk.

The potential of radon to contaminate homes was reported as early as the 1950s (National Research Council. Committee on Health Risks of Exposure to Radon 1999). It received relatively little attention outside of Scandinavia, until the 1984 identification of a US home with concentrations equal to those in underground mines where miners had suffered excess lung cancer (Henderson 1989). The emergence of the indoor radon problem sparked epidemiological studies of the risks, mechanistic research, and applied research on mitigation approaches. Programs were launched in many countries to identify homes needing mitigation and guidelines were elaborated for acceptable concentrations. Numerous authoritative reports have now addressed the risks of radon, most recently that from the United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR) (2020).

Sources and Exposure

Radon is a naturally occurring pollutant generated in the decay series of uranium 238. Its immediate precursor is radium, which is present in rocks and sediments at concentrations that vary with geological characteristics. Radon, an inert gas, has a half-life of 3.8 days; thus, once formed, it has sufficient time to move through the soil and enter the atmosphere. Structures, including homes, create a pressure gradient across the soil that draws soil gas inside. Portals of entry include cracks in foundations and openings into basements. While soil gas is the dominant source, radon contamination of indoor environments may also occur in homes with high concentrations of radon in well water used in the home and in the unusual circumstance of radium-containing building materials, e.g., gypsum wallboard.

The radon concentration within a home reflects the microgeological circumstances of the home, the portals by which radon can enter the home, and the air exchange of the indoor of the home with outdoor air. The potential for a home to have a high radon concentration can be anticipated based on local and regional geology and also on prior testing in the area. However, the presence of homes with high concentrations is patchy; neighboring homes may have quite different concentrations. As shown in Fig. 1, the distribution of indoor concentrations in homes is lognormal with a substantial tail of high concentrations in homes (US EPA 1992).

Risks

Radon and its progeny are a well-established cause of lung cancer. By the 1950s–1960s, the epidemiological evidence was strong and initial understanding of the dosimetry of the alpha particles emitted by radon progeny had been achieved (Harley 1953; Bale 1980). The epidemiological evidence causally links radon to increased lung cancer risk in both never smokers and smokers and documents synergism between the two exposures (National Research Council. Committee on Health Risks of Exposure to Radon 1999). Other health consequences of radon exposure have been investigated in the miner cohorts and in the general population, including cancers other than lung cancer, childhood leukemia, and respiratory and cardiovascular diseases. To date, the evidence is mixed for these other health outcomes (United Nations Scientific Committee on the Effects of Atomic Radiation 2020). In addition to the studies of underground miners, epidemiological studies have been carried out to directly estimate the risk of indoor radon (National Research Council and VI) 1999). Most of the studies are case-control in design, involving comparison of residential radon exposures of cases with those of controls of comparable demographics but without lung cancer. The findings from the studies of miners and these general population studies are convergent.

Analyses of the underground miner data have provided risk models that have been extended to indoor exposures of the general population to radon. The analyses show that risk increases with the cumulative exposure, diminishes with the time since exposure and chronological age, and increases at lower exposure rates. Lifetable methods have been used to estimate the risk of death from lung cancer with different patterns of exposure (National Research Council and Committee on the Biological Effects of Ionizing Radiation 1988).

Management

Strategies for reduction of the lung cancer risk associated with indoor radon exposure are now well worked out, involving measurement of indoor radon levels with devices that have been proven to be accurate, comparison of the measured level to guideline values, and implementation of mitigation if needed (US EPA 2021). These strategies have evolved over the three decades since the widespread nature of the indoor radon problem was noted. In general, indoor radon concentration in homes is not regulated and the guideline values are just that. In some jurisdictions, however, measurement of indoor radon is required at the time of purchase of a home, particularly in locations where there is a potential for high levels of radon in homes.

Fortunately, radon concentrations can be measured relatively cheaply and with sufficient accuracy to determine the need for mitigation (US EPA 2012). Devices are available that measure radon concentration in real time, that can provide concentration over several days, and that can measure radon concentration over longer periods of times, e.g., months. The continuous reading devices would generally not be needed for the indoor setting, except during installation of radon-reduction equipment. The guidelines for indoor concentration are generally based on annual or longer-term average, which is indicative of lung cancer risk. Track-etch detectors provide longer-term average values. However, such longer-term measurements are not compatible with the timing of home sales and are replaced by shorter-term measurements, which can be made with charcoal detectors. The US Environmental Protection Agency protocol for such measurements screens for the potential for higher concentrations, calling for closing the home to reduce ventilation and placing the detector in the lowest potentially habitable area of the home.

If a home or other property is shown to exceed guideline values, there is an array of mitigation approaches, depending on the home's characteristics. These include sealing cracks and other points of entry in basements and ventilating basements or the space beneath foundation concrete slabs. Prevention of higher concentrations of indoor radon is possible through construction approaches, particularly in areas known to have the potential for higher concentrations. Radon-resistant construction techniques have been developed and tested and are now widely used. The US Environmental Protection Agency offers recommendations (US EP 2021).

Volatile and Semi-Volatile Compounds

Introduction

Volatile organic compounds, generally referred to as VOCs, are a diverse group of compounds unified by having a high vapor pressure and hence are present as gases in indoor air. The US EPA offers a general definition of VOCs as follows: “Volatile organic compounds, or VOCs are organic chemical compounds whose composition makes it possible for them to evaporate under normal indoor atmospheric conditions of temperature and pressure” (US EPA 2021f). The sources are myriad in indoor environments (Table 5), first edition (Tucker 2001) and diverse VOCs may be present in indoor air. Because the VOCs are present in a mixture, concerns about health risks relate both to the total mixture and to some individual VOCs, e.g., formaldehyde, that have been specifically investigated. Semi-volatile

Table 5 Examples of hazardous VOCs that have been measured in indoor air, and their potential indoor sources

Compound	Categories of indoor sources with reported emissions data (Not all products in the category contain or emit the compound)
Acetaldehyde ^a	Floor materials, HVAC systems and components, machines, wood products
Benzene ^a	Furnishings, paints and coatings, wood products
Carbon tetrachloride ^a	Pesticides
Chloroform ^a	Furnishings, pesticides
Ethylbenzene	Floor materials, insulation products, machines, paints, and coatings
Formaldehyde ^a	Cabinetry, floor materials, furnishings, HVAC systems and components, indoor air reactions, insulation products, miscellaneous materials, paints and coatings, space heating and cooking equipment, wall and ceiling materials, wood products
Hexane	Floor materials, furnishings, paints and coatings, wood products
Methylene chloride ^a	Furnishings
Naphthalene	Pesticides (moth crystals)
Paradichlorobenzene ^a	Pesticides, floor materials
Styrene	Cabinetry, floor materials, insulation products, machines, miscellaneous materials, paints and coatings, wood products
Tetrachloroethylene ^a	Caulks and sealants, miscellaneous materials
Toluene	Adhesives, caulk and sealants, floor materials, furnishings, machines, paints and coatings, wall and ceiling materials, wood products
Trichloroethylene ^a	Furnishings
Xylenes (<i>o</i> , <i>m</i> , <i>p</i>)	Floor materials, furnishings, machines, paints and coatings, wall and ceiling materials

Sources: Tucker (2001), U.S. Environmental Protection Agency (1999)

^aIncluded in a list of 33 hazardous air pollutants proposed by the U.S. Environmental Protection Agency as urban air toxics, which are thought to pose the greatest health threat to people living in urban areas (US EPA 1999)

organic compounds, sometime abbreviated as SVOCs, may also be of concern with regard to health risks. Some of these compounds are quite well known because of their ubiquity and the concern for a wide range of health effects, e.g., formaldehyde.

There has been substantial work on emissions of VOCs from various materials along with efforts to reduce emissions through changes in manufacturing and composition of materials. Emissions testing of products and the then available data were covered in the first edition of this handbook (Tucker 2001).

The health consequences of exposure to these compounds are both specific to the toxicity of individual compounds and also general, reflecting the consequences of inhaling a mixture of VOCs, typically measured as total VOCs or TVOCs. The range of health effects is very broad, covering acute and chronic outcomes, including cancer and noncancer effects. Some are quite well studied, e.g., formaldehyde and benzene for which epidemiological and toxicological data are available, while for others toxicity is unstudied and potential risks are assessed based on structure and information from other compounds (Agency for Toxic Substances and Disease Registry 1999, 2007). One useful resource on toxicity is the Toxicological Profiles compiled by the Agency for Toxic Substances and Disease Registry (ATSDR) of the Centers for Disease Control and Prevention (2021). Some compounds are covered by the US EPA's Integrated Risk Information System (IRIS) program and have also been considered in specific reports from the US National Research Council, for example, arsenic and trichlorethylene (US EPA 2010b; National Research Council 2006; US EPA 2021e).

Sources and Exposure

Pioneering research from decades ago, the Total Exposure Assessment Methodology (TEAM) study (described in detail in the first edition) identified that indoor exposure to VOCs was ubiquitous and driven by widely used household products, furnishings, and common processes, such as dry-cleaning (Wallace 1987, 2001). At the time, tobacco smoking was a contributor for some VOCs, such as benzene. This study highlighted the importance of activities indoors as a source, e.g., hobbies involving use of solvents or other materials. Summarizing the key findings, concentrations of the various VOCs considered were far higher in indoor air than in comparison outdoor samples, reflecting the dominance of indoor sources for the VOCs; and outdoor sources were relatively minor contributors to personal exposures. Vapor intrusion, the entrainment of contaminated soil gas into homes, can be a prominent source of VOCs for homes built over contaminated ground (US EPA 2020c). Homes affected by vapor intrusion have been described with extremely high indoor levels of contaminants, leading to acute intoxication.

Risks

A lengthy array of adverse health effects has been linked to VOCs generally and to specific VOCs (US EPA 2021g). As summarized by the US Environmental Protection Agency, VOCs are linked to:

- “Eye, nose and throat irritation
- Headaches, loss of coordination and nausea
- Damage to liver, kidney and central nervous system
- Some organics can cause cancer in animals, some are suspected or known to cause cancer in humans.”

For some of the better-studied VOCs, the evidence is quite certain as to the causation of adverse effects, e.g., benzene is a known leukemogen based on epidemiological and toxicological evidence (Agency for Toxic Substances and Disease Registry 2007). Additionally, higher exposures to mixtures of VOCs have been linked to symptoms of irritation and impairment of neurocognitive functioning. Research on the risks to health of this diverse group of compounds has been complicated by their occurrence in mixtures that can be quite variable. For particular compounds, e.g., benzene, much of the evidence on risks comes from studies of exposed workers. Substantial effort has been directed at quantitative characterization of the risks of some of the regulated compounds: formaldehyde, benzene, and tetrachlorethylene (TCE). Further detail on these well-studied compounds follows.

Formaldehyde: With its many uses, formaldehyde is one of the world’s highest production volume chemicals. It is a simple molecule (HCHO) that exists as a gas at room temperature with an irritating and distinctive odor. Formaldehyde is widely used in commercial products, such as fiberboard, paneling, particleboard, various furnishing, and even clothing to make them easy to care for (US EPA 2021b). Formaldehyde is also used in the production of urea formaldehyde foam insulation (UFFI). Improperly cured UFFI led to widespread indoor air pollution with formaldehyde during the 1970s and 1980s and a ban on its use.

The risks of formaldehyde have been examined in toxicological and epidemiological studies, involving diverse populations with occupational exposure in particular. Both cancer and noncancer adverse effects have been identified and exposure to formaldehyde causes acute irritative effects and possibly exacerbates asthma. Because formaldehyde is widely used and regulated, its risks have been examined quantitatively in a number of major risk assessments, including by the EPA IRIS program. Risks for both cancer and noncancer outcomes have been quantified.

Benzene: Benzene is a widely used agent in manufacturing and as a solvent. Indoors, entrainment of gasoline vapor from an attached garage is a common source and it may be emitted by some household products, although use is declining. Homes with smokers tend to have higher concentrations in indoor air than homes where no smokers reside. Studies of workers exposed to benzene provide definitive evidence that affects the cells of the bone marrow and causes acute myelogenous leukemia (AML) (Agency for Toxic Substances and Disease Registry 2007). There is strong mechanistic understanding of the basis for these adverse effects. These findings have led to changes in product formulation intended to reduce benzene exposure.

Trichlorethylene (TCE): Trichlorethylene is another well-known VOC that has been widely used in various household products, including products for cleaning and

furniture care (US EPA 2021e). One of the intriguing findings from the TEAM study was the elevation of TCE levels in homes when dry-cleaned clothing was brought into the home. TCE is a carcinogen and there is concern about noncancer adverse effects (Agency for Toxic Substances and Disease Registry 2019).

Bioaerosols

Introduction

Bioaerosols are ubiquitous in indoor environments throughout the world, whether in high-, middle-, or low-income countries. The sources are myriad and include bacteria and the endotoxins that they produce, fungi and fungal toxins, allergens from insects, e.g., the house dust mite, and domestic animals, including pets and livestock, which may be kept within the living space, and also rodents. There are multiple mechanisms by which these agents can have adverse effects: primarily direct toxicity and immune mechanisms. They may cause specific diseases, e.g., hypersensitivity pneumonitis and exacerbate chronic diseases, particularly asthma. In the parts of the USA subject to high levels of indoor moisture and also to flooding, indoor mold growth is a major problem and one that leads to litigation.

Sources and Exposure

The prevalence of indoor mold has been 5–10% in cold climates and 10–30% in moderate and warm climates. Thus, a substantial proportion of the world's population is exposed to dampness-related exposures (Quansah et al. 2012). Indoor dampness and mold have been associated with increased upper and lower respiratory symptom prevalence and greater morbidity among those with underlying pulmonary diseases (King and Auger 2002; Kennedy and Grimes 2013; Hernberg et al. 2014). Molds can become airborne through single or aggregated spores, as well as mycelial and hyphal fragments and can affect human health through direct toxicity, production of mycotoxins, infection, or allergic sensitization (Holme et al. 2020). Given that exposure to fungi is ubiquitous, it is estimated that at least 10% of the population has allergic antibodies to fungal antigens, yet only a small percentage of those sensitive have clinical manifestations (Hardin et al. 2003). Most species are not pathogenic, yet some species can cause significant disease in immunocompromised patients or in healthy individuals when exposed to large concentrations (Hardin et al. 2003).

Risk

According to the World Health Organization's (WHO) guidelines on indoor pollution, there is sufficient epidemiological evidence to show that indoor exposure to damp or moldy areas, in both houses and public buildings, is associated with increased risk of increased respiratory symptoms, respiratory infections, and with greater risk for developing or exacerbating asthma (World Health Organization 2010). In a cross-sectional study of 46,000 participants from 20 countries in the International Study of Allergy and Asthma in Children (ISAAC), self-

reported dampness and visible mold were associated with increased odds of wheezing (OR 1.7 95%CI. 1.47, 1.99), rhinoconjunctivitis (OR 2.1; 95% CI 1.9, 2.5), and respiratory symptoms, such as cough and phlegm. Similar findings have been reported in other large cohort studies and meta-analyses (Fisk et al. 2007; Antova et al. 2008). In longitudinal and incident case-control studies, mold and dampness have been shown to increase the risk for developing asthma by as much as 50%, although the quantitative relationship of risk with cumulative exposure is uncertain (Quansah et al. 2012). It has been difficult to establish whether specific fungi are responsible for particular respiratory health effects associated with visible mold or dampness, given variations in sampling methodology, exposure misclassification, and confounding exposures (O'Connor et al. 2004). Yet the finding that ergosterol levels (as a measure of fungal biomass and a principal sterol of fungal membrane) and hydrophilic fungi have been associated with asthma and wheezing strengthens the potential for a causal relationship (Matheson et al. 2005; Park et al. 2008).

Several specific sources of bioaerosols are described below, including those generated by dust mites, cockroaches, and animals.

Dust mites: Dust mites are the source of widespread exposure to antigens that are excreted in their feces. There are multiple species with the most common in homes being those of the genus *Dermatophagoides*. The critical antigen from this species is Der p 1, which can be measured in house dust samples. Exposure to Der p 1 has been linked to respiratory allergic symptoms and particularly to asthma. Its presence in furnishings and beddings is driven by moisture so that dust mite allergy is particularly prominent in damp climates. Identifying that house dust mite antigens may be contributing to allergic symptoms and asthma in children, or less frequently in adults, requires awareness of the problem and potentially analysis of dust samples for Der p 1. Sensitization can be assessed with skin testing and measurement of antibody levels.

Proven strategies are available to control house dust mite growth and limit exposure (Wilson and Platts-Mills 2018). These strategies include: (1) careful selection of the materials used for pillow covers and mattresses so as to not provide a breeding ground; (2) humidity control to maintain humidity as low as possible, particularly in high-humidity circumstances; (3) room air cleaners, which have a limited role; (4) carpets, which should be limited in coverage and readily cleaned; and (5) vacuum cleaners, particularly if equipped with a HEPA filter. In clinical trials, interventions have been shown to reduce levels of Der p 1 antigen and to improve health outcomes.

Cockroaches: The presence of cockroaches and sensitization to proteins derived from them is well recognized and is problematic in inner-city housing, particularly if poorly maintained (Sheehan et al. 2010). The German cockroach, *Blattella Germanica*, is best studied. It produces multiple allergens that may contribute to allergy and to causation and exacerbation of asthma (Sohn and Kim 2012). These antigens can be detected in house dust samples. Cockroaches are important contributors to the problem termed “inner city asthma” (see below). Mitigation lies with identification of the problem and control of the infestation.

Pets and rodents: Household pets, particularly cats, can be a potent source of indoor allergen exposure. Cats shed the antigen Fel d 1, which is highly persistent in indoor environments. Dogs, while less allergenic, also shed sensitizing antigens. The relationship of pet dander with the development of sensitization, asthma, and allergic rhinitis is complex, and may ultimately depend on other factors such as atopy and other determinants of individual susceptibility, and the timing of exposure (Svanes et al. 2003). Finally, environments with infestation with rats and mice or where rats, mice, guinea pigs, and other small mammals are kept as pets may also be contaminated with allergens.

Asthma. Asthma, one of the most common diseases in children and adults, is characterized by chronic airway inflammation resulting in variable airway obstruction, which can be exacerbated by many triggers, including bioaerosols (National Asthma Education and Prevention Program Coordinating Committee Expert Panel Working Group 2020). This association with bioaerosols may explain why the severity is worse and the prevalence of this disease more common in urban and inner-city neighborhoods with poor housing conditions in which the exposure burden to indoor air pollutants is often substantial.

Indoor pollutants have been known to play an important role with the developing and worsening of asthma and other allergic diseases in urban or inner-city environments (Gergen and Togias 2015). These large urban areas often have a higher and more severe asthma prevalence and children living in such locations are more likely to be from minority and socioeconomically disadvantaged populations (Busse and Mitchell 2007). In the USA, inner-city African American and Hispanic children have nearly double the rates of allergic indoor sensitization compared with non-Hispanic Whites (Stevenson et al. 2001). The National Cooperative Inner-City Asthma Study (NCICAS), which is a network of investigators in multiple cities, found among 1528 children with asthma the following frequencies of skin reactivity: 36.8% for cockroach, 34.9% for house dust mite allergen, and 22.7% for cat dander (Kattan et al. 1997). The NCICAS showed that cockroach allergy, but not dust mite or cat allergies, is associated with increased hospitalizations, wheezing, and unscheduled medical visits. In a subsequent study, the National Cooperative Inner-City Study showed in a randomized study that educating caregivers on asthma management and environmental mitigation leads to substantial long-lasting reductions in morbidity (Evans 3rd et al. 1999). Pharmacological interventions can also be useful in reducing the disease burden associated with indoor allergens. Omalizumab, a monoclonal anti-IgE antibody substantially reduces asthma exacerbations and severity in inner-city asthmatic children. In subgroup analyses of NICAS participants who were sensitized and exposed to cockroach allergen, omalizumab reduced the rate of asthma exacerbations and inhaled corticosteroid dosage while increasing the number of asthma control days (Busse et al. 2011).

Mitigation/Management

Prevention through humidity control is critical for molds as is immediate attention to water leaks and floods. Pets are a known source of allergens and endotoxins and guidance should be offered as to their potential risks, particularly for people with

asthma and allergies. Home remediation interventions to eliminate dampness sources and visible mold improve asthma and upper airway allergy symptoms (Kercsmar et al. 2006; Burr et al. 2007). As such, the WHO's Indoor Air Pollution guidelines recommend that remediation should be given priority to prevent an additional contribution to poor health in populations who are already living with an increased burden (World Health Organization 2009). Both the WHO and the CDC acknowledge that the relations between dampness, microbial exposure, and health effects cannot be quantified precisely, and therefore argue against measuring molds in the environment, as no specific thresholds can be recommended for acceptable levels of contamination with microorganisms and standards for judging what is an acceptable, tolerable, or normal quantity of mold have not been established. Instead, both agencies recommend reducing exposure by focusing on removing contaminated structures and working to prevent subsequent mold growth.

Addressing health problems related to bioaerosols can be challenging. A health issue may be the triggering event for a search for its cause, possibly leading to the finding of mold and mildew, or there may be a clear indication that a home or other indoor environment has been affected by moisture. Problems that cannot be immediately diagnosed or that are refractory should be brought to the attention of an experienced indoor air quality specialist. See, for example, the several books by Jeffrey and Connie May (May and May 2008, 2020).

Respiratory Infections

Introduction

Indoor environments are a critical locus for transmission of respiratory infections. People mix indoors, inhale air that may be contaminated with infectious microbes, and touch surfaces (fomites) that may harbor viable organisms. Indoor transmission of airborne infection and its control have a long history that dates back nearly a century to the pioneering work of William Wells who proposed the theory of droplet transmission and explored related mechanisms for controlling transmission. From the pioneering work of Wells in the 1930s (Wells 1934) until the present, there was surprisingly little research on airborne transmission of respiratory pathogens until the twenty-first century when attention was given to influenza and SARS (severe acute respiratory syndrome), and more recently to SARS-CoV-2, the cause of COVID-19.

This section provides brief coverage of some of the major respiratory pathogens that are transmitted indoors and in association with the building environment. The material provides an overview of clinical and epidemiological features of these infections (Table 6); textbooks are available that provide full coverage (Nelson and Williams 2014).

There are several unifying concepts concerning airborne infectious agents. These relate to how agents are transmitted and their infectiousness as well as control strategies. For respiratory infections, there are four potential modes of transmission with two involving inhalation directly (Tang et al. 2021). Exhaled air from people

Table 6 Overview of clinical and epidemiological features of respiratory infections

Respiratory infection	Causes	Risk factors	Clinical characteristics	Prevention	Cases per year, the USA
Legionnaire's disease ^a	Bacteria of the Legionella type	Older age, smoking history, chronic lung disease, poor immune system	Cough, shortness of breath, fever, muscle pains, headaches	Good maintenance of water systems	10,000
Tuberculosis ^b	Mycobacterium tuberculosis	Smoking; HIV/AIDS	Chronic cough, fever, cough with bloody mucus, weight loss	Screening of those at high risk, vaccination	<200,000
Influenza ^c	Influenza A virus Influenza B virus Influenza C virus	Young children, older adults, pregnant women, people with chronic disease or weak immune systems	Fever, chills, muscle aches, cough, congestion, runny nose, headaches, fatigue	Handwashing, vaccination	>3 million
SARS ^d	SARS-associated coronavirus	Those in close contact with infected persons	Fever, dry cough, headaches, muscle aches, difficulty breathing	Handwashing, cough etiquette, avoiding close contact with those infected, avoid travel to affected areas	<1000*
SARS-CoV-2 ^e	SARS-associated coronavirus-2	Older adults, people with severe chronic underlying medical conditions	Fever or chills, cough, shortness of breath, difficulty breathing, fatigue, muscle or body aches, headache, new loss of taste or smell, sore throat, congestion or runny nose, nausea or vomiting, diarrhea	Handwashing, cough etiquette, masks, avoiding close contact with those infected, avoid travel to affected areas	Pandemic ongoing: >34 million cases

with an active respiratory infection contains infectious particles in the form of larger particles (droplets) and smaller particles (aerosols) (Wang et al. 2021). The larger particles are typically generated by coughing and sneezing, sometimes referred to as “spray” transmission. The smaller particles are produced during exhalation and their numbers are increased by talking louder, singing, playing musical instruments, and other activities that increase the force of exhalation. Droplets and aerosols can contaminate the surfaces where they deposit, leading to fomite transmission. Transmission may be direct from person to person, e.g., by touching.

The characteristics of indoor environments have direct relevance to transmission of infection, particularly by the indoor aerosol, referring to particles less than 100 microns in aerodynamic diameter. Particularly at the smaller end of the size range of aerosols, the particles will remain airborne for hours and move widely across spaces. Thus, for aerosols, building ventilation is a determinant of concentration and air cleaning may also be a factor if designed to remove smaller airborne particles in the size range of aerosols.

Several other concepts extend to transmission of respiratory pathogens. In particular, the transmissibility of the infectiousness of the agent is a critical determinant of the course of an epidemic or outbreak (Van Sechteren and Hochberg 2017). The transmissibility is generally measured by the R_0 , which refers to the number of people becoming infected by contact with an infected individual at the start of an epidemic when all are susceptible. An epidemic propagates when the value of R_0 is greater than one such that the infection can spread and grow.

Risks

Discussions of several major, specific respiratory pathogens that are transmitted indoors follow.

Tuberculosis: At the start of the twentieth century, tuberculosis was the leading cause of death in the USA. Now, there are less than 10,000 new cases in the USA, but tuberculosis remains a leading cause of disease burden worldwide with an estimated 10,000,000 cases in 2019 (World Health Organization 2020a). Through the 1950s, the mode of transmission of tuberculosis was uncertain – fomites or airborne. Many campaigns to control tuberculosis had been based around the premise that transmission was by fomites, leading to campaigns to limit spitting, for example.

Riley and colleagues provided experimental proof of airborne transmission (Riley et al. 1962). They ducted the air from the tuberculosis ward at a Baltimore hotel through remotely placed cages holding guinea pigs. The animals developed tuberculosis. Analogous human exposure scenarios reaffirmed the findings. Airborne outbreaks have been reported on airplanes, in homeless shelters, and other indoor locations. Today’s measures to control tuberculosis build on the foundational work of Riley: isolation of the air from rooms containing people with infectious tuberculosis.

Legionnaires’ disease: Legionnaires’ disease was identified as the cause of a dramatic 1976 epidemic of severe and even fatal pneumonia among attendees at a Legionnaire’s convention in Philadelphia (Fraser et al. 1977). The outbreak was linked to a previously unknown genus of bacteria – the *Legionella*, which live in soil and

water. Infection occurs when water contaminated with *Legionella* is aerosolized. Documented outbreaks come from contaminated water systems and aerosolization by showers or other devices and from cooling towers, as with the index outbreak (World Health Organization 2007). Contaminated water within cooling towers may spread through the heating, ventilating, and air-conditioning system and also from spray released by the cooling tower. Cases have been reported among passersby near buildings with contaminated systems and contaminated aerosol may travel some distances and lead to infection. The problem of contaminated cooling towers with *Legionella* is well known and has led to the development of protocols for combatting contamination.

From the clinical perspective, Legionnaire's disease presents as a severe, acute respiratory infection, often with pneumonia. It can be fatal with a case fatality rate of 10% (25% for health care associated) (Centers for Disease Control and Prevention, National Center for Immunization and Respiratory Diseases et al. 2021b). Its diagnosis depends on the clinical picture and taking a history that may reveal potential locations for exposure to the responsible agent, e.g., a hotel stay, or the occurrence of other, similar cases.

SARS-CoV-2: As this chapter is written, the world is in its second year of a global pandemic with a coronavirus, SARS-CoV-2, which causes the disease COVID-19. To date (May, 2020), there have been an estimated 161,381,569 cases and 3,348,952 deaths globally (Center for Systems Science and Engineering [CSSE] at Johns Hopkins University 2021). The course of the pandemic is unknown for the short term and long term. Effective vaccines have been developed and are being delivered, but variants have been isolated worldwide, some having higher transmissibility and/or greater virulence than previously circulating strains.

The pandemic led to a notable acceleration in research on airborne transmission of respiratory infections and particularly of SARS-CoV-2. When SARS-CoV-2 emerged, severe acute respiratory syndrome (SARS) was known to be caused by the SARS-CoV-1 virus. Airborne transmission of that virus was well established, having been documented in airplanes, apartment blocks, and a hotel. Initially, transmission of SARS-CoV-2 was assumed to be transmitted by fomites and also via the airborne route (World Health Organization 2020b). However, there was uncertainty as to the mode of airborne transmission and the relative importance of larger droplets and smaller aerosols in transmission. The relative contributions of these different routes of transmission – fomites, larger droplets that travel only a few feet, and smaller aerosols that can remain suspended in indoor spaces, travel widely, and remain suspended for hours – are directly relevant to control strategies.

The shock of this pandemic exposed the many gaps in understanding of the transmission of respiratory viruses. Perhaps because of the implications for pandemic control, debate over the droplet vs aerosol transmission was strident. However, a consensus has been reached that gives emphasis to the critical role of aerosols.

Management

Prior to the COVID-19 pandemic, the role of the building environment in transmission of airborne pathogens was recognized but prevention of infection spread

indoors was not considered a primary design goal. Standard 61.1 of the American Society of Heating, Refrigerating, and Air Conditioning Engineers (ASHRAE) “...outlines minimum ventilation rates and other measures intended to provide IAQ that is acceptable to human occupants and that minimize adverse health effects” (ASHRAE 2019a, b). ASHRAE has commented on ventilation and air cleaning in limiting transmission of airborne infection in position papers (ASHRAE 2014, 2020). A 2020 document addresses infectious aerosols, acknowledging that infectious transmission by aerosols occurs through pathways involving the heating, ventilating, and air conditioning (HVAC) system (ASHRAE 2020). The document calls for attention to infection spread in the design and lists the following specific strategies for operations of HVAC systems, along with the strength of evidence:

- Enhanced filtration (higher minimum efficiency reporting value [MERV] filters over code minimums in occupant-dense and/or higher-risk spaces) (Evidence Level A – strongly recommend)
- Upper-room UVGI (with possible in-room fans) as a supplement to supply airflow (Evidence Level A)
- Local exhaust ventilation for source control (Evidence Level A)
- Personalized ventilation systems for certain high-risk tasks (Evidence Level B – recommend)
- Portable, free-standing high-efficiency particulate air (HEPA) filters (Evidence Level B)
- Temperature and humidity control (Evidence Level B)

During the course of the COVID-19 pandemic, the potential for transmission in poorly ventilated locations, particularly if crowded, has been recognized. The WHO has released an algorithm for assessing and improving ventilation (World Health Organization 2021). Responding to the pandemic, recommendations have also been made to incorporate infection-control measures into the design of buildings, a proposed paradigm shift that could come into play for users of this volume (Morawska et al. 2021).

Specific Diseases Associated with Indoor Air Quality

Overview

Given time-activity patterns, indoor environments are the predominant locus for inhaling diverse injurious pollutants. This topic is covered in depth in ► Chap. 37, “Time-Activity Patterns.” Additionally, outdoor air pollutants variably contribute to contamination of indoor environments. These exposures contribute to the exacerbation and causation of common diseases: asthma, chronic obstructive pulmonary disease (COPD), lung cancer, and cardiovascular disease. For lung cancer, for example, both radon and SHS are well-characterized causes (Table 2). Exposure to indoor air pollution may also reduce general well-being through irritation of mucous

membranes and other pathways. In addition to these contributions to the burden of morbidity and mortality from noncommunicable diseases, indoor air pollution is also linked to two specific clinical entities: multiple chemical sensitivity and sick building syndrome, both addressed subsequently. Antigens with indoor sources, e.g., from birds, cause the relatively uncommon disease of hypersensitivity pneumonitis.

With regard to noncommunicable diseases, exacerbation of asthma by indoor exposures is well described and consideration of indoor air pollution should be part of the clinical assessment, particularly for patients with more severe asthma. An extensive literature links SHS with exacerbation of asthma, particularly in children. Other irritants should also be queried clinically, including potential exposure to formaldehyde or other volatile organic compounds. Bioaerosols, covered elsewhere in this chapter, are also contributors to the burden of morbidity from asthma. For other noncommunicable diseases, radon is considered to be the second leading cause of lung cancer in the USA, following tobacco smoking, and indoor air pollution exacerbates COPD, in addition to asthma. Household air pollution is causally associated with COPD, particularly at the high exposure levels experienced in low-income countries.

The following sections address multiple chemical sensitivity, sick building syndrome, and hypersensitivity pneumonitis, all challenging problems for clinicians.

Multiple Chemical Sensitivity

Introduction

The syndrome of multiple chemical sensitivity, also referred to as MCS, has a long and controversial history. The underlying hypothesized mechanism dates to the 1950s and the allergist Theron Randolph ([1954](#), [1962](#)). He proposed that sensitization by one or more chemicals could lead to a more general sensitivity to additional chemicals, even at levels of exposure lower than those at which direct effects would not be anticipated. Since then, the concept of the MCS syndrome has been variably viewed from being considered as a valid clinical syndrome stemming from chemical-driven responses to a largely psychologically based phenomenon.

The first edition of the handbook described the history and manifestations of MCS in detail, and deeper background can be found in the second edition of *Chemical Exposures: Low Levels and High Stakes* by Ashford and Miller ([1998](#)). Randolph advanced the concept of *chemical susceptibility* in the 1950s, based on observation of a woman who sold cosmetics and seemed to have general responses to chemicals from products ([1954](#)). The subsequent history of the problem most often referred to as multiple chemical sensitivity is one of controversy with conflicting views of the underlying mechanisms and the “legitimacy” of MCS as a disease. Regardless of this controversy, patients do present with challenging clinical pictures that reflect sometimes debilitating symptoms in response to one or more chemicals, often with a generalization of symptom responses to a broader range of agents in a nonspecific fashion.

Various definitions have been offered; perhaps the most widely cited is that proposed by Cullen in 1987: “Multiple chemical sensitivity (MCS) is an acquired disorder characterized by recurrent symptoms, referable to multiple organ systems, occurring in response to demonstrable exposure to many chemically unrelated compounds at doses far below those established in the general population to cause harmful effects. No single widely accepted physiological function can be shown to correlate with these symptoms” (Cullen 1987). The definition speaks to the non-specificity of MCS and, there is still no single diagnostic test for the syndrome. Rather, the diagnosis rests on a skilled clinical evaluation and exclusion of alternative diagnoses before the diagnosis of MCS should be made.

A further broad and historical perspective is provided by the proceedings of workshop convened in 1988 by the National Research Council (National Research 1992). That workshop brought together a diverse group of participants, some with divergent views of MCS. It includes proposals for research that were not implemented in a comprehensive way and it provides individually authored chapters that set out the understanding at the time. Since then, there have been a substantial number of publications, although research funding has been limited. A 2018 systematic review, covering the period 1998–2015, identified 73 articles that met search criteria (Rossi and Pitidis 2018). Definitive conclusions were not reached and the authors called for more research.

Etiology

The name – multiple chemical sensitivity – speaks to the construct of etiology. Through one or more underlying mechanisms, exposure to one or more chemicals leads to sustained sensitivity to additional chemicals, triggering diverse symptoms that appear to reflect responses from different organs. Hence, viewed in this framework, the etiological agents are chemicals, although a single triggering mechanism has not been identified. Research has explored a variety of mechanisms but research has yet to point to a single mechanistic process that could underlie the broad manifestations of MCS. Miller, who has focused on MCS, proposed “toxicant induced loss of tolerance” (TILT) as an underlying and unifying mechanism. In this hypothesis, an initial high-level exposure or multiple lower-level exposures cause a loss of tolerance that leads to subsequent triggering by other agents at low levels. This hypothesis matches the clinical phenotype but leaves underlying mechanisms unspecified.

A range of research methods has been used to explore etiology: biomarkers of inflammation and imaging in particular. Etiological mechanisms remain unclear, however, beyond the broad mechanisms described previously, e.g., TILT, and there may be heterogeneity in the determinants of MCS that has yet to be identified.

Clinical and Epidemiological Picture

The clinical picture is well captured by Cullen’s definition: a broad array of manifestations and a history of triggering by chemical exposures, sometimes linked to a clear triggering event. In practice, the lack of specificity complicates, making a firm diagnosis and epidemiological investigation. In addition, while MCS is well known

among physicians who address environmental illness, it is obscure to many primary care physicians who are likely to be the first to see patients with MCS.

To facilitate research and care, two instruments have been developed for capturing the picture of MCS: the Environmental Exposure and Sensitivity Intolerance (EESI) instrument and the short version, the Quick Environmental Exposure and Sensitivity Intolerance (QEESI) instrument (Miller and Prihoda 1999a, b). Other instruments have been developed as well, but the most abundant data are based on the EESI and its variants.

The EESI is a standardized approach for identifying individuals with chemical sensitivities. A shorter version of the EESI, the Quick Environmental Exposure and Sensitivity Inventory (QEESI), is the most commonly used form of the inventory. Four scales are used in both the EESI and QEESI instruments: Symptom Severity, Chemical (Inhalant) Intolerance, Other Intolerance, and Life Impact, which measure features consistent with MCS. A fifth scale, the Masking Index, measures regular, ongoing exposures. The Symptom Severity, Chemical Intolerance, Other Intolerance, and Life Impact scales each have ten items rated from 0–10, while the Masking Index consists of 10 items answered “Yes” or “No.” The ten items in each scale are intended to cover a wide range of measures reflective of the causes, manifestations, and consequences of MCS.

A third inventory, the Brief Environmental Exposure and Sensitivity Inventory (BREESI), has been developed as a short, three-question, screener for chemical intolerance (Palmer et al. 2020). The BREESI compresses the Chemical Exposure and Other Intolerances scales into three, “Yes” or “No” questions. The Chemical Exposure scale is condensed into one question to assess the exposure to any of the chemical categories. The Other Intolerances scale is condensed into two questions, one related to food intolerances and one related to drug intolerances. Given the length of both the EESI and QEESI, the BREESI provides a simple way to determine if further investigation of an individual’s symptoms as MCS is warranted.

Surveys have been carried out in the USA and elsewhere to establish the prevalence of MCS. These surveys have used a variety of instruments, including the QEESI. Early surveys employed questions developed by the California Department of Health Services. Across the surveys, the reported prevalence figures for symptoms related to chemical exposures are around 10% with several percent reporting physician-diagnosed MCS.

The most recent survey in the USA was carried out in 2016 using a national sample of over 1,100 participants (Steinemann 2018). The instrument used covered a range of typical MCS symptoms and exposures linked to triggering. The results estimated the prevalence of medically diagnosed MCS as 12.8% among adults, self-reported chemical sensitivity as 25.9%, and either or both as 27.5%. The range of symptoms reported from exposure to fragranced consumer products is broad (Table 7) (Steinemann 2018). The multisystem nature of MCS is illustrated by the range of problems reported (Table 8). While the results of such surveys are subject to various types of bias, the prevalence rates indicate that substantial numbers of people experience chemical insensitivity.

Table 7 Health problems (frequency and type) reported from exposure to fragranced consumer products

	Gen Pop	MCS Diag	ChemSens	MCS/ ChemSens
Total (<i>N</i>) (% relative to general population)	1,137	145	294	313
	100.0%	12.8%	25.9%	27.5%

Management

Management of people with MCS poses complexities, given the nonspecificity of the syndrome and the lack of understanding of underlying mechanisms. An initial task for the clinician is to exclude specific disorders for which treatment may be

Table 8 Reported symptoms of multiple chemical sensitivity

Symptom	Source
Rapid heart rate Chest pain Sweating Shortness of breath Fatigue Flushing Dizziness Nausea Choking Trembling Numbness Coughing Hoarseness Difficulty concentrating	https://www.merckmanuals.com/home/special-subjects/idiopathic-environmental-intolerance/idiopathic-environmental-intolerance
Headaches Rashes Asthma Muscle and joint aches Memory loss Confusion	https://www.hopkinsmedicine.org/health/conditions-and-diseases/multiple-chemical-sensitivity
Burning, stinging eyes Wheezing, breathlessness Nausea Extreme fatigue/lethargy Headache/migraine/vertigo/dizziness Poor memory and concentration Runny nose (rhinitis) Sore throat, cough Sinus problems Skin rashes and/or itching skin Sensitivity to light and noise Sleeping problems Digestive upset Muscle and joint pain	https://www.multiplechemicalsensitivity.org/the-symptoms-of-multiple-chemical-sensitivity/

available, such as autoimmune disorders, e.g., polymyalgia rheumatica. From a patient's perspective, the path to a knowledgeable health-care provider may be long and frustrating. Often, the physicians seeing MCS patients initially may not have any knowledge of the syndrome and pursue extensive testing and alternative diagnoses, particularly psychiatric diagnoses. Patients may become distrustful of the health-care system, a barrier to further care and reaching a knowledgeable provider.

Exclusion of alternative diagnoses for which specific therapies are available is the first step clinically. The typical clinical picture will lead a knowledgeable provider to a diagnosis of MCS. Critical for management is the identification of triggers and

potential triggers and guidance on avoiding them. Ongoing supportive care is critical. The provider may also become involved in the broader dimensions of MCS, such as workplace accommodations and disability.

Sick Building Syndrome

Introduction

The syndrome of sick building syndrome or SBS received initial attention and definition in the late 1970s (Passarelli 2009). At that time, there were increasing reports of buildings where multiple occupants were experiencing symptoms that occurred in relationship to building occupancy. The manifestations were diverse and not specific. From clinical and epidemiological perspectives, the critical linkage was the timing of symptoms in relation to exposures to agents within the buildings and the occurrence of symptoms among multiple building occupants. SBS emerged at a time when tobacco smoking was still generally allowed in buildings and, by anecdote, building maintenance had not received sufficient attention as building aged. Additionally, the myriad sources of air pollution in work environments were not yet well recognized, including routine office products, furnishings, and building materials.

As SBS emerged, the tobacco industry made efforts to divert attention away from SHS as a cause of SBS, even though cigarette smoking was by then known to be a potent source of airborne particles and volatile and semi-volatile compounds, including nicotine (Proctor 2012). These efforts included influencing the findings of indoor air quality investigations and vigorous opposition to an attempt by the Occupational Safety and Health Administration (OSHA) to promulgate an indoor air quality standard that covered smoking in workplaces.

The first edition of the *Indoor Air Quality Handbook* included two chapters relevant to SBS, one on “occupant reactions to indoor air quality” and the other on “building-related illnesses.” The distinction remains useful with the first referring to symptoms and complexes of symptoms related to indoor environments and indoor air quality and the second referring to a range of specific and definable clinical entities for which medical treatment might be sought and lead to a diagnosis and therapeutic interventions. By contrast, SBS is nonspecific with the tautology of its name describing its origins and the nature of the symptoms.

Etiology

The syndrome’s name, sick building syndrome, inherently captures its etiology. People with SBS and buildings where SBS occurred have been an elusive target for systematic investigation using epidemiological approaches. Affected individuals have been largely cared for by individual clinicians who may or may not find the link to the responsible building environment. Numerous buildings have been investigated by the National Institute for Occupational Safety and Health (NIOSH) and by private consultant groups. The findings of NIOSH investigations through 1990, not subsequently updated, provide some insights with regard to causal factors at the time (OSHA 1999):

- Inadequate ventilation 52%
- Contamination from inside building 16%
- Contamination from outside building 10%
- Microbial contamination 5%
- Contamination from building fabric 4%
- Unknown sources 13%

Lacking, and complicating interpretation of these data, is the denominator: that is the underlying total population of buildings contributing those where sick building syndrome has occurred. In other words, these case investigations represent the numerator for an unclear denominator. Consequently, we lack a clear understanding of the epidemiology of SBS including its prevalence over time and how etiological drivers may have changed as the syndrome was recognized and preventive maintenance implemented. The relevance of these findings from three decades ago to today's buildings is uncertain, given the many changes in building design and operations and changes in sources, particularly smoking indoors.

Nonetheless, these data provide a broad understanding the etiology of SBS. Inadequate ventilation contributed to about half of the cases. By anecdote, many affected buildings had not been well maintained when the syndrome emerged. Unfortunately, in the USA and elsewhere, we lack a longitudinal data stream to define changing etiology, particularly with the banning of smoking indoors in most building environments around the world. Links to specific chemicals have not been made among the mixtures in indoor environments, but suspects include formaldehyde, various volatile organic compounds, and other agents that may have irritant, neuropsychological, or other effects.

Clinical Picture

People affected by SBS report a broad array of symptoms, often in relation to spending time in the building where exposure occurs. Typically prominent are symptoms related to the air-exposed mucous membranes of the eyes, nose, and throat, and upper airway. Commonly reported symptoms include irritation and burning of the eyes, nose, and throat, cough, and wheezing. Some reports also include symptoms of impaired neurocognition, such as confusion and also dizziness.

These symptoms are not specific and SBS is defined by their connection to the building environment. With such nonspecific symptoms, affected people are far more likely to have initial clinical contact with a generalist, rather than someone with training in environmental or occupational medicine who may make the connection to the building environment. Clinical history formats have been developed for that purpose. At times, people working in affected buildings have made the connection of their symptoms to their workplaces through discussions that have identified the commonality being in the building to the occurrence of symptoms in multiple people. One indicator of the link to the building is the lessening or disappearance of symptoms over the weekend or while on vacation followed by recurrence with return to work. The epidemiological context can affirm the link to

the building if there are multiple people working in the building who are affected or who work in the same place within the building.

Management

By definition, the occurrence of sick building syndrome reflects exposure(s) within the building as the causal agent(s). While specific symptoms may need clinical management, such as treatment of wheezing or eye irritation, resolution of the problems affecting building occupants requires finding the etiology within the building. The path to finding a solution may be complex as cooperation and collaboration with building owners and operators and business management may be needed. Litigation and labor relations may further cloud the course to a solution.

The general approach to patients with SBS remains making the clinical link to the building environment and assuring that the needed building survey and etiological investigations are made. For health-care providers, a first step is to connect a patient's symptoms to the problem building. To confirm the diagnosis and to initiate inquiry about the suspect building, referral to an experienced occupational/environmental medicine physician may prove valuable. The steps to resolution can be complicated, but necessarily involve actions that end with an assessment of the building to diagnose and correct the building's problems. The path to mitigation may flow through the patient, contact with the employer, an employee organization, the building owner, or other routes, sometimes including litigation. The health-care provider would typically be a source of information, but not be in the lead. An experienced building professional is needed.

Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis, or allergic alveolitis, refers to a set of clinical disorders associated with inhaled antigens that cause lung injury via cell-mediated immunity. With sustained exposure, the underlying inflammatory process can lead to fibrosis with permanent lung injury. Among the antigens linked to hypersensitivity pneumonitis are those from pigeons (pigeon breeder's disease) and other birds, e.g., parakeets (bird fancier's disease), those from improperly maintained humidifiers, particularly thermophilic actinomycetes (humidifier lung), and those encountered by farmers, thermophilic actinomycetes and fungi (farmer's lung). These diseases are generally diagnosed by medical specialists, e.g., pulmonologists, and the relevant history will generally lead to an effort to mitigate exposures, if possible. In managing hypersensitivity pneumonitis, removal from exposure is essential; administration of glucocorticoids may be helpful. Questionnaires have been developed for patients diagnosed with hypersensitivity pneumonitis to survey for exposures to potential causal agents.

Conclusions

Indoor air pollution harms public health and causes symptoms and disease that bring people to the attention of health-care providers. Globally, HAP is now a well-established contributor to a substantial burden of morbidity and premature mortality.

It is one of several causes of acute respiratory infections in children and of chronic respiratory and cardiovascular diseases in adults. Solutions are in progress through national and global initiatives. One global indoor air pollution problem has been lessened, but not eliminated – exposure to SHS. A multi-pronged approach has reduced this once ubiquitous exposure: a decline in smoking, a change in social norms with nonsmokers claiming their right to smoke-free environments, legislation at local, state, and national levels, and WHO's global treaty, the FCTC. Public health approaches are also directed at emissions reductions from building materials and products, indoor radon mitigation, and airborne infection control, the last being accelerated greatly by the COVID-19 pandemic.

For people made ill by indoor air pollution and their health-care providers, establishing a link to indoor air pollution and finding a solution through eliminating exposure may be challenging. As covered in this review, indoor air pollution contributes to the causation and exacerbation of common diseases, such as asthma, but the links may not be readily discerned in particular individuals. Careful histories that cover environmental exposures may be helpful in identifying triggers, such as exposure to animal dander or the presence of a cockroach infestation. Consultation with a health-care provider skilled in management of environmental health problems may be needed as may services of an indoor air professional.

For patients and providers, the syndromes of MCS and sick building syndrome may be particularly challenging and frustrating. Specific diagnostic tests are not available and making the correct diagnosis demands a detailed history and exclusion of other conditions that may mimic symptoms of these entities. Affected individuals may become frustrated as a diagnosis and treatment are not offered. Additionally, the illness reflects external exposures that may not be subject to control in the instance of sick building syndrome nor to avoidance in the instance of MCS.

Looking to the future, indoor air quality will continue to affect health and well-being. Most importantly, as indoor environments and sources change, preserving and advancing health should remain an overarching consideration.

Abstract

People spend as much as 90% of their time in confined environments. A large number of previous environmental epidemiological studies have confirmed the association between indoor air pollution and population health, but there are still some limitations and deficiencies in the epidemiological studies on indoor air quality and population health. This chapter discusses the health effects of indoor air pollution on the cardiovascular system, respiratory system, and other systems from the perspective of short-term health effects and long-term health effects. The health outcome indexes commonly used in indoor air quality and population health research were summarized. The epidemiological studies on indoor smoking, nitrogen dioxide, TVOC, and radon were discussed as special

examples in detail. This chapter also points out the problems existing in the current research on indoor air quality and population health and puts forward the prospect of future research.

Indoor air · Epidemiology · Short-term health effects · Long-term health effects · Cardiovascular health · Respiratory health

Introduction

People spend as much as 90% of their time in confined environments, especially at home, and the concentrations of some air pollutants may be two- to five-fold higher indoors than outdoors (Marion et al. 2012). Poor indoor air quality poses a risk to the health of over half of the world's population, especially affecting poor people. Indoor air pollution is the eighth most important risk factor, being responsible for 2.7% of the global burden of disease (between 1.5 and two million deaths yearly) (Viegi et al. 2004). Therefore, concern over the health effects of indoor air pollution is increasing. Epidemiologic investigations on indoor air pollutants are of important practical significance for identifying countermeasures to control indoor air pollution, improve indoor air quality, and protect human health.

This chapter introduced the adverse health effects of indoor air pollution and reviews conventional outcome measures in epidemiological studies of indoor air pollution. We also took important indoor pollutants as examples and introduced the related epidemiology studies and guidelines.

Conventional Outcome Measures in Epidemiological Studies of Indoor Air Pollution

Mortality, Morbidity, and Prevalence

Mortality is the proportion of the total number of deaths in a given population in a given period of time. Morbidity (also called incidence rate) is defined as the number of new cases of disease (incident number) divided by the person-time over the period. Prevalence of a disease is the proportion of the population with the disease at the specified time. They are common outcome variables in cross-sectional studies and cohort studies and are usually used to assess the effect of long-term exposure to indoor air pollution.

Subclinical Outcome Measures

Outcome Measures for Respiratory System

Pulmonary function: Spirometry is the most common physiological test to measure the maximal inhales or exhales volumes of air of an individual with maximal effort

(Graham et al. 2019; Miller et al. 2005). In 1979, the American Thoracic Society (ATS) proposed the first statement on the standardization of spirometry. In 2005, a new document of standardization of spirometry bringing the views of the ATS and European Respiratory Society (ERS) was published and has been applied widely (Miller et al. 2005). This standard was updated again in 2019 (Graham et al. 2019). Through this test, some lung function indicators can be obtained, mainly including the forced vital capacity (FVC), forced expiratory volume in the first second (FEV₁, FEV₁/FVC, peak expiratory flow (PEF), and so on. FVC is the volume delivered during an expiration made as forcefully and completely as possible starting from full inspiration. FEV₁ is the volume delivered in the first second of an FVC maneuver. FEV₁/FVC is the ratio of FEV₁ to FVC and has been used to diagnose lung diseases such as chronic obstructive pulmonary disease (COPD). PEF is the largest flow during a forced expiration. Lung function has become one of the most commonly used outcome variables in assessing the respiratory health effects of indoor air pollution. Impaired lung function has been linked to short- and long-term exposure to indoor air pollution from fuel or incense burning and cooking oil fumes and certain indoor air pollutants including particulate matter among all kinds of people.

Airway inflammation: Airway inflammation is a central process in many lung diseases including asthma and COPD. Fractional exhaled nitric oxide (FeNO) and hydrogen sulfide (FeH₂S) have been developed as two noninvasive biomarkers of airway inflammation, reflecting eosinophilic and neutrophilic inflammation, respectively. In 2005, ATS and ERS recommended the standardized procedures for online and offline measurement of FeNO (American Thoracic Society; European Respiratory Society 2005). The FeNO is expressed in parts per billion, which is equivalent to nanoliters per liter. The exhalation flow rate used for a particular test can be expressed as a subscript of the flow rate in ml/s: for example, FeNO₅₀ at a flow rate of 50 ml/s. It's important to note that NO analysis should be performed before spirometry because spirometric maneuvers have been shown to transiently reduce exhaled NO levels. NO measurements can be performed using exhaled gas collected in a reservoir and subsequently analyzed for NO concentrations, which is called offline FeNO measurement. Other NO indicators have been developed to reflect the airway inflammation in different parts. For example, CaNO is the concentration of NO in the gas phase of the alveolar or acinar region (ppb), and CawNO is the tissue concentration of NO of the airway wall (ppb). FeNO and FeH₂S have been widely used in studies concerning respiratory health effects of ambient air pollutants. But in general, the evidence on the association of indoor air pollution with FeNO and FeH₂S is limited.

Induced sputum: In recent years, increasing evidence suggests that the respiratory microbiome is closely related to the occurrence and development of respiratory diseases, especially for some chronic lung diseases. Sputum induction has been recognized as the preferred sampling technique for assessing the respiratory microbiome. Sputum is an extracellular gel, including water, heavily glycosylated mucins, inhaled toxins and particulate matter, host cells, and bacteria and their associated products. Sputum may be induced through inhalation of saline solutions and it is noninvasive. Sputum inherently represents a variable mixture of upper and lower airway microbiota. Current knowledge of the respiratory microbiome still relies

mainly on the 16S rRNA gene sequencing approach. Other high-throughput techniques, such as metagenomics, metatranscriptomics, and metabolomics, can aid in both a broader investigation of microbial genomes and the examination of associated functional aspects and are increasingly used. Changes in the respiratory microbiome may also be involved in indoor air pollution-mediated pulmonary effects, which is worth investigating in the future.

Respiratory symptoms: Increased risks of some respiratory symptoms such as wheeze, cough, phlegm, rhinitis, and dyspnea have been associated with short- and long-term exposure to indoor air pollution. Some questionnaires have been developed to measure the symptoms of patients with chronic respiratory diseases. For example, the Modified British Medical Research Council (mMRC) questionnaire was used to assess the degree of dyspnea and it relates well to the prognosis of COPD. In addition, COPD Assessment Test (CAT) and the COPD Control Questionnaire (CCQ) have been developed to comprehensively assess the health status of COPD patients. CAT is an eight-item uni-dimensional measure of health status impairment in COPD. Another widely used questionnaire, St. George's Respiratory Questionnaire (SGRQ), can evaluate disease symptoms, patient's daily activity, and the impact of COPD on a patient's life, but it is too complex to use in routine practice.

Outcome Measures for Cardiovascular Health

Blood pressure: Blood pressure is defined as the pressure exerted by the blood upon the walls of the blood vessels. Elevated blood pressure, even under the threshold of hypertensive disorders, has been associated with increased cardiovascular diseases and mortality. The conventional indicators used is resting arterial blood pressure (ABP), mainly including systolic blood pressure (SBP), diastolic blood pressure (DBP), pulse pressure (PP), and also mean arterial blood pressure (MABP) calculated as the weighted average of SBP and DBP with weights of 1/3 and 2/3, respectively (Xia et al. 2021a). Recently, increasing studies show solicitude for ambulatory blood pressure allowing for repeated measurements of blood pressure. The ambulatory blood pressure can more sensitively capture the short-term associations of indoor air pollutants with blood pressure.

Cardiac function: Numerous studies have linked indoor air pollutants exposure to decreased cardiac autonomic function, as represented by heart rate variability (HRV). HRV is usually measured by an ambulatory electrocardiogram. The repeated measurements allow for capturing the cardiovascular effects of short-term indoor air pollutant exposures. The conventional measurements used are indicators for two major domains. The time-domain includes the standard deviation of normal-to-normal intervals (SDNN), and the frequency domain includes the very low-frequency (VLF) power (0.0033–0.04 Hz), the low-frequency (LF) power (0.04–0.15 Hz), the high-frequency (HF) power (0.15–0.40 Hz), and also LF/HF ratio, etc.

Other less used measures are cardiac structure indicators usually assessed by echocardiography. The outcomes are parameters describing the forms and structures of heart chambers, including left ventricular internal diameter in diastole, left

ventricular mass, left ventricular ejection fraction, left ventricular internal diameter in systole, left atrial anterior-posterior diameter, left atrial area (four- and two-chamber), lateral and septal E' velocity, lateral and septal A' velocity, lateral and septal S' velocity, E/A ratio, right ventricular width at the base and mid-cavity, right ventricular length, right ventricular systolic pressure, tricuspid annular plane systolic excursion, and right ventricular outflow tract time to peak velocity, etc. (Burroughs Peña et al. 2017). The cardiac structure is closely related to the blood-pumping functions of the heart.

Metabolic indicators: Traditionally used metabolic indicators are gluco-lipid parameters examined by clinical blood biochemistry tests, including fasting plasma glucose (FPG), total cholesterol (TC), high-density lipoprotein cholesterol (HDL-C), low-density lipoprotein cholesterol (LDL-C), triglycerides (TG), and very low-density lipoprotein cholesterol (VLDL-C). Meanwhile, hemoglobin A1C (HbA1C), fasting insulin, and C-peptide are also important circulating biomarkers for glucose metabolism. Noteworthily, C-peptide is the concurrent product of insulin derived from proinsulin, and secreted in equimolar dose. Emerging studies have found that C-peptide can more accurately characterize the real release amount of insulin, and also more sensitively predict the risks of multiple cardiovascular diseases.

Recent studies have also developed a series of novel indices based on these indicators, such as homoeostasis model assessment of insulin resistance index (HOMA-IR), homoeostasis model assessment of β -cell function (HOMA-B), non-high-density lipoprotein cholesterol (non-HDL-C), which is calculated as TC minus HDL-C, and TC/HDL-C, non-HDL-C/HDL-C, LDL-C/HDL-C, and TG/HDL-C. These indices have been found to be strong predictors for risks of cardiovascular diseases and mortality. In addition, further technologies have also been used to examine the apolipoprotein A1 (ApoA1), apolipoprotein B (ApoB), and ApoB/ApoA1 ratio. ApoA1 is an important apolipoprotein in HDL-C particles, and has potential protective effects for atherosclerosis. Meanwhile, ApoB is a major apolipoprotein in atherogenic lipoprotein particles, which may promote atherosclerosis. Increased ApoB/ApoA1 is associated with increased risks of cardiovascular diseases (He et al. 2021).

Inflammatory and oxidative indicators: Systematic inflammation and oxidative stress are two classic mechanisms for the adverse effects associated with indoor air pollution exposure. The widely used indicators of systematic inflammation are high-sensitivity C-reactive protein (hs-CRP) and fibrinogen. Hs-CRP is an acute-phase protein, which is considered as a robust predictor for cardiovascular diseases (Xia et al. 2021a). Meanwhile, fibrinogen is also a strong predictor for risks of coronary heart disease (CHD), and other vascular and nonvascular mortality. Other inflammatory indicators also include white blood cells (WBCs) and subgroups, including eosinophils, basophils, neutrophils, monocytes, and lymphocytes, as well as cytokines such as interleukin (IL)-6, IL-8, IL-1 β , IL-17, tumor necrosis factor- α (TNF- α), soluble intercellular cell adhesion molecule-1 (sICAM-1), monocyte chemotactic protein-1 (MCP-1), and macrophage inflammatory protein-1 α (MIP-1 α), etc. As for indicators for oxidative stress, superoxide dismutase (SOD), 8-hydroxy-2'-deoxyguanosine (8-OHdG), malondialdehyde (MDA), glutathione

peroxidase 1 (GPx-1), and oxidized low-density lipoprotein (Ox-LDL) are typical circulating biomarkers. SOD is an antioxidant enzyme preventing the potential adverse effects of oxidative stress. 8-OHdG is a sensitive biomarker to represent DNA damages. Meanwhile, MDA and Ox-LDL are also important indicators for lipid peroxidation.

Coagulation indicators: Increasing studies have identified the thrombosis-promoting effects of indoor air pollutants, which might be the underlying mechanisms for cardiovascular diseases such as stroke, CHD, and IHD (Chen et al. 2018). Typically used coagulation indicators include red blood cells (RBCs), platelets (PLT), plasminogen activator inhibitor-1 (PAI-1), soluble CD40 ligand (sCD40L), platelet aggregation rate (PAgT), P-selectin, tissue plasminogen activator (t-PA), d-dimer, etc. (Chen et al. 2015).

Metabolomics: Investigations on metabolomics aim at a systematic analysis of the metabolites produced by cells, tissues, or organisms. Metabolomics is a useful tool to identify the complex exposure biomarkers along with the changes in metabolic phenotypes related to adverse health outcomes, in order to elucidate the underlying mechanisms of health effects associated with indoor air pollutants exposure. Metabolomics methods can be divided into untargeted metabolomics and targeted metabolomics, both with the aim of identifying differentiated metabolites associated with exposures or health outcomes. To date, untargeted metabolomics has been more widely used, but current evidence on related biological pathways in human beings associated with indoor air pollution exposure is still limited.

Epigenetics: Studies on epigenetics focus on changes in gene functions and protein expressions that do not involve changes in DNA. MicroRNAs (miRNAs) are important factors in the epigenetic regulation of gene expressions. MiRNAs are composed of multiple small non-coding RNA molecules, which play a crucial role in messenger RNA (mRNA) silencing and gene expression regulation at the posttranscriptional level, and thus inhibit the process of protein synthesis (Chen et al. 2018; Vrijens et al. 2015). To date, miRNAs representative of miR-21, miR-34b, miR-125b, miR-146a, miR-223, and miR-340 associated with smoking, as well as miR-9, miR-10b, miR-21, miR-128, miR-143, miR-155, miR-222, miR-223, and miR-338 associated with air pollutants have been investigated (Vrijens et al. 2015). In addition, the associations of indoor air pollutants with mitochondrial DNA (mtDNA) methylation and DNA methylation have also received increasing attention. DNA methylation may induce the dysfunction of endothelium, which is firmly associated with cardiovascular diseases such as atherosclerosis and thrombosis.

Outcome Measures for Other Health Issues

Skin diseases and symptoms: Many indoor physical, chemical, and biological pollutants (e.g., cockroaches, rodents, pets, dust mites, fungus, air pollutants, endotoxin, tobacco, etc.) may be potential allergens leading to hypersensitivity reactions through inflammatory and other pathways. To date, most related studies centered around the effects on organs directly exposed to the indoor environment, such as skin and eyes. Air conditions have been associated with many allergic skin diseases and symptoms such as dermatitis, eczema, urticaria, and skin itching (Abolhasani et al. 2021).

However, to date, the outcome measures for clinical and subclinical skin conditions are still limited. Apart from self-reported disease history and physician diagnosis of skin diseases, there are few acknowledged indicators for skin issues. It deserves attention that recent studies found that interleukin-17 (IL-17), T-helper 17 (Th17) cell, and aryl hydrocarbon receptor (AhR) may be closely associated with several skin diseases such as atopic dermatitis, cellulitis, and psoriasis (Abolhasani et al. 2021). Further studies are still warranted to identify more sensitive outcome measures.

Eye diseases and symptoms: Studies have linked indoor air pollutants to eye diseases and symptoms, particularly dry eye symptoms and other eye irritations (Idarraga et al. 2020). Self-reported eye symptoms of a simple question (e.g., “Do you feel that your eyes are dry and uncomfortable?”) have widely been used in related studies. As for objective measures, the standardized questionnaires such as the Ocular Surface Disease Index (OSDI), the National Eye Institute Visual Functioning Questionnaire (NEI VFQ-25), the McMonnies Dry Eye Questionnaire, and the Short Form-12 (SF-12) Health Status Questionnaire are mostly used. The OSDI is a 12-item questionnaire composed of three major subscales including vision-related function, ocular symptoms, and environmental triggers (Schiffman et al. 2000). The main advantage of the OSDI is the capacity of capturing unique aspects of dry eye disease (Schiffman et al. 2000).

Mental health: Epidemiological studies have linked indoor air pollutants to mental disorders and subclinical mental health issues, such as anxiety, depression, and stress. Most of these studies used the results from standardized assessment tools as the primary outcome measures. Some widely used scales in related studies include the State-Trait Anxiety Inventory (STAI), the Beck Anxiety Inventory (BAI), the Hospital Anxiety and Depression Scale (HADS), the Center for Epidemiologic Studies Depression Scale (CES-D), the Beck Depression Inventory-II (BDI-II), the Geriatric Depression Scale (GDS), the Patient Health Questionnaire-9 (PHQ-9) for depression, and the Perceived Stress Scale (Liu et al. 2020a). In addition, the Depression Anxiety Stress Scales (DASS) has also been used to characterize the effects of indoor air pollutants on the mental health of the aforementioned three perspectives.

Cognitive health: Growing studies have found associations of indoor air pollutants with a variety of types of cognitive function including concentration, memory, perception, spatial orientation, and thinking. The outcome measures can be categorized into two major areas: brain function and work performance. Brain function refers to specific cognitive functions with dedicatedly designed tasks, while work performance involves links with real-world activities (Du et al. 2020). Comprehensive cognitive test batteries include the Behavioral Assessment and Research System (BARS), the Cognitive Drug Research (CDR), the Penn Computerized Neurocognitive Battery (CNB), and the CNS Vital Signs battery (CNS), etc.

Kidney health: The widely used outcome measures for kidney health for this topic are still limited to clinical indicators, representative of estimated glomerular filtration rate (eGFR), and urinary protein creatinine. The eGFR can be estimated based on age, gender, and serum creatinine concentrations. According to the National Kidney Foundation Kidney Disease Outcomes Quality Initiative

(NKF-K/DOQI), eGFR <60 ml/min/1.73 m² or urinary protein creatinine >30 mg/g is defined as chronic kidney disease (CKD) (Liang et al. 2021). However, some biomarkers associated with tubular injury, tubular function, kidney inflammation, and fibrosis used in clinical practice have still seldom been applied in studies on kidney effects of indoor air pollutants.

Classification of Adverse Health Effects of Indoor Air Pollution

Short-Term Health Effects

Effects on Respiratory System

The respiratory system is directly exposed to air pollutants, so it is the first to bear the brunt. People spend most of their time indoors, especially for susceptible populations like children, elderly, and patients with some chronic diseases. Therefore, it is imperative to explore the relationship between indoor air pollution and the respiratory health of the population.

Short-term exposure to indoor air pollution has been associated with some adverse respiratory outcomes, including lung function and respiratory symptoms. Particulate matter is one of the most widely investigated indoor air pollutants. It has been associated with impaired lung function among different populations. A panel study of 141 schoolchildren in Poland found that exposure to indoor PM₁ and PM_{2.5} was associated with the reduction of FEV₁ and PEF (Zwozdziaik et al. 2016). A study of 60 healthy adults found that increased PM_{2.5} in houses with houseplants was associated with a decreased percentage predicted peak expiratory flow rate (PEFR) (Chang et al. 2019). A panel study among healthy elderly women found outdoor-originated indoor PM_{2.5} was associated with decreased PEF in the non-heating season (Chi et al. 2019). Patients with respiratory problems may be more sensitive to indoor air pollution than healthy people. Chi et al. found that an inter-quartile range (IQR, 102.4 µg/m³) increase in indoor PM_{2.5} was associated with 1.7–2.3% reduction in FEV₁ of chronic obstructive pulmonary disease (COPD) patients during the heating season in Beijing, China (Chi et al. 2019). For respiratory symptoms, evidence from both developing and developed countries showed consistent associations between indoor particulate exposure and increased risks of wheeze symptoms and acute exacerbations in COPD patients (Hansel et al. 2013).

Particulate matter is a complex mixture consisting of various chemical components and comes from multiple sources. Compared with its mass concentration, some chemical constituents and sources may deserve more attention, but there is a limited literature for indoor PM_{2.5} components. It has been reported that indoor elemental carbon (EC) and primary organic carbon (POC) of PM_{2.5} were associated with decreased evening PEF of healthy young adults (Huang et al. 2019a). Indoor black carbon (BC), a marker of traffic-related PM_{2.5}, was reported to be associated with decreased FEV₁, FVC, and FEV₁/FVC of COPD patients (Hart et al. 2018). In addition, a panel study in Beijing found that indoor PM_{2.5} originated from indoor sources had stronger effects on lung function of COPD patients (Chi et al. 2019).

Some inorganic elements of indoor PM_{2.5} were observed to be negatively associated with FEV₁ and PEF of COPD patients (Zhang et al. 2021). However, the research evidence is still very limited, and the association of indoor particulate constituents and sources with respiratory health needs to be explored further.

Other indoor pollutants, such as ozone (O₃), carbon monoxide (CO), and total volatile organic compound (TVOC), may be also associated with poor respiratory outcomes in the population, but the literature is really limited.

Effects on the Cardiovascular System

The sample sizes in studies on the short-term health effects of indoor air pollutants are usually small. These studies make efforts to quantify the exposure-response associations for certain pollutants by utilizing real-time monitoring. Increasing attention has also been devoted to evaluate the health effects through a viewpoint of sources and constitutions, especially for indoor particulate matter (PM) pollution. Furthermore, the indoor condition provides an ideal opportunity to set a control group and take intervention measures. Accordingly, a wide range of studies also uses quasi-experimental and intervention designs to examine the protecting effects of reducing or controlling indoor air pollutants.

Evidence on this topic is generally limited, possibly due to the relatively small sample sizes and short study periods of related studies. However, studies found that indoor short-term exposures to outdoor air pollutants (PM and ozone) were significantly associated with increased mortality in the US cities (Chen et al. 2012).

Consistent evidence has reported the associations between short-term exposure to indoor air pollutants and elevation in blood pressure (Walzer et al. 2020; Xia et al. 2021a). A systematic review based on ten intervention studies focusing on non-smoking people in smoke-free homes demonstrated that, after using personal air cleaner at home over a median of 13.5 days, there was a significant decrease of 3.94 mmHg (95%CI: -7.00, -0.89) in mean systolic blood pressure (SBP) and an insignificant decrease trend of 0.95 mmHg (95% CI: -2.81, 0.91) in mean diastolic blood pressure (DBP), respectively (Walzer et al. 2020). Meanwhile, a meta-analysis based on 14 cross-over randomized controlled trials (RCTs) found that after utilizing indoor air purification interventions, there was a significant decrease of 2.28 mmHg (95% CI: -3.92, -0.64) in SBP, and a decrease of 0.35 mmHg (95% CI: -1.52, -0.83) in DBP and 0.86 mmHg (95% CI: -2.07, 0.34) in PP (Xia et al. 2021a).

Generally, increases in indoor air pollutants (size-fractionated PM, black carbon, O₃, etc.) are significantly associated with decreases in autonomic cardiac function indicators such as SDNN and HF (Huang et al. 2019b). In addition, a study even found reduced cardiac autonomic function among children under the background of relatively low-level ozone exposure (mean concentration of 8.7 ppb) (Huang et al. 2019b). Meanwhile, an intervention study found that lower household wood smoke exposure was associated with the occurrence of nonspecific ST-segment depression (McCracken et al. 2011).

Although not with consistent findings, most studies report that short-term exposure to indoor air pollutants are associated with activated systematic inflammatory and oxidative stress status representative of increased hs-CRP, IL-6, IL-8, TNF- α ,

fibrinogen, 8-OHdG, and MDA (Xia et al. 2021a). Summarizing the results of 14 RCTs found that utilizing indoor air purification interventions was associated with a 0.23 mg/L decrease (95% CI: -0.63, 0.18) in hs-CRP (Xia et al. 2021a). Furthermore, emerging evidence has reported benefits using biomarkers of coagulation and vasoconstriction (Chen et al. 2015) after filtration of indoor air for several days.

Genetics and omics are novel tools to explore the underlying mechanisms of the health effects associated with indoor air pollutants exposure. Increasing numbers of studies have linked indoor air pollutants to perturbation in metabolomics. Indicators of glucolipid metabolism, amino acid metabolism, and purine and urea cycles were identified as differentiated urinary metabolites in a series of studies indicating perturbations in energy metabolism, inflammation, and oxidative stress. The associations of indoor air pollutants with epigenetics have been increasingly investigated. Studies found that indoor air pollutants might be associated with DNA methylation in peripheral blood (Walker et al. 2020). In addition, PM_{2.5} may also affect micro RNAs (miRNAs) regulating the expression of systemic inflammation, coagulation, and vasoconstriction (Chen et al. 2018).

To date, no clear conclusions have been drawn for the cardiovascular hazards of sources and constitutions of indoor air pollutants due to the limited number of studies. However, combustion and road dust sources and related constituents have been considered important contributors to cardiovascular damages. Novel methods, such as exposomic approaches, and statistical methods like Bayesian Kernel Machine Regression (BKMR), weighted quantile sum (WQS) regression, and machine learning methods, have also been applied to further quantify the individual joint effects of certain sources and constitutions of indoor air pollutants on cardiovascular health.

It should be noted that a few studies have reported negative health effects after utilizing indoor air intervention facilities. A short-term intervention study among 44 children in Beijing, China reported that using an ionization air purifier was associated with negative alterations in cardiovascular health (Dong et al. 2019). The underlying mechanisms were explained to be the masking effects of massive production of negative air ions, which might shield the cardiovascular benefits of decreased indoor particles through lowering energy generation and anti-oxidation capacity with different metabolic pathways (Liu et al. 2020b). The findings stress the necessity of further evaluations on potential health hazards of indoor air intervention facilities, particularly among the susceptible subgroups.

Effects on Other Systems

Evidence for the effects of short-term exposure to indoor air pollution on other human systems is quite limited. A panel study conducted in 55 children with moderate-to-severe atopic dermatitis (AD) repeatedly measured indoor formaldehyde and their AD symptoms and found that a 10 ppb increase in formaldehyde increased AD symptoms by 79.2% (95% CI, 19.6–168.4%) in spring and by 39.9% (95% CI, 14.3–71.2%) in summer (Kim et al. 2021). Another prospective study of 30 children with AD in a day-care center found that indoor air pollutants including toluene increased the risk of AD aggravation (Kim et al. 2015b).

Long-Term Health Effects

Effects on the Respiratory System

Indoor air pollution is still severe in many regions and causes a heavy burden of the disease every year. Long-term exposure to indoor air pollution has been an important risk factor for many chronic non-communicable diseases such as COPD and asthma. Considering the cost and difficulty of long-term monitoring of indoor air pollutants with a large scale, solid fuel or biomass burning for cooking or heating is usually used as a measure of indoor air pollution. To date, indoor air pollution exposure has been linked to various respiratory diseases, including acute respiratory infections (ARIs), tuberculosis, asthma, chronic obstructive pulmonary disease, pneumoconiosis, and lung cancer. Current studies mainly focus on certain susceptible populations, including children, women, elderly people, and patients with chronic respiratory diseases, especially in developing countries.

Among the children, the analysis of data from the China Health and Nutrition Survey suggested that female children had an elevated risk of ARIs when exposed to solid fuel combustion emissions (Chen and Modrek 2018). When it comes to specific pollutants, evidence from birth cohort studies showed indoor particulate matter was associated with lower respiratory tract illness among children (Vanker et al. 2017). A panel study among 150 children found that increased in-home PM_{2.5} and PM_{2.5–10} concentrations were associated with significant increases in asthma symptoms and rescue medication use (McCormack et al. 2011). Additionally, a meta-analysis of the observational studies found that indoor formaldehyde was significantly associated with an increased risk of asthma in children (OR = 1.10, 95% CI: 1.00, 1.21, per 10 µg/m³) (Yu et al. 2020). These studies were mainly conducted in developing countries where household solid fuel was still widely used and indoor air pollution was severe. However, a meta-analysis of epidemiological studies from developed countries did not find significant association between indoor wood burning and respiratory outcomes in children including wheeze, cough, asthma, lower respiratory infection (LRI), and upper respiratory infection (URI) (Guercio et al. 2021).

Among the adults, previous studies also reported the significant association of indoor air pollution caused by wood or coal use for cooking and heating with increased risks of respiratory diseases, symptoms, such as cough, wheezing, dyspnea and phlegm, and lung function decline. A cohort study of 277,838 Chinese never-smokers found that compared with clean fuel users, solid fuel users had a higher risk for major respiratory diseases (HR = 1.36, 95% CI: 1.32, 1.40) including chronic lower respiratory disease (CLRD), COPD, and acute lower respiratory infection (ALRI) (Chan et al. 2019). Indoor air pollution has been also associated with the development of lung cancer. For example, a prospective cohort of never-smoking women in Shanghai ($N = 71,320$) found that indoor air pollution from poor ventilation of coal combustion could increase the risk of lung cancer (Kim et al. 2015a).

The elderly have shown higher sensitivity to particulate pollution and they tend to spend most of their time indoors. Therefore, the effect of indoor air pollution on the respiratory health of elderly people was also widely investigated. The evidence from

China Health and Retirement Longitudinal Study (CHARLS) suggested solid fuel use could significantly increase the possibility of chronic lung diseases and exacerbation of chronic lung diseases (Liu et al. 2018). A cohort study of 6,818 middle-aged and older adults found that solid fuel use in cooking and heating was associated with reduced PEF, especially in those aged >65 years, females, and smokers (Xia et al. 2021b). In general, indoor air pollution, especially those associated with solid fuel combustion, has been associated with multiple adverse respiratory outcomes in the population, and these effects should be of particular concern for certain susceptible populations.

Effects on the Cardiovascular System

A wide range of empirical investigations across different geographical regions and populations have been conducted to evaluate both pathogenic and subclinical effects on cardiovascular health associated with long-term cumulative exposure to indoor air pollutants. Meanwhile, the heterogeneity of exposure-health associations, particularly for the susceptible population subgroups have also received increasing attention.

It's difficult to perform long-term real-time indoor air pollutants monitoring in large population studies. Accordingly, most studies used qualitative variables as proxies for indoor pollutant exposures, representative of household fuels use, and passive smoking. Globally, polluting fuels and technologies were associated with excessive risks of 7% (95% CI: 4%, 11%) for cardiovascular mortality, as well as 9% (95% CI: 4%, 14%) for cerebrovascular diseases, 10% (95% CI: 9%, 11%) for ischaemic heart disease (IHD), and 13% (95% CI: 5%, 22%) for cardiovascular events (Lee et al. 2020). A meta-analysis based on 23 prospective and 17 case-control studies found that, compared to never smokers, exposure to second-hand smoking was significantly associated with increased risk of cardiovascular diseases (RR = 1.18, 95% CI: 1.10, 1.27) (Lv et al. 2015).

Interestingly, a cohort of 16,323 non-smoking women in Xuanwei, China, found that higher lifetime exposure intensity to smokeless coal was significantly associated with higher IHD mortality. However, the association between higher lifetime exposure to smoky coal and IHD mortality was much less significant (Bassig et al. 2020). The authors emphasized that, although smokeless coal was considered a cleaner fuel, it might be associated with excessive health risks (Bassig et al. 2020). From the ecological perspective, a cross-sectional study in England found that energy efficiency metrics (mean energy performance rating) were associated with a 0.5% increase in CVD hospital admissions, indicating that more energy efficiency improvements might result in higher admission rates for CVD (Sharpe et al. 2019).

Long-term associations of indoor air pollutants with subclinical outcomes are to a considerable extent beyond the debate of "adaptive theory," namely, the compensatory reactions to acute exposure to negative irritants in humans.

To date, evidence on associations of indoor air pollutants with blood pressure is still limited and also inconsistent. Based on 77,605 largely premenopausal women from 12 resource-poor countries, the Demographic and Health Surveys (DHS) found

that history of solid fuels use (vs clean fuels use) was associated with 0.58 mmHg higher SBP (95% CI: 0.23, 0.93), 0.30 mmHg higher DBP (95% CI: -0.12, 0.72), and 0.31 mmHg higher PP (95% CI: 0.14, 0.75) (Arku et al. 2018). However, with evidence on 43,313 rural participants in ten countries within the Prospective Urban and Rural Epidemiology (PURE) study, the authors found decreased SBP of 0.48 mmHg (95% CI: -0.95, -0.01) and decreased DBP of 0.44 mmHg (95% CI: -0.72, -0.15) among people using solid fuels compared to those using clean fuels (Arku et al. 2020). Chronic exposure to indoor biomass fuels was also associated with changes in biomarkers of oxidative stress and endothelial inflammation (Caravedo et al. 2016). As for cardiac function, daily biomass fuel has been linked to increased left ventricular internal diastolic diameter, left atrial diameter, and left atrial area, suggesting increased size and decreased systolic function of left ventricular (Burroughs Peña et al. 2017).

Trial methods, although not as widely as in short-term studies, have also been used to provide further evidence on this topic. A long-term randomized crossover intervention study based on 200 homemakers from Taiwan found that indoor air pollutants were significantly associated with increased BP, hs-CRP, and 8-OHDG. Meanwhile, compared to the control phase, those indicators were significantly better in the air filtration intervention phase, supporting the subclinical cardiovascular effects such as activated systematic inflammatory status when exposed to indoor air pollutants (Chuang et al. 2017). In addition, a real-world study found that, compared to women receiving energy packages (a facility promoted by the government of China as next-generation of clean technologies), those not receiving the packages had greater mean decreases in brachial SBP and DBP (Clark et al. 2019). This evidence implied the importance of further evaluations on the pros and cons of new measures (e.g., cleaner products) in the real-world context before formulating environmental policies at the population level.

Emerging studies on the health effects of indoor air pollutants are showing solicitude for the heterogeneity in exposure-response relations across regions in different urbanization stages. Urbanization profoundly shapes the environment, human settlements, lifestyles, and health behaviors, and thus posts mixed effects on population health (Liang et al. 2021). Areas with a lower social development index (SDI) were traditionally regarded as the susceptible regions of indoor air pollutants. One possible reason is the absence or delay of urbanization settings (e.g., cleaner technologies, which can effectively reduce the hazard composition of air pollution emissions) in less-developed areas. Meanwhile, regional age structures and sex proportions are also thought to be potential driving factors, but current evidence has still been unable to provide a clear conclusion (Lee et al. 2020; Lv et al. 2015).

There have also been several different findings. For instance, based on over 90,000 adults from 467 urban and rural communities in 11 low- to middle-income countries (LMIC), the aforementioned PURE study found stronger associations of the incidence of cardiovascular diseases with solid fuel use in people from urban areas, higher education levels, and with the highest home wealth index (Hystad et al. 2019), despite that the associations for all-cause mortality generally showed an inverse trend (Hystad et al. 2019). Apart from differences in disease characteristics,

further studies are still warranted to identify this susceptibility, particularly in terms of socio-economic factors associated with the regional urbanization process.

Effects on Other Systems

The health effect of long-term exposure to indoor air pollution has been also examined in other outcomes, mainly including mental health and abnormal development and physical function. An analysis of data from four visits of 7,005 middle- and old-age adults in the CHARLS found that long-term household air pollution exposure from solid fuel use was significantly associated with higher depression risk among Chinese older adults ($HR = 1.27$, 95% CI, 1.14–1.42 in heating; 1.26, 1.13–1.40 in cooking) (Li et al. 2021). This study also observed that longer durations of indoor air pollution exposure and the exposure from crop residue/wood burning were associated with higher depression risk. The evidence from CHARLS also found that solid fuel use for cooking and heating was significantly associated with a higher risk of cognitive impairment including episodic memory, orientation, and attention dimension, and the association was stronger among participants who were females, aged ≥ 65 years old, had low education level or had cardiovascular diseases (Luo et al. 2021). Indoor air pollution is also associated with abnormal growth and development in children and declined physical function of the elderly. A meta-analysis examined the association between indoor air pollution exposure and postnatal stunting and found that compared with cleaner fuels, exposure to indoor air pollution from solid fuel was significantly associated with a higher risk of stunting among children aged <5 years old ($OR = 1.19$, 95% CI, 1.10–1.29) (Pun et al. 2021). In addition, a study of 12,458 middle-aged and elder participants from CHARLS reported that solid fuel use in cooking was associated with the self-reported and performance-based physical functioning decline (Cao et al. 2021).

Specific Examples

Environmental Tobacco Smoke

Environmental tobacco smoke (ETS) itself is a complex mixture, representing the combination of side stream smoke with exhaled mainstream smoke. ETS is an irritant and significant indoor air pollutant. Active smoking exposes the smoker to approximately 16 times the ETS concentration, and 100- to 300-fold the total smoke dose experienced by a nonsmoker (Smith and Ogden 1998). Despite the much lower smoke exposure, it is known to cause lung cancer, heart disease, chronic obstructive pulmonary disease (COPD), emphysema, and other serious diseases in smokers and in non-smokers as well. According to EPA, ETS causes 3000 lung cancer deaths in adult nonsmokers (roughly 100 million never-smokers and long-term former smokers) in the United States each year; ETS is responsible for between 1,50,000 and 3,00,000 lower respiratory tract infections annually in the roughly 5.5 million children under 18 months of age, and that it exacerbates asthma in about 20% of asthmatic children (U.S.EPA 1992). WHO has estimated that 9–13% of all cancer

cases can be attributed to ETS in a nonsmoking population of which 50% are exposed to ETS (WHO 2009). The proportion of lower respiratory illness in infants attributed to ETS exposure can be estimated at 15–26% (WHO 2009).

Chemical Composition and Exposure Evaluation

ETS is a complex mixture of nearly 5,000 chemical compounds. This mixture contains 43 chemicals that have met the criteria of a known human or animal carcinogen established by the International Agency for Research on Cancer. Common carcinogens in ETS include arsenic, cadmium, benzo-pyrenes, nitrosamines, and vinyl chloride. Other chemical components that are likely to have detrimental effects on the cardio-respiratory system are carbon monoxide which causes the formation of carboxyhemoglobin, and polycyclic aromatic hydrocarbons which increase the size of spontaneous aortic lesions. Other toxicologically significant chemicals include aldehydes (acrolein, formaldehyde), hydrogen cyanide, nitrogen oxides, benzene, toluene, phenols (phenol, cresol), aromatic amines (nicotine, ABP (4-aminobiphenyl)), and harmala alkaloids (WHO 2009). The radioactive element polonium-210 is also known to occur in tobacco smoke (WHO 2009).

As ETS is a dynamic complex mixture of thousands of compounds in particulate and vapor phases, it cannot be measured directly as a whole. Instead, various marker compounds, such as nicotine and respirable suspended particles (RSPs), are used to quantify environmental exposure. In the United States, nicotine concentrations in homes where smoking occurs typically range from less than 1 $\mu\text{g}/\text{m}^3$ to over 10 $\mu\text{g}/\text{m}^3$ (U. S. EPA 1992). Concentrations in offices where people smoke typically range from near zero to over 30 $\mu\text{g}/\text{m}^3$. Levels in restaurants, and especially bars, tend to be even higher, and concentrations in confined spaces such as cars can be higher still. Measurements of ETS-associated RSPs in homes where people smoke range from a few $\mu\text{g}/\text{m}^3$ to over 500 $\mu\text{g}/\text{m}^3$, while levels in offices are generally less than 100 $\mu\text{g}/\text{m}^3$, and those in restaurants can exceed 1 mg/m³. ETS levels are directly related to smoker density; in countries with a higher smoking prevalence, average ETS levels could be higher (WHO 2000).

Health Effects

Experimental evidence has shown the presence of a tobacco-specific carcinogen in the urine of ETS-exposed nonsmokers (Hammond et al. 1993).

Lung cancer

Many health organizations concluded that exposure to ETS increases the risk of lung cancer. The U.S. Environmental protection Agency (EPA) has declared ETS as a known human lung carcinogen based on the following total weight of evidence: (1) chemical composition of ETS and MS, including over 40 known or suspected human carcinogens; (2) the known lung carcinogenicity of MS, with clear exposure-response relationships down to low levels and no evidence of a threshold; (3) supporting evidence from animal bioassays and genotoxicity tests; (4) measured exposure to, and bodily uptake of, ETS constituents; and (5) the consistent exposure-

related increases in risk seen in so many epidemiological studies from different countries using different designs.

The largest and best designed case-control study (Fontham et al. 1994), with 665 cases and a large percentage of direct case interviews, found statistically significant overall increases and exposure-response trends for never-smoking United States women exposed to spousal (30% excess risk), workplace (40% excess risk), and social (50% excess risk) ETS. Another study, the Dutch nested case-control study of de Waard et al. (1995), is noteworthy because although it consisted of only 212 nonsmoking females (23 cases and 191 controls), past nonsmoking status and ETS exposure were determined by biomarker measurements (cotinine level in a 12-h urine sample taken up to 15 years prior to case ascertainment) rather than on the basis of questionnaire responses as in the other ETS-lung cancer epidemiology studies. The results, although not statistically significant, yielded an odds ratio (OR) of about 2.6 for lung cancer from ETS exposure. A recent meta-analysis study (Hacksaw et al. 1997) used the data from 37 published epidemiological studies of nonsmokers who did and did not live with smokers. The excess risk of lung cancer was 24% (95% confidence interval (CI) 13–38%, $P < 0.001$) in nonsmokers who lived with a smoker. The excess risk-adjusted for the effects of bias and dietary confounding, was 26% (7–47%). The dose-response relationship for the risk of lung cancer with the number of cigarettes smoked by the spouse and with the duration of exposure were significant.

Other Cancers

The review by Tredaniel et al. (1994) evaluated the limited epidemiological evidence from studies of ETS and adult sinus, bladder, breast, and uterine cervix cancers, as well as possible cancers of other sites where the evidence is very scarce. They concluded that there was suggestive evidence of an association between ETS with sinus cancer. However, they found no association between ETS with bladder cancer, and equivocal evidence of associations with breast and cervical cancer.

The conclusion between ETS and sinus cancer was based on two positive studies on Japanese female never-smokers. Researchers found strong exposure-response relationships. However, the number of the total cases was only 60. A study in the United States has also reported a statistically significant increased risk for never-smoking men with wives who smoked ($OR = 3.0$, 95% CI = 1.0, 8.9), based on 28 cases (Zheng et al. 1994). Considering these consistent exposure-related responses and the strong supportive evidence, including the known causal association of active smoking and sinus cancer, the known causal association of ETS and lung cancer, and the fact that the nasal sinuses are generally the site of first contact of ETS. There is strong suggestive evidence that ETS is causally associated with sinus cancer.

It has been suggested that bladder cancer may be associated with exposure to ETS although the epidemiological evidence from the two studies reviewed by Tredaniel et al. (1994) and a study by Hirayama (1992) is equivocal. An association between ETS and cervical cancer has also been suggested, but few existing studies provide contradictory findings. The two studies of nonsmokers reviewed by Tredaniel et al.

are generally positive, and a third study found no consistent increases (Coker et al. 1992), while a Japanese cohort study reported a RR estimate of about 1.3 for nonsmoking wives of heavily smoking husbands (Hirayama 1992).

Wells (1991) reviewed data from two epidemiological studies and suggested that there may be an association between ETS exposure and breast cancer in nonsmokers. Two other studies have also found evidence of an association between EST and breast cancer (Smith et al. 1994; Morabia et al. 1994), with RR estimates ranging from about 1.3–2.4. However, no consistent association between active smoking and breast cancer has been established.

Non-cancer Respiratory Health Effects

ETS affects the developing respiratory system and causes an increased risk of the following health effects in children: (1) lower respiratory tract infections (e.g., bronchitis, bronchiolitis, and pneumonia) in infants and young children; (2) chronic middle-ear effusion in young children; (3) increased frequency and severity of asthma attacks in asthmatic children; (4) irritation of the upper respiratory tract; and (5) reduced lung function.

Adult nonsmokers exposed to ETS may experience small reductions in lung function and an increased frequency of respiratory symptoms. A review by Tredaniel et al. (1994) found no consistent evidence for an association between ETS and chronic respiratory symptoms or chronic obstructive pulmonary disease, including asthma, although decreased lung function from ETS exposure was noted. Symptoms of acute irritation of the eyes and respiratory tract were found to be associated with ETS exposure. Bascom et al. (1996) observed symptoms of eye and nose irritation, odor perception, and headache in subjects exposed to SS under controlled conditions. They also reported increased nasal congestion in the highest exposure group. Most of the field and laboratory studies of annoyance and acute irritation effects of ETS have focused on adults. However, these effects are likely to occur in children as well, since they are even more sensitive than adults to other non-cancer respiratory effects of ETS.

Cardiovascular Effects

According to the results of epidemiological and experimental studies, environmental tobacco smoke has significant harmful effects on the cardiovascular system. Epidemiological studies clearly show that active smoking has a causal relationship with cardiovascular disease. In addition, ETS also has an impact on cardiovascular disease in non-smokers. Studies of cardiovascular disease morbidity and mortality in ETS and non-smokers vary based on disease outcome (e.g., fatal and/or non-fatal events), gender, and alternative measures of ETS exposure (e.g., spouse smoking, cohabiting smoking, and work exposure). They also vary greatly in size and potential confounding factors for inspection. Steenland (1992) derived a quantitative risk estimate of 35,000–40,000 ETS-attributable deaths from heart disease per year among never-smokers and long-term smokers in the United States.

Mechanism studies have shown that acute ETS exposure will have cardiovascular effects on the human body. The main effects include decreased oxygen-carrying capacity leading to decreased exercise capacity and potential ischemia, as well as increased platelet activation, endothelial damage, changes in lipoprotein levels, and increased arterial wall thickness, which promotes atherosclerosis. In the case of platelet activation, ischemia, and atherosclerosis increase the risk of myocardial infarction and other serious cardiovascular diseases.

In different studies from different countries, the overall risk increase and exposure-response increase trends are consistent. The increased risk of these fatal and non-fatal cardiovascular events was observed from exposures to actual environmental levels of ETS. A large cohort study (Helsing et al. 1988) reported the estimated RR of death from arteriosclerosis caused by family ETS exposure, which was 1.31 for men and 1.24 for women, adjusted for a series of confounding factors. A significant exposure-response relationship was observed in women, but not in men. This study did not adjust for important cardiovascular disease risk factors, such as high blood pressure, diet, and serum cholesterol. The second large-scale study (Hirayama 1984, 1990) observed that women have a slightly increased risk of death from coronary heart disease due to their spouse smoking, and the exposure-response trend is significant. Both studies indicate that, as observed for active smoking, the relative risk increase in younger age groups may be greater. Smaller cohort studies reported that after adjusting for various confounding factors, marrying or cohabiting with a smoker resulted in an increased overall risk of many fatal and non-fatal cardiovascular disease endpoints (WHO 2000). Svendsen et al. (1987) reported an estimated adjusted RR of 2.23 (95% CI, 0.72–6.92) for deaths from coronary heart disease, and an estimated RR of 1.61 (95% CI, 0.96–2.71) for fatal or non-fatal coronary heart disease events caused by wife smoking and positive exposure. Case-control studies (He et al. 1989; La Vecchia et al. 1993; He et al. 1994) also examined a large number of risk factors for cardiovascular disease. The odds ratio of acute myocardial infarction resulting from a combination of marriage and current smoker is 1.21 (95% CI, 0.57–2.52); 1.50 (95% CI, 1.28–1.77) represents female coronary heart disease, 1.85 (95% CI, 0.86–4.00) represents women's non-fatal disease cases due to exposure at work, and 1.24 (95% CI, 0.56–2.72) from reports of husband smoking. In addition, positive contact trends were reported. In addition to cohort studies and case-control studies, there are also cross-sectional studies examining cardiovascular disease incidence and ETS. A statistically significant exposure-response relationship was observed. Serum cotinine is only closely related to diagnosed coronary heart disease.

Other Health Effects

Furthermore, as with active smoking, ETS reduces birth weight in the offspring of nonsmoking mothers. In infants, recent evidence suggests that ETS is a risk factor for sudden infant death syndrome (WHO 2000).

Guidelines

ETS has been found to be carcinogenic in humans and to produce a substantial amount of morbidity and mortality from other serious health effects at levels of 1–10 µg/m³ nicotine (taken as an indicator of ETS). Acute and chronic respiratory health effects on children have been demonstrated in homes with smokers (nicotine 1–10 µg/m³) and even in homes with occasional smoking (0.1–1 µg/m³). There is no evidence of a safe exposure level. The unit risk of cancer associated with lifetime ETS exposure in a home where one person smokes is approximately 1×10^{-3} (WHO 2000).

Radon

Radon is a radioactive gas that has no smell, color, or taste. Radon emanates from rocks and soils and tends to concentrate in enclosed spaces like underground mines or houses. Radon is a major contributor to the ionizing radiation dose received by the general population. The most important source of residential radon is soil gas infiltration. Other indoor sources are building materials.

Radon is the second cause of lung cancer in the general population, after smoking. The majority of radon-induced lung cancers are caused by low and moderate radon concentrations rather than by high radon concentrations, because in general less people are exposed to high indoor radon concentrations. Current estimates of the proportion of lung cancers attributable to radon range from 3% to 14%, depending on the average radon concentration in the country concerned and the calculation methods (WHO 2009). Most of the radon-induced lung cancer cases occur among smokers due to a strong combined effect of smoking and radon.

The World Health Organization first drew attention to the health effects from residential radon exposures in 1979, through a European working group on indoor air quality. Further, radon was classified as a human carcinogen in 1988 by International Agency for Research on Cancer (IARC), the WHO specialized cancer research agency.

Health Effects

Lung Cancer

There is overwhelming evidence that radon is acting as a cause of lung cancer in the general population at concentrations found in ordinary homes. In addition, the dose-response relationship appeared to be linear, with no evidence of a threshold, and there was substantial evidence of a risk increase even below 200 Bq/m³, the concentration at which action is currently advocated in many countries (WHO 2009).

According to Gray et al. (2009), 3.3% of deaths from lung cancer in the UK (one in 516 of all deaths) were caused by radon in the home in 2006 with an average Rn level of 21 Bq/m³. Overall, 48% of radon-related deaths occurred in adults aged 55–74. Most of the remainder occurred in those aged more than 75, with only 6% at ages less than 55, and virtually none below age 35. 58% of radon-related deaths were in

men. The risk for former smokers is substantially lower than for continuing smokers, even for those stopping as late as age 50, but it remains considerably above the risk for lifelong non-smokers.

Only an estimated 0.4% of homes in the UK would have measured radon concentrations of 200 (mean 304) Bq/m³ or higher. Although people living in such homes have a greater risk than those living in homes with lower measurements, few such people exist. The estimated percentage of deaths from radon-related lung cancer in homes with measurements of 200 Bq/m³ or more is 4%, with measurements of 100–199 Bq/m³ is 9%, and with measurements of 50–99 Bq/m³ is 17%. The remaining 70% of deaths from radon-related lung cancer are in homes where the measurement would be below 50 Bq/m³.

Surveys have been carried out to determine the distribution of residential radon concentrations in most of the 30 member countries of the Organization for Economic Co-operation and Development (OECD). The worldwide average indoor radon concentration has been estimated at 39 Bq/m³. Detailed calculations of the numbers of radon-induced lung cancers attributable to radon exposure have previously been published for a number of countries. The calculations are based on the estimated concentrations of indoor radon from the surveys and the indirect estimates of risk provided either by the studies of miners in the BEIR VI analysis or by the direct evidence provided by the European pooling studies (Table 1).

Other Diseases

Other diseases that can be induced by indoor radon include leukemia, and multiple sclerosis. Cardiovascular disease may be also associated with indoor radon.

Table 1 Estimates of the proportion of lung cancer attributable to radon in selected countries (WHO 2009)

Country	Mean indoor radon (Bq/m ³)	Percentage of lung cancer attributed to radon	Estimated no. of death due to radon-induced lung cancer each year
Canada (Brand et al. 2005)	28	7.8	1400
Germany (Menzler et al. 2008)	49	5	1896
Switzerland (Menzler et al. 2008)	78	8.3	132
United Kingdom (AGIR 2009)	21	3.3	1089
		6	2005
France (Catelinois et al. 2006)	89	5	1234
		12	2913
United States (BEIR VI 1999)	46	10–14	15,400–21,800

Rericha et al. (2006) evaluated the incidence of leukemia, lymphoma, and multiple myeloma in Czech uranium miners. They found a positive association between radon exposure and leukemia, including chronic lymphocytic leukemia. The relationship between radon exposure and cardiovascular disease has been examined in a number of cohorts of radon-exposed miners, but none has found evidence that radon could cause heart disease. A case-control study of stomach cancer in an area where there were high concentrations of natural uranium and other radionuclides in drinking water gave no indication of an increased risk (Auvinen et al. 2005).

About 20 ecological studies of exposure to radon in the general population and leukemia either in children or in adults have been carried out. Several of these, including a recent methodologically advanced study by Smith et al. (2007), have found associations between indoor radon concentration and the risk of leukemia (including chronic lymphocytic leukemia in the Smith et al. study) at the geographic level. An ecological study performed in Norway showed an association between multiple sclerosis and indoor radon concentration (Bolviken et al. 2003). Generally, these associations have been confirmed in a high-quality case-control or cohort study, either in radon-exposed miners or in the general population, although several such studies have been carried out (Laurier et al. 2001, Mohner et al. 2006). As with the studies of radon exposure and lung cancer, these ecological studies are prone to a number of biases. They are therefore likely to give misleading answers and should not be taken as evidence that radon is acting as a cause of these diseases.

Guidelines

Currently, no federal regulations govern acceptable radon levels for indoor residential and school environments. However, guidelines are available. The United States Environmental Protection Agency (US EPA) and the Surgeon General strongly recommend that all homes be tested for radon and, if levels are elevated, residents are urged to consider remediation. The US EPA's action guideline is 4 pCi/L (148 Bq/m³) for the indoor radon concentration (WHO 2009).

Nitrogen Dioxide (NO₂)

Nitrogen dioxide (NO₂) is a nitrogen oxide associated with combustion sources. It exists in the air in its gaseous form. NO₂ is volatile, reddish-brown in color, and heavier than air, and has a characteristic pungent odor perceptible from a concentration of 188 µg/m³ (0.1 ppm) (WHO 2010). Indoor levels of nitrogen dioxide are a function of both indoor and outdoor sources. The most important indoor sources of NO₂ include tobacco smoke and gas-, wood-, oil-, kerosene-, and coal-burning appliances such as stoves, ovens, space and water heaters, and fireplaces, particularly ones without chimneys or poorly maintained appliances. Outdoor NO₂ from natural and anthropogenic sources also influences indoor levels. Road traffic is the principal outdoor source of nitrogen dioxide.

Health Effects

There is evidence that NO₂ is associated with an increase in respiratory symptoms among the general population, particularly in children, in a range of epidemiological studies that the authors have previously reviewed. Results of longitudinal studies on asthmatic populations or subjects at risk of developing asthma are quite conclusive: an increase in NO₂ concentration was also associated with increased wheezing, breathing difficulty, chest tightness, shortness of breath, and cough. However, data at the general population level are more controversial. Few studies have found significantly increased risks of respiratory symptoms and asthma in association with a higher concentration of NO₂ at home or at school. Moreover, whether chronic exposure to indoor NO₂ contributes to the development of respiratory illness is unclear. Two longitudinal studies including children found a positive association between long-term exposure to indoor NO₂ and the risk of lower respiratory symptoms (U.S.EPA 2008; Brauer et al. 2006). In a Japanese cohort, exposure to NO₂ was associated with an increased risk of doctor-diagnosed asthma and bronchitis, but not with the incidence of these diseases (Morgenstern et al. 2008). Two birth cohort studies that followed 1,611 infants for one yr. and 1,205 for 18 months, and one cohort survey including 842 children enrolled at 9–10 yrs. of age did not confirm these results (Shima and Adachi 2000; Samet et al. 1993; Sunyer et al. 2004). Reasons for these conflicting results are unknown, but the difficulties in determining real exposure to indoor nitrogen dioxide could explain them in part. In homes, exposure can fluctuate depending mainly on the season of measurement in conjunction with the use of specific sources, such as gas appliances. Therefore, assessment over 1 week could not be representative of nitrogen dioxide exposure and, in particular, of peak concentrations during cooking or heating activities. Evidence of an association between exposure to indoor combustion, such as gas appliances, and asthma development and severity exists. In a randomized controlled trial, the replacement of unvented gas heaters with flued gas or electric heaters showed a decrease in nitrogen dioxide concentration (15.5 vs. 47.0 ppb, $p < 0.0001$) and a significantly reduced risk of breathing difficulty during the day and the night, chest tightness during the day and daytime asthma attacks in the intervention group (Linn et al. 1985). Finally, inconsistencies among studies may also be due to modification by other pollutants or higher susceptibility in some subgroups, such as female children (Morgenstern et al. 2008).

Guidelines

According to WHO, a one-hour indoor NO₂ guideline is 200 µg/m³; An annual average indoor nitrogen dioxide guideline is 40 µg/m³. Recent well-conducted epidemiological studies that have used measured indoor nitrogen dioxide levels support the occurrence of respiratory health effects at the level of the guideline (WHO 2010).

Formaldehyde and Volatile Organic Compounds (VOCs)

Formaldehyde and Volatile organic compounds (VOCs) are emitted as gases from certain solids or liquids. Concentrations of formaldehyde and many VOCs are consistently higher indoors (up to 10 times higher) than outdoors. Indoor sources of VOCs include building materials and furnishings, household products (paints, paint strippers and other solvents, wood preservatives, aerosol sprays, cleansers and disinfectants, moth repellents and air fresheners, stored fuels and automotive products, hobby supplies, dry-cleaned clothing, and pesticide), office equipment (such as copiers and printers, correction fluids, and carbonless copy paper), and graphics and craft materials (including glues and adhesives, permanent markers, and photographic solutions) (WHO 2010).

Health Effects

The health effects caused by formaldehyde and VOCs depend on the concentration and length of exposure to the chemicals. VOCs include a variety of chemicals that can cause eye, nose and throat irritation, shortness of breath, headaches, fatigue, nausea, dizziness, and skin problems. Higher concentrations may cause irritation of the lungs, as well as damage to the liver, kidney, or central nervous system. Long-term exposure may also cause damage to the liver, kidneys, or central nervous system. Some VOCs are suspected of causing cancer and some have been shown to cause cancer in humans.

Cancer

A number of the VOCs that are present in indoor air have been shown to cause cancer in animals exposed to high concentrations. The International Agency for Research on Cancer (IARC) has classified formaldehyde and benzene as carcinogens to humans. Estimates of the magnitudes of cancer risks posed by indoor air VOCs vary widely, with most estimates indicating that total excess individual risks for developing cancer with lifetime exposures for specific VOCs are between one in 10,000 and one in a million. Given the uncertainties in cancer risk assessment, particularly the uncertainties of extrapolating from high concentrations to typical lower indoor concentrations, or from animals to humans, as well as the limited available information on the effects of VOC mixtures, and the effects of VOCs on susceptible populations, the magnitude of the cancer risks posed by indoor VOCs will continue to have a high level of uncertainty.

Respiratory Health

Formaldehyde is one of the most studied pollutants in indoor air. Several cross-sectional studies showed an increased risk of asthma with high exposure to indoor formaldehyde, whereas some did not find any significant results (Marion et al. 2012). The first longitudinal study on the respiratory effects of indoor formaldehyde found a

significant positive association between formaldehyde concentration and incidence of asthma diagnosis (OR 1.7, 95% CI 1.1–2.6, for each formaldehyde increment of $10 \mu\text{g}\cdot\text{m}^{-3}$), but only among non-atopic children (U.S. EPA 2010). In a recent meta-analysis, McGwin et al. (2010) calculated a 17% increase in the risk of asthma (OR 1.17, 95% CI 1.01–1.36) for every $10 \mu\text{g}\cdot\text{m}^{-3}$ unit increase in formaldehyde concentration. Lastly, there is some convincing evidence of an effect of formaldehyde in asthma morbidities, such as respiratory symptoms or lung function (Marion et al. 2012).

Other indoor VOCs have been studied in relation to respiratory health. Significant associations between the indoor concentration of VOCs and asthma or asthma-like symptoms were found (Rumchev et al. 2004). This was confirmed by a survey using personal assessment of VOC exposure (Arif and Shah 2007), showing an increased risk of doctor-diagnosed asthma among those exposed to VOCs and, in particular, to aromatic compounds (OR 1.63, 95% CI 1.17–2.27). While existing studies suggest that exposure to VOC in utero could have an impact on the immune status of newborns (Baiz et al. 2011), no epidemiological study using objective measurements reports significant associations between exposure to formaldehyde and allergic sensitization.

Guidelines

For formaldehyde, the no-observed-adverse-effect-level (NOAEL) of $0.6 \text{ mg}/\text{m}^3$ for the eyeblink response is adjusted using an assessment factor of five derived from the standard deviation of nasal pungency (sensory irritation) thresholds, leading to a value of $0.12 \text{ mg}/\text{m}^3$, which has been rounded down to $0.1 \text{ mg}/\text{m}^3$. This threshold should not be exceeded at any 30-min interval during the day. The NOAEL for cell proliferation is $1.25 \text{ mg}/\text{m}^3$ for long-term exposures. An interspecies assessment factor of three is proposed because the effect is local (non-systemic) and directly due to formaldehyde itself; for inter-individual variation, an assessment factor as low as two is proposed because sensitivity differences are not seen among different populations (asthmatics, children, and older people). This process would lead to a proposed guideline of $0.21 \text{ mg}/\text{m}^3$ for the protection of health for long-term effects, including cancer (WHO 2010).

For benzene, there is no known exposure threshold for the risks of benzene exposure. The concentrations of airborne benzene associated with an excess lifetime risk of 1/10,000, 1/100,000, and 1/1,000,000 are 17, 1.7, and $0.17 \mu\text{g}/\text{m}^3$, respectively. Therefore, from a practical standpoint, it is expedient to reduce indoor exposure levels to as low as possible (WHO 2010).

For trichloroethylene (ACE), carcinogenicity (with the assumption of genotoxicity) is selected as the end-point for setting the guideline value. The unit risk estimate of $4.3 \times 10^{-7} (\mu\text{g}/\text{m}^3)^{-1}$, derived on the basis of increased Leydig cell tumors (testicular tumors) in rats, is proposed as the indoor air quality guideline. The concentrations of airborne TCE associated with an excess lifetime cancer risk of 1:10,000, 1:100,000, and 1:1,000,000 are respectively 230, 23, and $2.3 \mu\text{g}/\text{m}^3$ (WHO 2010).

For tetrachloroethylene (PERC), on the basis of the overall health risk evaluation, the recommended guideline for year-long exposure is $0.25 \text{ mg}/\text{m}^3$ (WHO 2010).

Conclusions and Outlook

In summary, the adverse health effect of indoor air pollution cannot be ignored. Even low-level exposure to indoor pollutants may have adverse health effects, especially for children, pregnant women, and people with chronic diseases. In general, the research on indoor air pollution and health has made some progress in the past 10 years, but there are still some shortcomings, and it is expected that in-depth systematic research will be carried out in the future.

1. Previous studies have mostly focused on indoor particulate matter and population health, and the population epidemiological research on indoor gaseous pollutants is relatively limited, especially in developing countries such as China where indoor pollution is more serious. Current researchers mostly focus on the short-term effects of pollutants. It is necessary to carry out more long-term research in the future to clarify the effect of indoor particulate matter on the cardiopulmonary health of patients with COPD.
2. Studies on the indoor environment and population health mostly focused on healthy people. Research evidence specifically for chronic disease patients, children, pregnant women, and other susceptible populations is relatively insufficient. The health outcomes are mostly cardiopulmonary health. In the future, the health effects of indoor air pollution on other organs and systems of the population need more attention.
3. There is insufficient evidence on the sources, characteristics, and health contributions of indoor air pollutants. In addition to outdoor penetration, the sources of indoor pollutants also include indoor cooking, human activities, smoking, and other important indoor sources, which may be more complex. In addition, the health threats of biological components of indoor particulate matter cannot be ignored.
4. So far, research on the biological mechanism of the human health hazards caused by different indoor pollutants is very limited: the population exposure and its biological mechanism are not very clear, and the relationship between the population's exposures to indoor pollutants has not been clearly established. Therefore, in-depth mechanism research is still needed. The rapid development of transcriptomics, proteomics, metabolomics, microbiome, and other omics technologies provides a good opportunity for mechanism research.
5. The intervention of indoor air pollution and its population health impact is also an emerging topic.

Abstract

Public awareness of the importance of air quality in general, and of indoor air in particular, has grown over the past few decades. Sick building syndrome was an early indicator of this awareness, but harmful chemicals are still used in the manufacture of building materials, furniture, carpets, and other items used daily. Since people spend a significant amount of time indoors, extensive attention is being paid to health problems caused by indoor air pollutants. By examining changes in biomarker levels after an animal is exposed to indoor air pollutants, animal tests have been shown to be an effective way to evaluate health impacts, and to understand the underlying toxicological mechanisms, before examining the impacts on people. In this chapter, we discuss the fundamental principles of animal testing and describe the latest progress in the study of health impacts of indoor air pollutants. We review a number of experiments where laboratory animals are exposed to certain environmental pollutants and present their findings. Detailed descriptions of the toxicity mechanisms and the corresponding intervention measures are given, and strategies for the prevention and treatment of related diseases caused by indoor pollutants are also outlined.

Toxicology study · Animal models · Health risks · Exposure · Molecular mechanism · Toxicity

Introduction

As has been noted in other chapters of this handbook, one of the reasons that so much research is focused on indoor air pollution is that people generally spend a significant portion of their time indoors, which makes indoor air quality extremely important to human health. Extensive research has shown that poor indoor air quality can induce or exacerbate a number of diseases such as allergic asthma and some types of cancers. To avoid these health impacts, it is indispensable to understand how and why these pollutants affect the body. Human epidemiological studies are limited, since it is impossible for us to conduct some biomedical analysis on human being, for example, the irreversible exposure and tissue slice analysis, and this has limited in-depth study. Thus, animal tests are needed to enable us to rigorously investigate the underlying mechanisms that result in negative health outcomes from being exposed to various pollutants.

Definition of Animal Test

Normally, animal test, also known as in vivo testing, refers to the use of nonhuman living organisms in experiments, in order to control the variables that could influence the behavior or biological system under study. On the one hand, animal testing is in contrast to studies of animals in their natural habitats (Franco et al. 2017), and on the other hand, animal testing is in contrast to in vitro studies that are conducted with microorganisms, cells, or biological molecules outside of their normal living environments (Barré-Sinoussi and Montagutelli 2015).

A Brief History of Animal Test

The origins of animal experiments can be traced back to the ancient Greek period in which written records from as early as the fourth century BC has been found. Writings by Aristotle and Erasistratus are among the earliest recorded accounts of experiments being performed on living animals (Cohen and Loew 2002). Animal testing has played a vital role in advancing scientific and medical research since its beginnings. In the twelfth century, an experimental method for testing surgical procedures on animals before using them on human patients was introduced by an Arabic physician named Avenzoar (Abdel-Halim 2005, 2006). The germ theory of medicine was convincingly demonstrated by introducing anthrax in sheep in the 1880s by Louis Pasteur, the famous French chemist and microbiologist (Mock and Fouet 2001). In the 1890s, Ivan Pavlov, a Russian physiologist, conducted a series of famous experiments on dogs to demonstrate what he called classical conditioning (Windholz 1987). In 1922, the first isolation of insulin from dogs was achieved, and thereafter the hormone has helped millions people who suffer from diabetes (Gorden 1997). The first transgenic mammal was created in 1974 by integrating simian DNA into the mouse genome, marking an important milestone in the genetic modification of animals (Jaenisch and Mintz 1974). Later, the birth of the first cloned sheep, Dolly, in 1996, demonstrated the possibility of producing cloned mammals from mature cells in specific body parts (Niemann et al. 2008).

Controversy and Principles

Although animal testing has contributed significantly to the advancement of human biomedicine, criticism and controversy have also followed. In 1655, the Irish physiologist Edmund O'Meara wrote that “the miserable torture of vivisection places the body in an unnatural state” (Maehle and Trohler 1987; Ryder 1989). O'Meara believed that vivisection caused so much pain to the animal, that it could affect the actual physiology during the process, leading to unreliable results. There were also ethical objections to the abuse of animals for the sole benefit of humans (Maehle and Trohler 1987). On the other side of the debate, people believed that animal testing was necessary to increase knowledge from both medical and biological perspectives. Claude Bernard, a renowned physiologist who considered

vivisection to be essential for physiological research (Lafollette and Shanks 1994), believed that “the science of life is a superb and dazzlingly lighted hall which may be reached only by passing through a long and ghastly kitchen” (Nurunnabi et al. 2012). Another physiologist, Dr. Walter B. Cannon said “The antivivisectionists are the second of the two types Theodore Roosevelt described when he said, ‘Common sense without conscience may lead to crime, but conscience without common sense may lead to folly, which is the handmaiden of crime.’” (Nicoll 1991).

Since it is really hard to determine whether or not humans should use animal testing for our own benefit, guiding principles for more ethical use of experimental animals (the 3Rs) must be taken seriously. First proposed by Russell and Burch in 1959 (Russell and Burch 1960), these principles are:

Replacement: the substitution for conscious living higher animals with insentient material.

Reduction: reducing the numbers of animals used to obtain sufficient information of a given precision.

Refinement: improvement in living conditions or experimental procedures to minimize pain and distress of the animals, and to enhance the welfare of these animals from birth to death.

The 3Rs are frequently presented as “the ways in which inhumanity can be and is being diminished or removed.” However, we can expand on this as follows (Tannenbaum and Bennett 2015): “Replacement minimizes research animal distress by substituting animals that can experience distress with insentient material that is incapable of feeling anything and therefore cannot experience distress. Reduction minimizes research animal distress by decreasing the number of animals that can experience distress. Refinement is, by definition, diminution or elimination of distress. This definition of refinement is not intended to suggest that replacement and reduction have a different aim. Refinement is presented as a distinct method of removing inhumanity because it focuses on the actual conduct of the research, and on how sentient research animals are treated.”

The 3Rs encourage researchers to find alternatives to animal testing, but in cases where this is not possible, animal welfare and scientific quality need to be prioritized. Globally, most researchers who are involved in animal testing implement the 3Rs, and these rules have even been incorporated into various regulations and laws (Liguori et al. 2017).

To more thoroughly implement the 3R principles, countries and organizations around the world have promulgated a set of ethical requirements for animal tests. In general, to ensure that animal experiments are performed only when necessary, any experiment that uses animals must first pass a rigorous set of ethical approvals before commencing.

Indoor Volatile Organic Compound (VOC) Pollution

VOCs are among the most important indoor air pollutants, because they are present in most building materials and can be continuously emitted over a long period, thus posing a greater health risk due to this long-term exposure (Rumchev et al. 2007).

Several hundred different VOCs have been identified in indoor air by both academic researchers and governmental organizations (Schlink et al. 2010; Zhu et al. 2013). VOCs can be divided into subgroups, including aromatic, aliphatic, chlorinated, and oxygenated hydrocarbons (Tsai 2019). The nature of indoor VOCs and their health effects are described in other chapters and will not be repeated here. There is increasing animal experimental evidence that some of these VOCs have toxic properties. In this chapter, we will introduce toxicological animal studies related to formaldehyde, benzene, and radon.

Formaldehyde and Toxic Effects

Formaldehyde (FA) is a colorless, pungent-smelling gas at room temperature, with a molecular mass of 30.03, and is easily soluble in water and ethanol (Dan et al. 2020). It is produced on a large scale and is very widely used in resins that go into a range of wood-based products including particle board and paper, plastics, and industrial chemicals. It is also used as a disinfectant and as a preservative (formalin) (Zhang et al. 2010). Due to the diversity of indoor formaldehyde sources as well as its characteristic of sustained release over a long period, indoor formaldehyde exposure is extremely common. ► [Chapter 2, “Very Volatile Organic Compounds \(VVOCs\),”](#) discusses formaldehyde in detail.

The impact of indoor formaldehyde pollution on human health can be wide ranging, quite severe, of long duration, and highly toxic. Different toxic effects on different tissues of the human body can be induced by formaldehyde, including irritation of the respiratory tract (asthma) (Neghab et al. 2011; Bono et al. 2016; Yu et al. 2020), neurotoxicity (Tang et al. 2013; Tulpule and Dringen 2013), reproductive toxicity (Merzoug and Toumi 2017), and immunotoxicity (Yu et al. 2014a; Jafari et al. 2015). High-dose formaldehyde exposure will increase the risk of acute poisoning, while low-dose formaldehyde exposure over a long period may result in chronic poisoning or even have carcinogenic effects.

In 2004, the International Agency for Research on Cancer (IARC) formed an expert working group to investigate the carcinogenicity of formaldehyde. Based on data from a systematic review of the literature, the group concluded that there was sufficient evidence that formaldehyde causes nasopharyngeal cancer in humans and classified it as a Category 1A carcinogen (WHO 2006). The group also concluded that there was “strong but not sufficient evidence for a causal association between leukemia and occupational exposure to formaldehyde” (Cogliano et al. 2005).

Health Impacts on the Respiratory System

Asthma is a complex pulmonary inflammatory disease, with typical symptoms including airway hyperresponsiveness, airflow obstruction, and airway inflammation. It is known that exposure to a number of chemicals including formaldehyde can induce asthma. To understand the underlying mechanism of FA exposure in asthma occurrence, especially when it is combined with allergen exposure, Liu et al. conducted a study with BALB/c mice, looking at the effects of combined exposure

to OVA and FA for 3 weeks, followed by a 1-week challenge with aerosolized OVA (Liu et al. 2011). Their results showed that mice exposed to both OVA and FA developed airway hyperresponsiveness and pulmonary tissue damage. There was also eosinophil infiltration, and increased levels of interleukin IL-4 and IL-6 in the lung tissue, suggesting that FA exposure can induce and aggravate asthma in BALB/c mice when it is combined with OVA immunization.

Indoor formaldehyde concentrations will vary according to changes in fresh air intake or air purification measures taken in the indoor environment. To study the effect of real daily indoor formaldehyde concentrations, Zhang et al. (2018) conducted a study exposing BALB/c mice to formaldehyde with fixed total concentrations but different exposure modes in an actual residence, and examined biomarkers related to the respiratory and the immune systems. After exposure, bronchoalveolar lavage fluid (BALF) and lung tissue homogenate were prepared and examined for oxidative stress, histopathological changes, and levels of typical inflammatory factors such as IL-4 and NF- κ B. It was found that intermittent exposure to fluctuating formaldehyde concentrations resulted in greater increases in BALF inflammatory cell numbers, and greater biological changes including apoptosis, and signs of more severe health damage compared to that seen when formaldehyde concentrations were constant. This study provides insights related to ventilation strategies that could be adopted to minimize the adverse health effects of indoor formaldehyde exposure. For example, a ventilation strategy that avoids higher peak concentrations will reduce health risks for the same average indoor formaldehyde concentration over the same time frame.

Health Impacts on the Nervous System

Individuals subjected to occupational FA exposure often exhibit abnormal behaviors such as sleep disorders, aggression, anxiety, depression, and especially, cognitive impairment. Coincidentally, patients suffering from a deficiency of melatonin (MT) also have cognitive problems such as those listed above. Mei et al. explored whether, and how, FA influences endogenous MT metabolism and induces cognitive decline by exposing healthy adult male mice to gaseous FA (3 mg/m^3) for 7 consecutive days (Mei et al. 2016). They found that FA exposure damaged spatial memory, which is linked to the death of hippocampal neurons. Biochemical analysis showed that FA exposure induced severe oxidative stress by decreasing systemic glutathione levels, especially, reducing MT levels in the brain. An intraperitoneal injection of MT obviously eased FA-induced hippocampal neuronal death, recovered MT levels in the brain, and attenuated memory decline. Injection of FA into the hippocampus markedly decreased brain MT concentrations at the tissue level. Moreover, FA was proved to directly inactivate MT in vitro and in vivo, at both cellular and molecular levels. These findings proposed that MT supplementation could be used to halt or reverse cognitive decline and can relieve mental disorders in occupationally FA-exposed populations. A recent study showed that pretreating mice with melatonin before exposing them to FA resulted in less inflammatory and oxidative impairment in the lung and liver tissues, and reduced micronuclei formation in bone marrow cells. The histological observation of lung tissue further confirmed the

parameters obtained in the biochemical studies, illustrating the possible beneficial effect of melatonin to reverse FA-induced damage (Bernardini et al. 2020).

Alzheimer's disease (AD) is a progressive neurological disorder. The number of AD cases is increasing every year, and patients are getting younger and younger. Exposure to FA occurs primarily indoors, with elderly people being more exposed because they spend more time indoors. To determine whether exposure to FA contributes to the development of AD, Liu et al. (2018) exposed C57BL/6 mice daily to FA (0, 0.155, 1.55, and 15.5 mg/kg/day) for 1 week and found that after FA exposure to high concentrations of FA (1.55 or 15.5 mg/kg/day), some early AD-like alterations, including cognitive deficits, pathological changes, accumulation of total β -amyloid plaques1-42 ($A\beta$ 1-42) and hyper-phosphorylation of tau (Tau-P) in the cerebral cortex, were found, while exposure to a low concentration of FA (0.155 mg/kg/day) had hardly any effect on the mouse brain. This study demonstrated that acute FA exposure at certain concentrations would elicit early AD-like alterations in the mouse brain. A recent study found that via upregulation of the Warburg effect, FA could induce ferroptosis in hippocampal neuronal cells (Li et al. 2021). The researchers explored the new mechanism of FA-induced neurotoxicity to help understand how to control damage to the central nervous system caused by environmental FA in normal daily life. Understanding the mechanism has provided new approaches for prevention and treatment of AD induced by FA.

Previous studies have found that the ionic receptor, N-methyl-D-aspartic acid receptor (NMDA2R), plays an important role in the development of the central nervous system and in cardiovascular regulation. Lu et al. (2008) exposed Kunming mice to formaldehyde, and then, using the Morris water maze (MWM), looked for any changes in their behavior. The forebrain tissue was examined showing that superoxide dismutase (SOD) activity and levels of glutathione (GSH) decreased remarkably in the 3 mg FA/m³ group ($P < 0.01$, compared with control group). The MWM results indicated that inhaled formaldehyde has a negative effect on learning and memory at 3 mg/m³ of gaseous formaldehyde but not at lower levels. Neuronal damage induced by oxidative stress may be the possible mechanism for these effects.

Health Impacts on the Hematopoietic System

To investigate whether formaldehyde adversely affects the bone marrow, Yu et al. (2014b) used SPF male ICR mice as the experimental animals for the study. After being exposed to formaldehyde at 20, 40, and 80 mg/m³, respectively, for 15 days in the isolated inhalation chambers, bone marrow cells were extracted. The number of WBCs and PLTs in the 40 and 80 mg/m³ groups were obviously reduced, but there was no change in the RBC numbers. There was also a reduction in the numbers of bone marrow cells and CFU-Fs in the 80 mg/m³ group. SOD activity was seen to decrease, and MDA levels increased. In addition, the researchers observed changes in cell cycling and found that there was an S phase arrest in the 80 mg/m³ group. The study proposed that formaldehyde, at a certain concentration, could induce hematopoietic toxicity by intensifying the oxidative stress. Using a similar animal experiment, this team also proved that changes in the expression of peroxidase 2 (Prx2)

(Yu et al. 2014a) and peroxidase 3 (prx3) (Yu et al. 2015) were involved in the hematopoietic toxicity of FA on bone marrow tissue.

Based on the findings that formaldehyde was considered to not directly damage hematopoietic stem/progenitor cells (HSC/HPC) in bone marrow, and that no one had previously explored whether FA had an effect on HSC/HPC cells in the mouse lung or rat nose, Zhao et al. (2021) investigated the effects of FA in this context. They hypothesized that FA inhalation could induce toxicity in the HSC/HPC cells present in the mouse lung and/or nose, rather than in the bone marrow. The researchers examined the cells of the lung, nose, bone marrow, and spleen of BALB/c mice after FA exposure. They found that in vivo exposure to FA at 3 mg/m³ or ex vivo exposure up to 400 μM FA reduced the formation of burst-forming unit-erythroid (BFU-E) cells, and colony-forming unit-granulocyte-macrophage (CFU-GM) colonies in the mouse lung and nose as well as in the bone marrow and spleen. Since these two colonies are formed by more stable myeloid progenitor cells, whether FA has a toxic effect on HSC/HPC can be judged from the quantitative changes in them. These findings were the first to empirically prove that FA exposure can damage mouse pulmonary and olfactory HSC/HPC, and provide potential biological plausibility for the induction of leukemia at the sites of entry rather than in the bone marrow.

Health Impacts on the Reproductive System

Previous studies have shown that FA exposure inhibits spermatogenesis and induces apoptosis of spermatogenic cells in testicular tissue of rodents (Zhou et al. 2006; Ozen et al. 2008). However, most of these studies involve the short-term effects from relatively high doses of FA exposure. Zhou et al. (2011) examined the more realistic situation where exposure is over a long period at a dose generally experienced indoors. They exposed 30 SD male rats to low doses of formaldehyde for 60 days. The results indicated that the reproductive toxicity of FA is dose-dependent. Sperm quantity and quality, testicular seminiferous tubular diameter, and the activities of superoxide dismutase and glutathione peroxidase were significantly decreased, while the level of malondialdehyde was significantly enhanced in rats from the 2.46 mg/m³ FA exposure group compared with those in the control group. They concluded that a level of 0.5 mg/m³ can be considered to be a safe level for FA exposure, but long-term FA exposure at a dose of 2.46 mg/m³ is harmful to the male reproductive system via inducing oxidative stress.

Merzoug and Toumi (2017) observed significant weight loss, blood immune system decline, reproductive failure, and other phenomena in young rats after exposing female Wistar rats to FA of 2 mg/kg/d during pregnancy. The phenomena of low fetal weight, fetal morphology measurement, and placental weight also appeared in the fetus. When the researchers administered the flavone hesperidin (HP), some hematological parameters improved, including reduced cortisol levels, and increased 17β-estradiol rates. This indicates that perinatal HP has a potentially preventive effect on FA toxicity.

Health Impact on Intestinal Microorganisms

After discovering that formaldehyde has toxic effects on lung tissues, neurons, and blood, Guo et al. (2018) wondered whether formaldehyde exposure could extend to the human intestinal system, and whether interactions between FA and the gut

microbiome may account for FA toxicity. This effect was confirmed by experimental animal research. Using BALB/c mice, the researchers determined through gene high-throughput sequencing, that the composition of intestinal microbiota in mice exposed to FA would change, and preliminarily explored the relevant potential metabolic processes that were behind these changes, such as α -linolenic acid metabolism and pathways in cancer. However, due to the small number of mice used in the experiment, the statistical analysis lacks certain reliability. In addition to changes in gate level, further confirmation is needed.

Benzene and Toxic Effects

Benzene, a toxic indoor ambient air pollutant, is a colorless and clear liquid at room temperature. It is volatile and soluble in water. In daily life, its main source is the combustion of wood and coal, as well as cigarettes and smoke (Loomis et al. 2017). Other indoor air sources of benzene include building materials, and furnishings, and as living standards improve, more sources of benzene have been introduced indoors. Indoor environmental pollution caused by volatile pollutants such as benzene has become more serious. Benzene is the chemical pollutant to which the human body is most frequently exposed. If it is not strictly controlled, benzene can cause strong irritation to human eyes, throat, and other parts, and poses a threat to human health (Williams et al. 2008). In 1974, the International Agency for Research on Cancer determined that benzene exposure can lead to hematopoietic toxic damage (IARC 1974). In 1982, scientists determined there was a significant correlation between benzene exposure and leukemia through a series of cohort studies (Tomatis 1982). Studies have shown that long-term exposure to benzene can cause obvious immunotoxicity in the human body, and can cause poisoning and reduce the number of red blood cells, total blood cells, and various types of white blood cells (Lan et al. 2004). In addition to leukemia, benzene exposure can increase the risk of other systemic tumors, such as lung cancer, non-Hodgkin's lymphoma, and multiple myeloma (Vlaanderen et al. 2012). The prevention and control of benzene pollution, and its influence on human health are still important indoor air pollution problems to be solved. The prevention, diagnosis, and treatment of benzene poisoning is still one of the hot issues in the field of public health.

To study the metabolic characteristics and hematopoietic toxicity mechanism of benzene poisoning, Sun et al. (2014) and others exposed C3H/HE mice by subcutaneous injection and successfully established a benzene poisoning mouse model. Histopathological examination showed that benzene inhibited the formation of hematopoietic cells in bone marrow and spleen, resulting in abnormal bone marrow morphology and differentiation. Metabolites of peripheral circulation and hematopoietic cells of the mice were obtained using the LC-MS method, and the expression levels of related protein pathways were compared. This showed that the fatty acid β oxidative metabolism pathway is a significant differential metabolic pathway. Therefore, it is of great practical significance to understand the key events in the occurrence of benzene hematopoietic toxicity and to explore the relevant mechanisms for the diagnosis, intervention, and early prevention of benzene poisoning.

To explore the immunological mechanisms of aplastic anemia, myelodysplastic syndrome, and acute myeloid leukemia, a benzene-induced hematopoietic toxicity BALB/c mouse model was established, and any changes in immune organs and T helper cell subsets (Th1, Th2, Th17, and Treg cells) were explored (Huang et al. 2021). After subcutaneous injection of 150 mg/kg benzene daily, for 28 days, the mice exhibited pancytopenia, and obvious pathological damage to bone marrow, spleen, and thymus. Flow cytometry demonstrated that the number of CD⁴⁺CD²⁵⁺Foxp³⁺ Treg cells in the spleen increased significantly. The level of IL-10 in the spleen, serum, and bone marrow increased, and levels of IL-17 in the spleen and serum decreased. These findings reveal that immunosuppression occurred in the benzene-induced hematopoietic toxicity model mice, and Treg cells and secreted IL-10 may play a key role in the process.

Formaldehyde and benzene (BZ) are both leukemic agents. Wei et al. (2017) exposed BALB/c mice to 3 mg/m³ of formaldehyde for 2 weeks, and then monitored the mice for 7 days after the exposure. The researchers included benzene (BZ) as a positive control, separately and together with FA because co-exposure occurs frequently. After 7 days of recovery, the CFU-transgenic and BFU-hepatitis E progenitor cell colonies and nucleated bone marrow cells in the mice exposed to FA were comparable to the control group, even though they were significantly reduced during the exposure period. In addition, although the increase in 8-hydroxydeoxyguanosine was not significant, the levels of reactive oxygen species (ROS) and 8-hydroxy-2'-deoxyguanosine (8-OHdG) in CFUGM and BFU-E from the mice exposed to FA did increase significantly. Levels of 8-OHdG were also higher than the controls, and levels of granulocyte-macrophage colony stimulating factor in the FA group were lower than that in the control group, while the receptor expression level was not upregulated. It is suggested that HSCs/HPCs of FA-exposed mice respond to a small amount of GM-CSF and proliferate rapidly, which may cause the possible risk of clonal expansion of abnormal stem/progenitor cells. In the postexposure period, co-exposure to FA and BZ is more effective in promoting the formation of CFU-GM and inducing the reactive oxygen species in 8-OHDG of BFU-E and CFU-GM. Compensation of myeloid progenitor cells with elevated ROS and 8-OHDG may lead to the risk of converting normal HSCs/HPCs into leukemia stem cells/progenitor cells. Therefore, co-exposure may bring a greater risk of leukemia.

Indoor Semi-Volatile Organic Compound (SVOC) Pollution

In addition to the common organic indoor air pollutants such as formaldehyde and benzene, the effect of semi-volatile organic compounds (SVOCs) on indoor air quality has attracted extensive attention. According to the World Health Organization (WHO 1989), SVOCs are a class of organic compounds with boiling points in the range of 240–400 °C and vapor pressures of $(0.1\text{--}10^{-7}) \times 133.322$ Pa, and include dioxins, polycyclic aromatic hydrocarbons (PAHs), organic pesticides, quinolines, nitrobenzenes, and phthalates. In indoor air, SVOCs are mainly found in gaseous and aerosol forms. Compared with VOCs, SVOCs have a higher boiling

point, a lower saturation vapor pressure, and stronger adsorption. Thus, it is more difficult to degrade and persists in air, water, soil, much like outdoor persistent organic compounds (Weschler and Nazaroff 2008).

The sources of SVOCs are widespread and complex, mostly man-made chemicals, including building and decorative materials, daily necessities, pollutants emitted during production and use (solvents, unreacted monomers and additives, etc.), such as plasticizers, flame retardants, monomeric raw materials, combustion products, and household insecticides (Pelletier et al. 2017). According to the research, indoor SVOCs are mainly plasticizer-like substances represented by phthalates, and high concentrations of these substances are found in some rooms which increases the risk to occupants' health (Mercier et al. 2012, 2014).

Studies have shown that SVOCs may induce multiple negative effects on the human respiratory system, endocrine system, and reproductive/genetic system through inhalation, or via oral or dermal routes, and these effects can lead to various diseases, including asthma, and allergies (Bornehag and Nanberg 2010). Using phthalates (PAEs) as an example, we analyze the relationship between indoor SVOCs and health effects.

There are currently more than 20 kinds of PAEs, that include diisononyl phthalate (DINP), di(2-ethylhexyl) phthalate (DEHP), and dibutyl phthalate (DNBP). Feng et al. (2020b) found that DIBP, DMEP, and DBP are the most common indoor PAEs. PAEs are semi-volatile, cumulative and highly toxic, are stable and long-lasting in the environment, and are common indoors. PAEs usually enter the body through breathing, the digestive tract, intravenous injection, and dermal contact. Although most PAEs are released by metabolic action, the small amount of residual PAEs may cause serious harm to humans (Latini et al. 2004; Koch et al. 2005, 2006). Several PAEs and their metabolites have been shown to have growth and developmental toxicity for animals, particularly for the reproductive development of males, with endocrine disrupting and modulating effects (Reynolds et al. 2004). Some PAEs are also carcinogenic for rodents, but their carcinogenicity has not been conclusively determined for humans (Latini et al. 2004).

Effects of PAEs on the Immune System

Epidemiological studies have suggested a possible association between exposure to DINP and the development of allergies. However, it is controversial to discuss the pathogenesis of allergic diseases caused by DINP because of a lack of sufficient scientific evidence of how or even whether DINP influences allergic immune responses. Kang et al. (2017) orally administered DINP for 3 weeks to BALB/c mice after they had been sensitized with fluorescein isothiocyanate (FITC). They found that oral administration of DINP exacerbated tissue damage in allergic dermatitis in the FITC-sensitized mice. This was accompanied by increased expression of TRPA1, IgG1, IL-6, and IL-13. The authors found that blocking TRPA1 using HC030031 effectively prevented the development of the allergic dermatitis induced by oral exposure to DINP, including downregulation of IgG1, IL-6, IL-13,

and a decrease of mast cell degranulation. Their findings also suggested that blocking NF- κ B inhibited TRPA1 expression, but that blocking TRPA1 has no significant effect on NF- κ B activation or TSLP expression. This study helped people understand the role of DINP in the development of allergic dermatitis and provides new insights into the mechanisms of adjuvant effects induced by DINP.

Similarly, Shen et al. (2017) found that oral administration of di-isodecyl phthalate (DIDP) exacerbated allergic dermatitis in mice. The combination of DIDP and FITC induces the synthesis of TSLP by activating the NF- κ B signaling pathway, which causes the activation of STATs and degranulation of skin mast cells, ultimately exacerbating allergic dermatitis. This study also showed that melatonin enhanced the expression of Nrf2, upregulated the antioxidant genes HO-1 and NQO1, decreased oxidative stress and TSLP levels, and thereby relieved allergic dermatitis. The results suggest that DIDP may exacerbate allergic dermatitis through oxidative stress and increased TSLP expression.

DEHP, a common plasticizer, was found to have an adjuvant effect in combination with ovalbumin (OVA). To further investigate the connection between thymic stromal lymphopoietin (TSLP) and the adjuvant effect of DEHP, You et al. (2016) sensitized BALB/c mice with OVA through daily oral administration, and neutralized the effect of TSLP with an anti-TSLP monoclonal antibody. The results showed a significant Th2 response in the DEHP-treatment group with upregulation of Th2-type cytokines such as interleukin 4 (IL-4), IL-5, and IL-13. In addition, eosinophil counts and pulmonary eosinophil cationic proteins (ECP) in the bronchoalveolar lavage fluid (BALF) were significantly increased. Neutralization of TSLP with an anti-TSLP monoclonal antibody reversed the adjuvant effect of DEHP on airway inflammation, airway wall structure, and airway hyper-responsiveness of acetylcholine, induced by OVA, indicating that TSLP is an effective target for inhibiting the adjuvant effect of OVA and DEHP exposure.

Exposing 5-week-old ICR male mice to vehicle saline, DEHP or DINP daily by oral administration, Gu et al. (2021) observed increased levels of reactive oxygen species and malondialdehyde, and decreased levels of glutathione, in the kidney, suggesting oxidative damage to the kidney. Elevated levels of renal inflammatory cytokines, tumor necrosis factor- α , and IL-6 further implied inflammation due to PAE exposure. Targeted lipidomics showed that a high dose of DEHP had a pronounced effect on the kidney, but DINP also caused significant changes in phosphatidylglycerol content, which is associated with glomerular podocyte lipid accumulation and inflammatory responses.

Effects of PAEs on the Nervous System

A lot is known about the characteristics of PAEs as endocrine disrupting chemicals; however, the effects and potential mechanisms of PAEs on neurotoxicity are still unclear. Tran et al. (2021) used zebrafish to investigate the effects of six phthalates, dimethyl phthalate (DMP), diethyl phthalate (DEP), benzyl butyl phthalate (BBZP), di(2-ethylhexyl) phthalate (DEHP), di-n-octyl phthalate (DNOP), and diisononyl

phthalate (DINP) on the motility of zebrafish embryos. After exposure to one of the six phthalates, the green fluorescent protein (GFP) transgenic (Tg) line was measured, and any changes to the expression profiles of genes related to the cholinergic and dopaminergic systems were assessed. The results prove that exposure to phthalates impairs development of the nervous system and neurochemicals in zebrafish embryos, although the specific mechanisms vary depending on the phthalate.

Poopal et al. (2020) studied the toxic effects of diheptyl phthalate (DHP) and diisodecyl phthalate (DIDP) on zebrafish at median lethal concentration (LC₅₀ 96-h). The intensity of swimming behavior and tissue biomarkers, including total antioxidant capacity (TAOC), aminotransferase, and acetylcholinesterase (ACHE), were evaluated after exposure. Zebrafish exposed to either of these phthalates for 15 days exhibited maladjusted swimming behavior and circadian rhythms. After the exposure period, the activity of aminotransferase in the liver and heart tissue was observed to have increased in both DHP and DIDP-treated zebrafish compared to the controls. TAOC and ACHE activity was reduced in the brain-, gill-, intestinal-, and muscle-tissues of the phthalate-treated zebrafish compared to the controls. The comparative study of swimming behavior and biomarkers makes it possible to determine whether the swimming response is mediated by external or internal stresses. Further research is needed to evaluate more molecular mechanisms and biomarkers to explore the toxicity of pollutants.

Feng et al. (2020a) investigated the neurotoxicity and mechanisms of di(2-ethylhexyl) phthalate (DEHP) exposure versus adolescent normal (P-normal) and adolescent type 2 diabetic (P-T2DM) ICR mice using typical neurobehavioral methods and transcriptome analysis. In open field experiments, DEHP exposure significantly increased the length of time spent in the central zone, and decreased the total distance covered and clockwise rotation. Morris water maze experiments showed that DEHP exposure significantly increased the time it took mice to locate the platform, and decreased the time spent in the target quadrant for both P-normal and P-T2DM mice. The results of transcriptome analysis demonstrated the effects of DEHP exposure on neural signaling pathways, including biogenic amines, neurotransmitters, neuroreceptors, and neurobiological processes. The analysis showed that P-T2DM mice were more sensitive than P-normal mice to the effects of DEHP. This study demonstrates the toxic effects of DEHP on the nervous system and suggests that potential neurotoxic mechanisms may be involved in synergy with cAMP-PKA-ERK1/2-CREB signaling pathways and Ca²⁺ signaling pathways.

Of all the phthalate esters, dibutyl phthalate (DBP) is second only to DEHP in terms of adverse health consequences, and its potential neurotoxicity has drawn extensive attention in recent years. To determine whether DBP induces neurotoxicity and anxiety-like behavior through oxidative stress, Yan et al. (2016a) used Kunming mice, and after exposure to DBP, used the elevated plus maze (EPM) and open field tests to observe any neurobehavioral changes, such as anxiety-like behavior. Oxidative stress levels were assessed by determining reactive oxygen species (ROS), glutathione (GSH), malondialdehyde (MDA), and DPC coefficients (DPC) to explore key upstream events. In addition, an antioxidant, monoacylglycerol

(MAG), was administered, to protect cells from antioxidant damage since it has been shown to improve memory and reduce learning impairment in rodents. The results showed a statistical association between oral exposure to DBP and anxiety-like effects in mice, as measured by EPM and the open field test. DBP exposure significantly increased the levels of ROS and MDA in the brain, and significantly reduced the levels of GSH in a dose-dependent manner, suggesting a correlation between oral exposure to DBP (25–125 mg/kg/day) and oxidative stress in the brain tissue of mice. MAG administration reduced the neurotoxicity and oxidative damage induced by oxidative stress.

Effects of PAEs on the Reproductive System

Di(2-ethylhexyl) phthalate (DEHP) is a typical endocrine disrupting chemical and is toxic to the reproductive system. Shi et al. (2019) found relatively few studies focusing on the effects of DEHP exposure on reproductive development in adolescence. The JAZF1/TR4 pathway plays a key role in male reproduction and includes the JAZF1, TR4, sperm 1, and cell cycle protein A1 genes. Therefore, Shi et al. examined testicular zinc and oxidative stress levels in SD rats exposed to increasing concentrations of DEHP by oral administration for 30 days. The results showed that DEHP exposure led to oxidative stress and a decrease in testicular zinc levels. In addition, hematoxylin and eosin staining, and terminal deoxynucleotidyl transferase-mediated notch and labeling assays showed significant morphological changes and apoptosis in the testicular tissue of the DEHP-exposed mice. Also, gene expression of JAZF1 increased, and expression of TR4, spermatozoa 1, and cell cycle protein A1 decreased. These results indicate that *in vivo* exposure to DEHP may induce reproductive toxicity in adolescent male rats through the JAZF1/TR4 pathway, and to oxidative stress.

To verify whether prenatal exposure to DEHP affects early onset gonadal dysfunction and subsequent reproductive aging in male mice, Barakat et al. (2017) administered DEHP orally to pregnant female CD-1 mice from day 11 of gestation to birth. The results showed that compared to control mice of the same age, all DEHP-exposed mice presented lower serum testosterone levels, higher serum estradiol levels, and higher luteinizing hormone (LH) levels. Histological evaluation showed that mice exposed prenatally to DEHP had apparent abnormalities of the gonad and epididymis, such as increasing germ cell apoptosis, degeneration of germinal tubules, oligospermia, hypospemia, and teratospermia. These observations confirm that prenatal exposure to DEHP may lead to premature reproductive aging in male mice.

Wang et al. (2017b) used SD female rats and exposed them to DEHP alone or in combination with vitamin E by daily oral administration from 12.5 days after gestation to 3 days postnatal. Results showed that vitamin E supplementation (200 mg/kg) reduced malformations, increased testicular weight, and prevented DEHP-induced maternal weight loss. Litter size, sex ratio, and live litter size were not affected, but the vitamin E supplementation had a protective effect on DEHP-induced testicular toxicity including reducing testicular apoptosis, decreasing PPAR expression, and maintaining testicular integrity.

Effects of PAEs on Diabetes

To explore the potential role of DEHP in diabetes-like symptoms, Wang et al. (2016) subjected BALB/c mice to streptozotocin (STZ) and a high-fat diet to establish a diabetes model. These mice were then exposed to DEHP, and their physiological indicators were monitored, including body weight and water consumption and blood biomarkers, including serum insulin and fasting blood sugar levels. At the end of the exposure regime, histopathological examinations of the pancreas and liver were performed. The level of oxidative stress was determined by assaying ROS and MDA in hepatocytes. As is commonly known, the most important histopathological changes in diabetes are increased blood sugar and decreased serum insulin. The results showed that DEHP did not directly induce diabetes at the treatment level but decreased serum insulin levels in DEHP-exposed nondiabetic animals. Histopathological observation showed there was dose-dependent impairment in the pancreatic tissue of the DEHP-exposed with STZ-treated group, accompanied by increased oxidative stress levels. It is hypothesized that oxidative stress may be involved in regulating this pathological process. This study contributes to elucidating the role of DEHP in the exacerbation of the disease in mice models of diabetes.

Radon and its Toxic Effects

Radon is a colorless, odorless, and chemically inert gas that can migrate from soil and rocks and accumulate in areas such as indoor houses and buildings. Indoor radon largely comes from indoor building materials such as brick, concrete, cement, ceramic tile, etc. Natural gas and domestic water are also important sources of indoor radon (Rozas et al. 2016).

Radon decay products are easily adsorbed onto particles, which can enter the human body through the respiratory tract, and be deposited in the lungs, causing damage to human health. Studies have shown that exposure to radon and radon daughters is closely related to lung cancer. Indoor radon pollution is the second largest risk factor for lung cancer after smoking, and about 10–30% of lung cancer deaths of nonsmokers are attributed to radon radiation (Gawełek et al. 2017; Casal-Mouriño et al. 2019; Lorenzo-González et al. 2019). The incidence rate of lung cancer caused by radon and radon decay products is estimated to be 10% of all lung cancer cases (Belpomme et al. 2007), of which 6–12% are in the UK, 7% in Germany, 10–14% in the USA, and the estimated value for China is 15%. Canada has investigated radon levels and the risk of lung cancer caused by radon in 19 cities since 1970, and in 2009, they reported that the indoor radon concentration was $4109 \pm 2.8 \text{ Bq/m}^3$, and the lung cancer caused by indoor radon exposure accounted for about 16% of the total lung cancer mortality (Chen et al. 2012).

The International Agency for Research on Cancer (IARC) has classified radon and daughters as Class I carcinogens, and the WHO also regards radon as one of the 19 known important human carcinogens. Lung cancer is included in the global burden of diseases list (IPCS 1999). It is generally believed that the risk of radon

to the human body is related to the indoor radon concentration, the age of the exposed person, and other factors (Pearce and Boyle 2005; Wichmann et al. 2005). The higher the indoor radon concentration is, the higher the risk of exposure to radon for people under the age of 55 (Pearce and Boyle 2005).

The Effects of Radon on the Respiratory System

Epithelial mesenchymal transition (EMT) plays an important role in tumorigenesis. However, the carcinogenic mechanism of EMT induced by chronic radon exposure is not clear. Chen et al. (2020) investigated the potential molecular mechanisms of EMT and lung cancer caused by repeated radon exposure. In animal experiments, BALB/c mice were exposed to radon gas at a cumulative dose of 60 and 120 working level months (WLM). Inhalation of radon gas caused lung damage and fibrosis in the mice, which was aggravated with increasing exposures. At the same time, a transformation similar to EMT occurred in the lung tissue of mice. Radon exposure increases p-PI3K, p-AKT, and p-mTOR in cells of mice. m-TOR and AKT inhibitors attenuate the EMT induced by radon exposure, by modulating the related biomarkers. These data demonstrate that radon exposure induces EMT through the PI3K/AKT/mTOR pathway in epithelial cells and lung tissue.

Wu et al. (2021) exposed male BALB/c mice to radon in an HD-3 radon chamber to determine the exact toxic effects that result from long-term radon exposure. Specific manifestations in the mouse lung were inflammatory responses and apoptosis, the severity of which were both dose-dependent and time-dependent. Furthermore, they found that melatonin treatment ameliorated mitochondrial dysfunction and attenuated the levels of oxidative stress and apoptosis caused by long-term radon exposure. This study provides a potential therapeutic application of melatonin for lung tissue injury caused by long-term radon exposure.

Nie et al. (2019) divided female BALB/c mice into two groups: a control group and a radon group (exposure to approximately 100,000 Bq/m³ which is equivalent to a maximum of 60 working months). Following exposure, it was discovered that about 1000 dysregulated lncRNA transcripts were found in the mice exposed to radon, and these lncRNAs may play an important role in the lung damage caused by radon exposure. Results from this study also indicate that the activation of ErbB2 and Notch pathways might be responsible for radon-induced pulmonary toxicity.

Other Health Effects of Radon

Radon and its decay products make a significant contribution to natural background radiation. Because of the complexity of radon exposure, the doses of radon exposures one experienced are difficult to quantify. Mirsch et al. (2020) has established a model with mice to assess tissue-specific radiation dose related to radon activity concentrations in order to propose a dependable means of evaluation for keeping from the harm by radon radiation. In their study, mice experienced radon exposure at

known concentrations while the number of 53BP1 foci consequently appeared was counted as an index of DNA damage induced by the exposure. This standard number was then compared with the number of foci induced by defined doses of other radiation as reference. Hence, the three-dimensional foci patterns were built based on image analysis, providing a way to assess the different types of radiation that caused DNA damage. It was demonstrated that α -particles induced two-thirds of the DNA damage in lung, while the other one-third in lung, as well as all in the kidney, heart, and liver were induced by β - and γ -rays. It is believed that biological dosimetry method proposed in this study can be used to calculate the risk level in application of the benchmark radiation protection guide.

To explore whether the oxidative damage caused may be involved in the carcinogenic process induced by radon, Nie et al. (2012) exposed Wistar rats to radon at a concentration of 100,000 Bq/m³. Levels of 8-OHDG, reactive oxygen species (ROS), and total antioxidants (T-AOC), and expression levels of some DNA repair enzymes were measured in rat urine and lungs. There was an increase in 8-OHDG and ROS levels, a decrease in T-AOC levels, and reduced OGG1 and MTH1 expression levels. The elevated levels of 8-OHDG in urine or lymphocytes was positively correlated with the cumulative exposure dose, whereas OGG1 and MHT1 expression levels in the lung were inversely correlated with cumulative exposure dose. Observations from this study have revealed that radon-induced carcinogenesis might originate with the induction of oxidative damage.

Kataoka et al. (2017) exposed BALB/c mice to different concentrations of radon for 24 h and then immediately analyzed SOD in brain tissue. The results showed that radon inhalation may cause SOD protein to pass through NF- κ B activation, causing DNA damage and oxidative stress.

Indoor Particulate Matter Pollution

Particulate matter pollution, especially PM_{2.5}, has been getting more attention as awareness of the health hazards has grown. In fact, particulate matter pollution is also one of the most significant indoor pollutants. The sources of particulate matter indoors include indoor sources such as particulate matter generation through metabolites such as dander (Yang et al. 2018), and several indoor activities such as smoking and cooking (Habre et al. 2014a; Pagel et al. 2016; Shao et al. 2017), and the ingress of outdoor particulate matter by gas exchange such as natural ventilation or wind seepage through walls (Ji and Zhao 2015). Other studies have shown that the use of indoor equipment such as vacuum cleaners and printers also generates indoor particulate matter pollution (Lioy et al. 1999). Indoor particulate matter varies depending on the building structure, ventilation methods, and particulate matter properties (Meng et al. 2005). Moreover, the composition of indoor particulate matter is higher in organic components than that found outdoors (Polidori et al. 2006).

PM_{2.5} is fine particulate matter with an aerodynamic diameter less than or equal to 2.5 μ m, which can be suspended in the air for a long time. PM_{2.5} is characterized by

small particle size, large surface area, strong activity, and the ability to easily adsorb a large number of harmful and toxic molecules. Studies have shown that the contribution of outdoor PM_{2.5} to indoor PM_{2.5} can be anywhere between 54% and 96% (Ji and Zhao 2015). Particles of this size, especially those below 0.1 μm, can penetrate deeply into the human respiratory system and even enter the circulatory system, thus causing various diseases (Pan et al. 2016).

The Effect of PM_{2.5} on the Respiratory System

Numerous epidemiological studies have shown that the increase in morbidity, hospitalization, and mortality of respiratory diseases is positively correlated with the increase in PM_{2.5} levels in the air, with a 1.13% increase in respiratory hospitalizations for every 10 μg/m³ increase in PM_{2.5} levels (Qiu et al. 2014). Roy et al. (2012) investigated the relationship between indoor air pollution indicators and lung function development in children aged 6–13 years ($n = 3273$) in four Chinese cities. Pulmonary function parameters (FVC and FEV1) were measured twice a year and the type of fuel used in the home was determined by questionnaire. The data showed that coal use in the home may contribute to impaired lung function development. Numerous studies have shown that high levels of PM_{2.5} results in airway inflammation (Davel et al. 2012; Wang et al. 2015), decreased lung function (Jacobson Lda et al. 2012; Wu et al. 2013), and the incidence and exacerbation of asthma and chronic obstructive pulmonary disease (COPD) (Nachman and Parker 2012; Gleason et al. 2014; Habre et al. 2014b).

Air pollution is linked to morbidity and mortality caused by respiratory diseases. However, the mechanisms involved have not been fully elucidated. Riva et al. (2011) investigated whether a single acute exposure to low doses of PM_{2.5} may lead to alterations in lung function and histology, and unleash inflammatory and oxidative stress processes, resulting in increased oxidative stress. They collected five samples from urban areas of São Paulo city and analyzed them for elemental and polycyclic aromatic hydrocarbon content. After intranasal drip administration of PM_{2.5} in male BALB/c mice, pulmonary function was determined, following which lung tissues were prepared for histological and biochemical analysis. Results revealed that this acute exposure to low doses of fine particulate matter led to lung inflammation, oxidative stress, and deterioration of lung impedance and histology in a dose-dependent manner.

To determine whether PM_{2.5} is involved in the exacerbation of asthma, Zhang et al. (2015) constructed an ovalbumin (OVA)-sensitized mouse model of asthma, and then subjected these mice to an airway drip of PM_{2.5}. PM_{2.5} was found to exacerbate inflammatory infiltration and structural lung damage in the asthmatic mice. The experiments demonstrated that acute exposure to PM_{2.5} may act synergistically with allergens to exacerbate asthma in sensitized mice, by promoting immune responses with Th2 imbalance.

Interleukin 17A (IL-17A), a representative member of the IL-17 family, is produced by secondary T lymphocytes and can be induced by IL-23. IL-17

cytokines can effectively recruit monocytes and neutrophils to sites of inflammation by increasing the production of chemokines in tissues, thereby delaying the inflammation. To explore the role of IL-17A in PM_{2.5}-induced lung injury, Cong et al. (2020) established a lung injury model by exposing C57BL/6J mice to PM_{2.5}. ELISA kits were used to examine the expression of inflammatory factors in the supernatant of alveolar lavage fluid. Primary bronchial epithelial cells (MBEC) were extracted and subjected to immunofluorescence analysis and Western blot assays. This study showed that PM_{2.5} promoted lung inflammation and fibrosis by inducing IL-17A secretion from $\gamma\delta$ T and Th17 cells, regulating the PI3K/Akt/mTOR signaling pathway, and inhibiting autophagy of bronchial epithelial cells. Exposure to PM_{2.5} can cause a variety of respiratory diseases. Since PM_{2.5} is ubiquitous in the environment, Zhang et al. (2021) explored the protective effect of IL-10 against PM_{2.5}-induced lung injury and its possible mechanisms. Wistar rats were exposed to PM_{2.5} and then treated with IL-10. Through these experiments, IL-10 treatment was found to ameliorate PM_{2.5}-induced acute lung injury, reduce mitochondrial damage, and inhibit inflammation, oxidative stress, and apoptosis in PM_{2.5}-treated rats.

Effect of PM_{2.5} on the Immune System

Yan et al. (2016b) explored whether indoor PM_{2.5} in the homes of children with allergic symptoms exacerbated their risk of allergy, not only compared with healthy children but also compared its toxicity with inflammatory response. The study collected indoor PM_{2.5} from the homes of allergic children and healthy children, and analyzed the composition of this indoor PM_{2.5}. Female Kunming mice were stimulated to produce large numbers of macrophages by intraperitoneal injection. After the mice were sacrificed, cell counts were performed and cells were cultured in a medium with two different PM_{2.5} suspensions. Based on the effect of PM_{2.5} on reactive oxygen species accumulation, lipid peroxidation, DNA damage, or cytokine production levels, PM_{2.5}-mediated oxidative damage and inflammatory responses in mouse peritoneal macrophages were evaluated. Oxidative stress may be associated with PM_{2.5}-induced toxicity, and PM_{2.5} in indoor environments housing allergic mice, led to more severe toxic effects and inflammatory responses in mouse peritoneal macrophages compared to effects in the non-allergic mice.

Chronic obstructive pulmonary disease (COPD) is associated with imbalances of T lymphocyte subsets (Th1/Th2, Th17/Treg). Gu et al. (2017) established a COPD mouse model through cigarette exposure with aerosol inhalation of PM_{2.5}. This study aimed to investigate whether PM_{2.5} could promote COPD development via Notch signaling pathways, leading to worsening immune disorders. The results showed that COPD mice had Th1- and Th17-mediated immune disorders and that the Notch signaling pathway was over-activated. The use of the inhibitor GSI partially inhibited activation of the Notch signaling pathway, and alleviated the immune disorders in the basal state and PM_{2.5}-induced immune disorders in COPD.

Ge et al. (2020) investigated the hematopoietic toxicity and associated molecular mechanisms in male BALB/c mice exposed to formaldehyde and PM_{2.5} alone or in

combination. The results showed that exposure to PM_{2.5} and formaldehyde may elicit hematopoietic toxicity by decreasing expression of hematopoietic growth factor, increasing oxidative stress and DNA damage, activating the “immune imbalance” pathway, and inhibiting the DNA repair-related mTOR pathway. DNA repair was significantly inhibited by deregulation of mammalian targets of the rapamycin (mTOR) pathway, while the researchers also found that treatment with vitamin E reduced these harmful effects.

Effects of PM_{2.5} on the Cardiovascular System

Numerous studies have shown that particulate matter (PM) in air pollution is associated with increased cardiovascular dysfunction, morbidity, and mortality (Dockery and Stone 2007). Ma et al. (2021) explored PM_{2.5} to induce myocardial inflammatory responses in Wistar rats by a new technique using a multifunctional aerosol concentration enrichment system. Histopathological examination of the left ventricular myocardial tissue was performed by direct oral and nasal exposure with hematoxylin-eosin (H&E) staining. Ultrastructural changes in cardiac specimens were observed by electron microscopy. Immunohistochemistry was used to detect CRP and ICAM-1 levels. The results showed that myocardial tissue in the exposed group was edematous, with widened myocardial gaps and inflammatory cell infiltration. The protein expression of CRP and ICAM-1 was increased in the exposed group. This experiment suggests that long-term exposure to PM_{2.5} inhalation promotes significant upregulation of ICAM-1 and CRP expression in myocardial tissues, ultrastructural changes in cardiomyocytes, and inward flow of inflammatory cells.

Zang et al. (2021) investigated the specific mechanism of PM_{2.5}-induced myocardial toxicity by drip injection of PM_{2.5} into the airway of SD male rats. Western blotting (WB) and real-time PCR (RT-PCR) were used to detect the expression of Ang II, ERK1/2, and TGF- β 1. The results indicated that the degree of myocardial fibrosis became more severe with increasing PM_{2.5} concentration, and the expression of Ang II, ERK1/2, and TGF- β 1 increased in the high-dose group, suggesting that activation of the renin-angiotensin system (RAS) may be involved in PM_{2.5}-induced myocardial fibrosis.

Duan et al. (2017) evaluated the multiple organ systems toxicity of PM_{2.5} in a zebrafish model. PM_{2.5}-induced embryotoxicity was dose- and time-dependent through mortality and hatching rate suppression. PM_{2.5} caused pericardial edema and decreased heart rate and cardiac output. The area of subintestinal vessels was significantly reduced in Tg(fli-1:EGFP) transgenic zebrafish strains, and morphological defects and yolk sac retention were associated with hepatocyte damage. In addition, PM_{2.5} disrupted axonal integrity in the Tg(NBT:EGFP) transgenic strain, altering axon length and pattern. Genes involved in cardiac function, angiogenesis, and neurological function were significantly downregulated, while genes related to liver metabolism were significantly upregulated. Their data suggest that PM_{2.5} causes cardiovascular toxicity, hepatotoxicity, and neurotoxicity in zebrafish.

Effects of PM_{2.5} on the Reproductive System

Liao et al. (2020) subjected female Kunming mice to PM_{2.5} exposure by airway drip for 28 days. They looked for apoptosis of mouse ovarian granulosa cells, oocytes, and quality of the embryos after insemination. The results showed that the number of apoptotic granulosa cells and oocytes increased after exposure to high concentrations of PM_{2.5}, indicating that PM_{2.5} induced apoptosis of mouse ovarian granulosa cells and oocytes and affected mouse embryo development.

There are only a limited number of toxicological studies of the effect of PM_{2.5} on the reproductive system and its potential mechanisms. In one study, Zhou et al. (2019) established a real-time whole-body PM_{2.5} exposure mouse model in C57BL/6 mice. PM_{2.5} exposure was found to lead to a significant increase in circulating leukocytes and lung inflammation, and also to testicular DNA damage and histopathological alterations, and a significant decrease in sperm density. PM_{2.5} exposure remarkably increased the expression of major components of NACHT, LRR, and PYD structure domains containing protein 3 (NALP3) inflammasomes, as well as increased expression of miR-183/96/182 targeting FOXO1 in testis. In addition, Yang et al. (2021) wondered whether the enzyme 1 (IRE1)/c-Jun NH 2-terminal kinase (JNK)/autophagy signaling pathway was activated by PM_{2.5} and whether this pathway mediates reproductive damage in male rats. After exposing male SD rats to PM_{2.5}, they found a loose structure of spermatogenic cells in the PM_{2.5} group and decreased numbers of both spermatogenic cells and mature spermatozoa. Structural damage of germ cells was ameliorated, and the number of exfoliative cells was reduced by intervention with the IRE1 inhibitor STF083010. Western blot analysis revealed significant upregulation of IRE1, phosphorylated JNK (p-JNK), beclin-1, and microtubule-associated protein 1 light chain 3 (LC3) II/LC3I protein expression, and downregulation of p62 protein. This study suggests that the activation of (IRE1)/c-Jun NH 2-terminal kinase (JNK)/autophagy signaling pathway may play a potential role in the mechanism of reproductive toxicity induced by PM_{2.5}.

Other Toxic Effects of PM_{2.5}

Ren et al. (2020) examined aromatic hydrocarbon receptor (AHR) activity and ROS levels in zebrafish embryo hearts, using fluorescence microscopy and qPCR. In addition, they looked for DNA damage and apoptosis by immunofluorescence. The results showed that inhibition of AHR, and elimination of ROS, significantly relieved PM_{2.5}-induced cardiac defects in the zebrafish embryos, suggesting that AHR mediates PM_{2.5} extractable organic matter (EOM)-induced oxidative stress, leading to DNA damage and apoptosis, which can be toxic to cardiac development.

Wang et al. (2017a) validated a Drosophila model for PM_{2.5} toxicity studies by the biological response of Drosophila exposed to high ambient concentrations of PM_{2.5}. Survival curves showed that exposure to PM_{2.5} significantly reduced the lifespan of Drosophila. This anti-longevity effect was observed in both male and female Drosophila, with males being more sensitive. Similar to the effects of human

exposure to concentrated ambient PM_{2.5}, exposure to PM_{2.5} may lead to premature death by inducing inflammation-related signals, oxidative stress, and metabolic abnormalities in the Drosophila, suggesting that Drosophila may also serve as a useful animal model for PM_{2.5} toxicity studies.

Limitations of and Alternatives to Animal Testing

Animal testing has contributed greatly to advancing understanding of the health risks that indoor air pollutants may cause, and an understanding of the underlying molecular mechanisms resulting in harm. Both, possible interventions to reverse harm, and suggestions for healthier living conditions and life-styles, have been proposed in this chapter, providing guidance for a healthier life. Increasingly researchers are using experimental animals to explore the toxicity of indoor air pollutants. Until recently, research using experimental animals was based on traditional anatomical technologies; however, the emergence of new technologies such as omics (Federico et al. 2020; Bode et al. 2021) and gene knockout (Chaix et al. 2019; Navabpour et al. 2020) provide new opportunities for the advancement of pollutant toxicity research. Seamless integrations of the traditional experimental animal exposure methods and some new research approaches, including transcriptomics (Ding et al. 2019; Wang et al. 2019), proteomics (Ma et al. 2018; Zhang et al. 2019), and metabolomics (Zhang et al. 1994; Costa et al. 2019), has provided an important platform for exploring the mechanisms responsible for the negative impact that ambient air pollutants have on human health.

However, the increased use of experimental animals has been controversial since conclusions drawn from animal research do not necessarily extrapolate to the human body (Robinson et al. 2019). In response, the use of experimental animals is restricted by ethics (Levy 2012), and the procedure for obtaining ethics approval in many countries around the world is quite strict. Secondly, different aspects of interspecies differences, including anatomy, metabolism, physiology, and genetics may greatly undermine the reliability of conducting animal experiments to explore underlying mechanisms of human disease or to foresee toxicity in humans induced by certain indoor pollutants (Langley 2009). People can partially improve the external validity by improving animal models. However, since the problem of interspecies differences cannot always be completely avoided, the external validity will always be weakened. Thus, the extrapolation of animal experimental results to humans will also be affected (Pound and Ritskes-Hoitinga 2018).

Therefore, there is an increasing trend to develop alternative (nonanimal) methods for toxicity testing, such as computer models (Knight et al. 2006), cultivated cells (Liu et al. 2013), and 3D cell cultures (Dutta et al. 2017).

1. 3D cell cultures, also known as organoids, have been substituted for animal models in certain types of research. Organoids can be grown *in vitro* on scaffolds (biological or synthetic hydrogels such as Matrigel) or in a culture medium (Corrò et al. 2020).

Embryonic pluripotent stem cells, adult stem cells, and induced pluripotent stem cells, three types of human or animal stem cells, are sources of organoids. Organoids grown in vitro can mimic the structure and function of different organs including the brain, liver, lung, kidney, and gut. Organoids are now being developed to study infectious diseases. Tumor 3D cell cultures from human patient biopsy cells can be applied to study the genomics and drug resistance of tumors in different organs. Organoids are also used to model genetic diseases such as cystic fibrosis (Artegiani and Clevers 2018), neurodegenerative diseases such as Alzheimer's and Parkinson's disease, infectious diseases such as MERS-COV and Norovirus, and parasitic infections such as *Toxoplasma gondii* (Corrò et al. 2020). Human and animal cell-derived organoids are also widely used in pharmacology and toxicology studies (Augustyniak et al. 2019; Steinberg et al. 2020).

2. Major alternatives to animal experiments also include the use of in vitro cell and tissue cultures. Cells and tissues from organs such as the liver, kidney, brain, and skin are removed from animals and can be stored in vitro in suitable growth media for days to months or even years. These methods are often used for preliminary screening of potential drug molecules/chemicals to examine their toxicity and efficacy (Shay and Wright 2000; Steinhoff et al. 2000). However, results obtained from in vitro experiments cannot generally be used directly to predict an organism's response to chemical exposure. Especially, due to the lack of interactions between different cell types, long-term and systemic responses cannot be modeled in vitro (Kim et al. 2019). Sometimes "human-on-a-chip" systems are applied to enhance the complexity of in vitro systems, where multiple cells can interact to mimic the cell-to-cell interactions that exist in human tissues (Sung et al. 2010), or numerically simulate the behavior of complex systems through mathematical modeling, using in vitro data to provide data for model development (Quignot and Bois 2013).
3. Various possible biological and toxic effects of chemicals or potential drug candidates can be predicted by computer-generated simulations, avoiding the use of animal testing. Only the most promising molecules from the initial screening will be tested in vivo. For example, in order to determine the receptor binding site of a drug, it is necessary to perform in vivo experiments. Computer-aided drug design (CADD) software can be used to predict receptor binding sites for potential drug molecules. CADD achieves the 3R goal by identifying possible binding sites and thus avoiding unnecessary animal testing of chemicals that are not biologically active, thus reducing the total number of experimental animals (Doke and Dhawale 2015). There are also objections, such as the National Academy of Sciences Institute for Laboratory Animal Research (National Research Council 2004), which argues that even sophisticated computer models cannot replace animal research and that computer models cannot handle the extremely complex interactions between molecules, cells, tissues, organs, organisms, and the environment.

Up to the present, use of animal testing to evaluate any health effect of indoor air pollutants remains the most effective, persuasive, and still irreplaceable research method, especially in explaining the molecular mechanism of pollutant

toxicity. Globally, in order to limit animal testing to those that fully consider all alternatives and minimize animal suffering, governmental and institutional review boards have developed legislative and ethical approval procedures (Festing and Wilkinson 2007). Those who use animal research in pursuit of academic goals must do so based on ethical principles and under regulated laboratory practices. Every researcher must make every effort to use animals in academic research in the most ethical and responsible manner, while contributing to the dissemination of knowledge without forgetting the ethical principles of legislation (Andersen and Winter 2019).

Conclusions

In order to have a deeper understanding of the health impacts of indoor air pollutants on humans, it is insufficient to rely only on epidemiological investigations and computer models. Through animal tests, the human body's response to exposure in the real environment can be simulated more comprehensively. Therefore, animal tests can help researchers gain effective insights into health impacts as well as the possible mechanisms, and potentially identify appropriate interventions in advance to prevent humans from being harmed by indoor air pollution. Although there are limitations to animal toxicology, it is still foreseeable that animal tests may be one of the most effective ways to understand the health effects of indoor pollution at present and in the future.

Abstract

Increasing attention has been paid on health risks of indoor air pollution since most people spend up to 90% of their time indoors. The indoor air pollution mixture is mainly comprised of particulate matter (PM) and gaseous pollutants such as volatile organic compounds (VOCs), nitrogen dioxide (NO_2), ozone (O_3), carbon monoxide (CO), carbon dioxide (CO_2), and sulfur dioxide (SO_2) as well as emerging contaminants such as semivolatile organic compounds (SVOCs). Indoor air pollution from solid fuel combustion is among the ten largest contributors to global burden of disease. Pathophysiology-based biomarkers are useful in the identification of early adverse health effects and in surveillance or monitoring of health status or disease progression. To facilitate appropriate applications of biomarkers in assessing health risk of indoor air pollutants, this chapter summarized researches exploring the adverse effects of indoor air pollutants exposure on the respiratory system, cardiovascular system, hematologic system, immune system, reproductive system, and other systems using representative biomarkers. The summary intends to facilitate understanding of the potential biological mechanisms through which the major indoor air pollutants would affect human health.

Keywords

Indoor air pollutants · Biomarkers · Adverse health effects · Biological mechanisms

Introduction

Indoor environmental conditions significantly affect human health, given that most people spend around 90% of their time indoors, mainly at home or in the workplace (Leech et al. 2002). Indoor air pollution is characterized as a complex mixture of particulate matter (PM), gaseous pollutants, and semivolatile compounds that partition between the particulate and gaseous phases. PM contains inorganic substances (e.g., metals) and organic compounds (e.g., larger molecular weight polycyclic aromatic hydrocarbons [PAHs]). Commonly measured gaseous pollutants include volatile organic compounds (VOCs, e.g., formaldehyde, benzene), nitrogen dioxide (NO_2), ozone (O_3), carbon monoxide (CO), carbon dioxide (CO_2), and sulfur

dioxide (SO_2). The outdoor environment, human activities in buildings, and building materials are the primary sources of indoor air pollutants (Tran et al. 2020). In households that use solid fuels (e.g., wood and other biomass, coal) for cooking and/or space heating, women and young children are particularly exposed to high levels of PM and gaseous products of incomplete combustion (e.g., fine particles, CO, and PAHs) of solid fuels (Bruce et al. 2000). According to the systematic analysis for the Global Burden of Disease Study, indoor air pollution is one of the ten largest contributors to global disability-adjusted life years (DALYs) between 1990 and 2015 (GBD 2015 Risk Factors Collaborators 2016).

Most recognized diseases associated with indoor air pollution are those of the respiratory and cardiovascular systems. The respiratory health effects of the smoke from solid-fuel combustion include chronic obstructive pulmonary disease (COPD), asthma, acute respiratory infection, and pulmonary tuberculosis in low- and medium-income countries (Kurmi et al. 2012). Indoor PM exposure has been associated with premature death in people with heart, nonfatal heart attacks, and irregular heartbeat (Tran et al. 2020). In addition, exposure to phthalates, a class of common indoor air pollutants, has been associated with adverse reproductive outcomes such as decreased semen quality in males (Radke et al. 2018), and preterm birth in females (Radke et al. 2019).

Pathophysiology-based biomarkers are useful in identifying preclinical effects and understanding biological mechanisms through which indoor air pollutants adversely affect health. In this chapter, we aim to summarize the applications of representative biomarkers in assessing health risks associated with indoor air pollutants. This summary is organized by biomarker responses in physiologic systems including respiratory system, cardiovascular system, immune system, reproductive system, and other systems (Fig. 1).

Application of Biomarkers in Assessing Health Risks of the Respiratory System

The Structure and Function of the Respiratory System

The respiratory system is comprised of upper respiratory tract (nasal passages), conducting airways (larynx, trachea, bronchi, bronchioles, and terminal bronchioles), and lower respiratory tract (alveolar ducts and alveoli) (Greeley 2016). The primary function of the respiratory system is ventilation, facilitating the exchange of gases between the air and blood and between the blood and body tissues.

Indoor Air Pollution Affects Respiratory Health

There is a large body of literature reporting the association between indoor air pollution and adverse health effects on the respiratory system. The health effects of indoor air pollution have been clarified clearly in the Handbook chapter

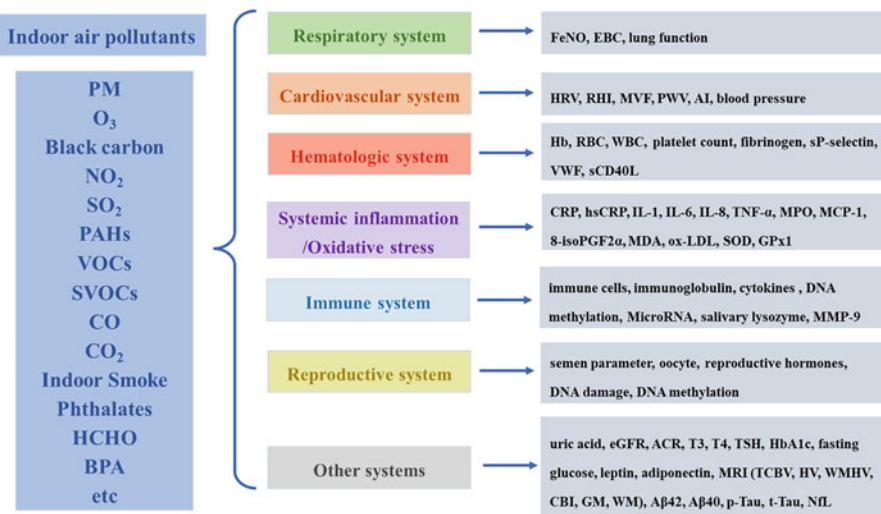

Fig. 1 Biomarkers used in assessing health risks of indoor air pollutants. PM: particulate matter, O₃: ozone, NO₂: nitrogen dioxide, SO₂: sulfur dioxide, PAHs: polycyclic aromatic hydrocarbons, TVOCs: total volatile organic compounds, CO: carbon monoxide, BPA: Bisphenol A, FeNO: fractional exhaled nitric oxide, EBC: exhaled breath condensate, HRV: heart rate variability, RHI: reactive hyperemia index, MVF: Microvascular function, PWV: Pulse wave velocity, AI: augmentation index, Hb: hemoglobin, RBC: red blood cell, WBC: white blood cell, sP-selectin: soluble P-selectin, VWF: Von Willebrand Factor, sCD40L: soluble CD40 ligand, CRP: C-reactive protein, hsCRP: high-sensitivity C-reactive protein, IL-1: interleukin-1, TNF- α : tumor necrosis factor- α , MPO: myeloperoxidase, MCP-1: monocyte chemoattractant protein-1, 8-isoPGF2 α : Iso-prostaglandin F2 α , MDA: malondialdehyde, ox-LDL: oxidized low-density lipoprotein, SOD: superoxide dismutase, GPx1: glutathione peroxidase, MMP-9: Matrix metalloproteinase 9, eGFR: estimated glomerular filtration rate, ACR: albumin to creatinine ratio, T3: triiodothyronine, T4: thyroxine, TSH: thyroid-stimulating hormone, HbA1c: glycated hemoglobin, TVBC: total cerebral brain volume, HV: hippocampal volume, WMHV: white matter hyperintensity volume, CBI: covert brain infarcts, GM: gray matter, WM: white matter, and NfL: neurofilament light

The Health Effects of Indoor Air Pollution by Jonathan Samet, Fernando Holguin, Meghan Buran. Indoor air pollution has been associated with incidence, prevalence, or exacerbation of respiratory diseases such as asthma, chronic bronchitis, and chronic obstructive pulmonary disease (COPD) as well (Hulin et al. 2012). To assess disease exacerbation or investigate biological mechanisms, biomarkers have been used to detect respiratory pathophysiological changes in human in response to indoor air pollution exposure, as described below and in Table 1.

Biomarkers of Respiratory Health Effects of Indoor Air Pollution

Fractional Exhaled Nitric Oxide (FeNO)

Fractional exhaled nitric oxide (FeNO) is derived from L-arginine with the action of inducible nitric oxide synthase (iNOS) in airway-epithelial cells. FeNO is a sensitive

PM: particulate matter, PM_{2.5}: particulate matter with an aerodynamic diameter $\leq 2.5 \mu\text{m}$, PM_{0.5}: particulate matter with an aerodynamic diameter $\leq 0.5 \mu\text{m}$, PM₁₀: particulate matter with an aerodynamic diameter $\leq 10 \mu\text{m}$, PAHs: polycyclic aromatic hydrocarbons, NO₂: nitrogen dioxide, SO₂: sulfur dioxide, BC: black carbon, UVM: ultraviolet light-absorbing particulate matter, PNC: particle number concentration, FeNO: fractional exhaled nitric oxide, EBC: exhaled breath condensate, MDA: malondialdehyde, EBCNN: the sum of EBC nitrite and nitrate, FVC: forced vital capacity, FEV₁: forced expiratory volume in one second, MMEF: maximal midexpiratory flow, PEF: peak expiratory flow rate, and FEF_{25–75}: forced expiratory flow at 25–75% of vital capacity

and noninvasive marker reflecting airway inflammation, which measures the levels of inflammation objectively and quantitatively. It appears to be high variability across different individuals in their FeNO in response to increasing levels of indoor air pollutants.

In a randomized, double-blind crossover trial of air purifiers conducted among 35 healthy college students in Shanghai, China, the researchers reported that the FeNO geometric mean level was significantly decreased by 17% (95% confidence interval (CI): 3.6%, 32.5%) following the true-purified air scenario compared to following the sham-purified air scenario. Furthermore, an interquartile range (IQR) increase in indoor PM_{2.5} was associated with an increase in FeNO of 11.3% (95% CI: 0.6%, 23.0%) (Chen et al. 2015b). Another randomized crossover trial conducted on 29 healthy young adults in Beijing, China, found that indoor PM_{2.5} concentrations were significantly lower during the true air filtration period than during the sham purification period. An IQR (71.3 µg/m³) increase in 24-h personal PM_{2.5} was associated with an increase of 16.0% (95% CI: 3.7%, 28.4%) in FeNO (Zhao et al. 2020). A pilot study conducted among 20 postgraduate students found that a one-unit increase in inhaled dose of PM_{2.5}-bound polycyclic aromatic hydrocarbons (PAHs) or in urinary concentrations of \sum OH-PAHs was associated with a maximum FeNO increase of 13.5% (95% CI: 5.4%, 22.2%) at lag 2 day or of 6.8% (95% CI: 3.4%, 10.2%) at lag 1 day, respectively (Li et al. 2019). A longitudinal study in 89 healthy adult participants living in a work campus in Changsha City, China, found that a 10-ppb increase in 24-hour personal ozone exposure was associated with a mean increase of 18.1% (95% CI: 4.5%, 33.5%) in FeNO (Day et al. 2017). However, a cross-sectional study conducted among 139 women in rural Honduras reported a null association of FeNO with exposure to household air pollution (Benka-Coker et al. 2018).

Children, the elderly, and people with preexisting diseases are more susceptible in FeNO in response to indoor air pollution exposure. A study conducted among 1635 southern California schoolchildren reported that traffic-related air pollution (TRAP) indoors was associated with proximal and distal airway inflammation by relating indoor nitric oxide (NO), a marker of TRAP exposure in the indoor microenvironment, to airway and alveolar sources of exhaled nitric oxide. A 10 ppb higher indoor NO concentration was associated with 0.10 ppb higher average alveolar NO concentration ($C_{\text{A}}\text{NO}$) (95% CI: 0.04–0.16), 4.0% higher maximum airway wall NO flux ($J'_{\text{aw}}\text{NO}$ (95% CI: -2.8–11.3)), and 0.2% lower airway wall tissue diffusing capacity ($D_{\text{aw}}\text{NO}$) (95% CI: -4.8–4.6) (Eckel et al. 2016). A randomized, double-blind crossover study among 44 healthy school children found that indoor PM_{0.5}, PM_{2.5}, PM₁₀, and black carbon (BC) were decreased significantly by 48%, 44%, 34%, and 50% with a real ionization air purifier. The use of ionization air purifier can effectively decrease FeNO by 14.7% (Dong et al. 2019), and an IQR increase in PM_{1.0} (22.2 µg/m³) and BC (3.6 µg/m³) was associated with the increase in FeNO of 23.5% and 22.1%, respectively. A study conducted among 16 older subjects with asthma or chronic obstructive pulmonary disease (COPD) in Seattle, Washington, reported that for the seven subjects with asthma, a 1 µg/m³ increase in indoor and personal BC was associated with the increase in FeNO of 4.0 ppb (95% CI: 2.0, 5.9) and 1.2 ppb (95% CI: 0.2, 2.2), respectively (Jansen et al. 2005).

Exhaled Breath Condensate (EBC)

Exhaled breath condensate (EBC), thought of either as a body fluid or a condensate of exhaled gas, has emerged as a promising biospecimen that can be used to measure biomarkers reflecting respiratory health. EBC contains biomarkers, some of which can be assessed in a way equivalent to using other biospecimens such as blood, sweat, tears, urine, and saliva (Davis et al. 2012). EBC is a noninvasive mean of sampling the airways, allowing biomarkers of airway inflammation and oxidative stress to be directly measured using this specimen.

Malondialdehyde in Exhaled Breath Condensate

As a stable product of lipid peroxidation, malondialdehyde (MDA) has long been considered a biomarker of oxidative stress. Increased oxidative stress levels can result from increasing concentrations of reactive oxygen species (ROS) in cells and tissues. ROS react with lipids in the cell membrane and in body fluids, generating peroxidation products including MDA. A longitudinal study involving 89 healthy office workers living in a work campus in Changsha City, China, was conducted to examine the association between ozone exposure and cardiopulmonary pathophysiologic mechanisms (Day et al. 2017). In this study, with single-pollutant models, a 10-ppb increase in 24-hour personal O₃ exposure concentration (largely driven by indoor concentration) was associated with a significant decrease in EBC MDA of 26.3% (95% CI: -37.9%, -12.4%). For 2-week O₃ exposure concentration, a 10-ppb increase was associated with a significant decrease in EBC MDA level of 52.0% (95% CI: -67.0%, -30.4%). For other pollutants including PM_{2.5}, NO₂, and SO₂, each of these pollutants shared various positive associations with EBC MDA level, with only the 2-week NO₂ exposure concentration significantly associated with the increase in EBC MDA level of 29.9% (95% CI: 11.5%, 51.2%) as well as the 2-week SO₂ exposure concentration significantly associated with the increase in EBC MDA level of 258.9% (95% CI: 92.4%, 569.4%) after multiple testing correction.

The Sum of EBC Nitrite and Nitrate (EBCNN)

The EBCNN level reflects NO metabolism in the airways and is related to pulmonary inflammation, as airway tissue inflammation results in extra production of NO (NO measured in exhaled breath, FeNO, is another biomarker of pulmonary inflammation, as discussed above) The same study in the 89 office workers as described above found that in single-pollutant models, a 10-ppb increase in 24-hour O₃ exposure concentration was associated with the significant increase in EBCNN of 53.8% (95% CI: 23.6%, 91.5%). For 2-week O₃ exposure concentration, a 10-ppb increase was associated with the significant increase in EBCNN of 158.9% (95% CI: 61.2%, 315.8%) (Day et al. 2017).

Lung Function Parameters

Lung function parameters, including forced vital capacity (FVC), forced expiratory volume in the first second (FEV₁), FEV₁/FVC, peak expiratory flow (PEF), and FEF_{25–75%}, can reflect the early health effects of indoor air pollution on the

respiratory system. The Framingham Heart Study concluded that short-term exposure to PM_{2.5}, NO₂, and O₃ within US EPA standards was associated with lower lung function (Rice et al. 2013). Based on observed adverse effects on lung function caused by outdoor air pollution, studies have explored the associations between indoor air pollutants and lung function. A cross-sectional study from the Colorado Home Energy Efficiency and Respiratory health (CHEER) reported that annual average infiltration rate (AAIR) was positively associated with increased FEV₁/FVC z-scores, such as 1-unit change in AAIR was corresponded to a half of a standard deviation in lung function ($\beta = 0.51$, CI: 0.02–0.99). The results indicated that increased home ventilation, which may alter the composition of indoor air, was associated with improvement of respiratory health (Humphrey et al. 2020). A population-based cross-sectional survey designed to be representative of the Canadian population reported that increasing indoor concentrations of certain VOCs were associated with decreasing lung function (Cakmak et al. 2014). A randomized crossover intervention study conducted in 32 healthy adults reported that an IQR increase of 4.09 µg/m³ in indoor PM_{10–2.5} was associated with a significant decrease in the FEV₁/FVC of 0.52% (95% CI: 0.05%, 1.00%); an IQR increase of 2.81 ppb in indoor O₃ was associated with a significant decrease in maximal midexpiratory flow (MMEF) of 0.23 L/s (95% CI: 0.07, 0.40) (Yoda et al. 2020). A randomized, double-blind crossover study in 37 people living in 20 residences on a First Nations Reserve in Manitoba, Canada, reported that indoor PM_{2.5} decreased substantially during air filtration and that air filter use was associated with a 217 mL (95% CI: 23, 410) increase in FEV₁. This study also reported consistent inverse associations between PM_{2.5} exposure and lung function parameters including FEV₁, FVC, and PEF_{25%–75%} (Weichenthal et al. 2013).

Several studies have explored the association between indoor air pollution and lung function among vulnerable people such as children, the elderly, and individuals with preexisting diseases. A panel study conducted among 125 patients with COPD reported that increasing indoor exposures to black carbon particles (BC) were associated with decreases in prebronchodilator FEV₁, FVC, and FEV₁/FVC. Each IQR increase in indoor BC from the weekly integrated filter was associated with a 17.87 mL (95% CI: 1.98, 33.76) decrease in prebronchodilator FEV₁ (Hart et al. 2018). Another study investigated the association between indoor air quality and respiratory morbidity and lung function among elderly people residing in nursing homes in seven European countries. One of the main findings was that the subjects exposed to indoor concentrations above the median values of ultrafine particles (PM_{0.1}) and NO₂ were more likely (adjusted OR of 8.16 and 95% CI of 2.24–29.3 for PM_{0.1} and adjusted OR of 3.74 and 95% CI of 1.06–13.1 for NO₂) to have a low FEV₁/FVC ratio (<70%, indicative of airway obstruction, compared to the subjects exposed to indoor concentrations below the median values) (Bentayeb et al. 2015). A randomized crossover trial conducted among 44 asthmatic children of 10–16 years old found that one-unit increase in the first principal component variable representing indoor PM (predominantly composed of ultraviolet light absorbing particulate matter (UVM) and PM_{2.5}) was associated with a decrease in FEV₁/FVC ratio by 4.1% (99% CI: 1.4%, 6.9%), and that 17.7 µg/m³ increase in indoor

PM_{2.5} was associated with 6.1% (99% CI: 1.9%, 10.2%) decrease in percent-predicted FEV₁/FVC ratio and 12.9% (99% CI: 1.0%, 24.9%) decrease in FEF_{25–75}. This study also found that indoor PM was more strongly associated with lung function than outdoor PM (Isiugo et al. 2019). A cross-sectional study investigating the relationship between exposure to indoor PM and respiratory health in middle-aged subjects in Copenhagen, Denmark, reported that high levels of indoor particle number concentrations (PNC, 10–300 nm) were associated with significantly lower lung function. One IQR increase in indoor PNC was associated with a decrease in FEV₁/FVC of 2.1% (95% CI: 0.4%, 3.8%) (Karottki et al. 2014). A randomized, double-blind crossover study among 44 school children in Beijing, China, demonstrated that indoor air purification by PM filtration was associated with significantly higher FEV₁. This beneficial effect of the intervention was consistent with other findings of the study that increasing indoor concentrations of sized-fractional PM was associated with decreasing FEV₁. Particularly, the most significant reduction of FEV₁ was 6.5% per IQR increase in PM_{0.5} (17.9 µg/m³) and 7.0% per IQR increase in BC (3.6 µg/m³) (Dong et al. 2019).

However, not all studies have shown a significant association between indoor air pollution and lung function. A randomized, double-blind, crossover intervention study in 48 nonsmoking subjects (51 to 81 years) in 27 homes reported that the particle filters reduced the concentration of PM_{2.5} indoors significantly; however, no beneficial effect on lung function was found in this elderly population (Karottki et al. 2013). A randomized, double-blind crossover trial among 35 healthy college students also measured reduced indoor PM_{2.5} concentrations during the use of air filtration but failed to observe a statistically significant improvement in lung function in Shanghai, China (Chen et al. 2015b). The inconsistent findings on the lung function effect of indoor air pollution exposure and the lung function effect of indoor air purification can be attributed to differences in study design and sample size, study participants, exposure levels or the magnitude of exposure reduction in intervention studies, and timing of lung function measurement relevant to exposure, and potential confounding factors including temperature, relative humidity, and other indoor air pollutants. Nevertheless, lung function parameters, such as FVC, FEV₁, FEV₁/FVC, PEF, and FEF_{25–75%}, are useful biomarkers in assessing the health effects of indoor air pollution.

Application of Biomarkers in Assessing Health Risks of the Cardiovascular System

The Structure and Function of the Cardiovascular System

The cardiovascular system comprises heart and blood vessels including arteries, veins, and capillaries. Two circulation systems, including pulmonary circulation and somatic circulation, are involved in the cardiovascular system. In the pulmonary circulation, the deoxygenated blood is transported from the right ventricle into the lungs through the pulmonary artery. After enriching with oxygen in the lungs, it flows into the left atrium through pulmonary veins. In somatic circulation, blood is

pumped through the left ventricle and the aorta to supply all the body with oxygen-enriched blood. After ingesting by organs and cells, the blood low in oxygen and enriched in CO₂ turns back toward the heart through veins. Inhaled air pollutants can disrupt the normal circulation of blood through a number of pathologic processes as described below.

Indoor Air Pollution Affects Cardiovascular Health

Previous studies have demonstrated the associations between outdoor air pollution and adverse cardiovascular health effects, including acute myocardial infarction, coronary artery disease, stroke, peripheral artery disease, congestive heart failure, and cardiovascular mortality (Brook et al. 2010; Kaufman et al. 2012). Indoor air pollution is considered to cause similar or greater adverse effects on the cardiovascular system when considering that a large fraction of outdoor air pollutants can penetrate into the indoor environment and that the majority of the total exposure actually occurs indoors (Xiang et al. 2019). In addition to pollutant infiltrating from outdoors, pollutants can be directly emitted to the indoor environment from indoor sources such as cooking, tobacco smoking, consumer products, and building material off gassing. The biomarkers of cardiovascular health effects of indoor air pollution were shown as below and in Table 2.

Biomarkers of Cardiovascular Health Effects of Indoor Air Pollution

Cardiac Autonomic Function

Previous studies demonstrate that air pollution may cause adverse effects on autonomic function, including decreased heart rate variability (HRV) (Chuang et al. 2007; Schwartz et al. 2005). HRV provides a noninvasive measurement by assessing the activity of the cardiac autonomic system and has been used to evaluate the cardiac effects of environmental exposures.

A randomized crossover study evaluated the effects of short-term indoor air filtration intervention on cardiovascular health in 35 nonsmoking elderly participants living in Beijing. The study found a positive association between indoor air pollution exposure and impaired cardiac autonomic nervous system (Liu et al. 2018). In the study, households were randomly allocated to receive 2-week true or sham filtration with portable air filtration. The authors reported that indoor PM_{2.5} and indoor black carbon (BC) decreased 34.8% and 35.3%, respectively, during the true filtration period. The results also indicated that the standard deviation of normal-to-normal intervals (SDNN) decreased by -1.25% (95% CI: -2.06, -0.42) with a 10 µg/m³ increase in 8-h indoor PM_{2.5}-moving average, whereas the results for the square root of the mean of the squared differences between adjacent normal-to-normal intervals (RSDNN), low frequency (LF), high frequency (HF), and total power (TP) were similar to the effect of PM_{2.5} on SDNN. In addition, RSDNN decreased by -5.93% (95% CI: -9.37, -2.35) with a 1 µg/m³ increase in 8-h indoor BC-moving average.

Table 2 Biomarkers of the cardiovascular system used in assessing health risk of indoor air pollutants

Study site	Year	Study design	Pollutant	Participant, N	Biomarker	Reference
Beijing	2018	Randomized crossover trial	PM _{2.5} , BC	Nonsmoking elderly, 35	SDNN, RMSSD, LF, HF, TP, SBP, DBP, and MAP	Liu et al. (2018)
Taipei	2013	Panel study	PM _{2.5} , PM ₁₀ , TVOCs, and CO	Healthy adults, 300	SDNN, RMSSD	Lin et al. (2013)
Beijing	2018	Repeated-measure study	PM, BC	Patients with chronic obstructive pulmonary disease, 43	SDNN, RMSSD, SDANN, pNN50, HR, LF, HF, TP, and LF/FF	Pan et al. (2018)
Beijing	2019	Repeated-measure study	Ozone	Middle-school children	SDNN, RMSSD, SDANN, pNN50, HR, LF, HF, TP, and LF/FF	Huang et al. (2019)
Beijing	2020	Randomized double-blind crossover trial	PM	Healthy children, 44	SDNN, RMSSD, pNN50, HR, LF, HF, TP, and LF/FF	Liu et al. (2020)
Beijing	2019	Randomized double-blind crossover trial	PM _{0.5} , PM _{1.0} , PM _{2.5} , PM ₁₀ , and BC	Children, 44	SDNN, RMSSD, SDANN, pNN50, HR, LF, HF, TP, LF/FF, II_ST, V2_ST, and V5_ST	Dong et al. (2019)
British Columbia	2011	Randomized crossover trial	PM _{2.5}	Healthy adults, 45	HRI, SBP, DBP	Allen et al. (2011)
Copenhagen	2008	Randomized double-blind crossover trial	PM _{2.5} , PM _{10-2.5}	Healthy elderly, 42	MVF, SBP, DBP	Brauner et al. (2008)
Copenhagen	2013	Randomized double-blind crossover trial	PNC, PM _{2.5}	Healthy elderly, 51	MVF, SBP, and DBP	Karotki et al. (2013)
Chaurikharka	2019	Observational study	PM ₁₀ , PM _{2.5} , and BC	Residents, 78	PWV, SBP, and DBP	Pratali et al. (2019)
Duisburg	2019	Randomized crossover trial	PM ₁₀ , PM _{2.5} , and PNC	Healthy adults, 55	AI, PWV	Soppa et al. (2019)

Shanghai	2015	Randomized double-blind crossover trial	$\text{PM}_{2.5}$	Healthy college students, 35	SBP, DBP, and PP	Chen et al. (2015b)
Shanghai	2017	Randomized double-blind crossover trial	$\text{PM}_{2.5}$	Healthy college students, 55	SBP, DBP, and PP	Li et al. (2017)
Detroit	2018	Randomized double-blind crossover trial	$\text{PM}_{2.5}$	Residents, 40	SBP, DBP, PWV, SDNN, LF/HF, and AI	Morishita et al. (2018)
Peru	2020	Cross-sectional study	$\text{PM}_{2.5}$, CO	Residents, 902	SBP, DBP	Kephart et al. (2020)
Somerville	2015	Randomized crossover trial	PNC	Residents living near highways, 20	SBP, DBP	Padró-Martínez et al. (2015)
Manitoba	2013	Randomized double-blind crossover trial	$\text{PM}_{2.5}$	Residents, 37	RHI, SBP, and DBP	Weichenthal et al. (2013)
New Jersey	2014	Randomized crossover trial	$\text{PM}_{2.5}$, BC, CO, and NO_2	Healthy adults, 21	SDNN, rSDNN, LF, HF, and HR	Laumbach et al. (2014)

PM_i : particulate matter, $\text{PM}_{2.5}$: particulate matter with an aerodynamic diameter $\leq 2.5 \mu\text{m}$, $\text{PM}_{0.5}$: particulate matter with an aerodynamic diameter $\leq 0.5 \mu\text{m}$, PM_{10} : particulate matter with an aerodynamic diameter $\leq 10 \mu\text{m}$, CO: carbon monoxide, TVOCs: total volatile organic compounds, BC: black carbon, FNC: particle number concentration, SDNN: standard deviation of normal-to-normal intervals, RMSSD: the square root of the mean of the squared differences between adjacent normal-to-normal intervals, LF: low frequency, HF: high frequency, TP: total power, SBP: systolic blood pressure, DBP: diastolic blood pressure, MAP: ambulatory mean arterial pressure, SDANN: standard deviation of the averages of normal-to-normal intervals in all 5-min segments of the entire recording, HR: heart rate, pNN50: percentage of number of normal-to-normal interval with difference ≥ 50 ms, RHI: reactive hyperemia index, MVF: microvascular function, PWV: pulse wave velocity, AI: pulse wave velocity, AI: augmentation index, and PP: pulse pressure

A panel study of 300 healthy subjects living in Taipei was conducted to explore the relationship between indoor air pollution and cardiovascular health. In the study, three exposure conditions were investigated: Participants were required to keep their windows open during the first two visits and closed during the next two visits. The closed window conditions were coupled with the use of air conditioning (Lin et al. 2013). The results of the Taipei study demonstrated decreases in HRV were associated with increased levels of indoor particles and total volatile organic compounds (VOCs). In specific, an IQR increase in indoor PM_{2.5} was associated with decreases in SDNN of 4.6% (95% CI: -5.5%, -3.7%) and 1.5% (95% CI: -2.0%, -1.0%) during the period of keeping windows open and the period of window closing and air conditioning use, respectively; an IQR increase in indoor PM_{2.5} was also associated with the decrease in RSDNN of 3.5% (95% CI: -6.5%, -0.5%) and 2.4% (95% CI: -4.5%, -0.3%) during the period of keeping windows open and the period of window closing and AC use, respectively. In the same panel study, the similar associations between total VOCs and SDNN, RSDNN were also reported; the effects of indoor PM_{2.5} and total VOCs on SDNN were significantly stronger with windows open compared with the period of keeping windows closed.

A repeated-measure study in 43 COPD patients in Beijing monitored indoor concentrations of size-fractioned PM, including PM_{0.5}, PM_{1.0}, PM_{2.5}, PM_{5.0}, and PM₁₀, and 24-h-ambulatory electrocardiogram (ECG) (Pan et al. 2018). The study indicated that increasing levels of size-fractioned PM and BC were associated with decreased HRV indices and increased heart rate (HR). In specific, an IQR (3.14 µg/m³) increase in 8-h BC-moving average and an IQR (20.72 µg/m³) increase in 5-min PM_{0.5}-moving average concentrations were associated with declines of 7.45% (95% CI: -10.89%, -3.88%) and 16.40% (95% CI: -21.06%, -11.41%) in LF, respectively. The smaller the particles size, the greater effects on HRV indices and HR. Similar strong inverse associations were found for HF and SDNN with size-fractioned PM and BC, respectively.

In another study, 46 middle-school children in Beijing were measured longitudinally for their personal exposure to ozone, PM, and BC as well as ECG (Huang et al. 2019). The study found that per IQR increase in ozone at 2-hour moving average was associated with -7.8% (95% CI: -9.9%, -5.6%) reduction in SDNN and 2.6% (95% CI: 1.6%, 3.6%) increment in HR. The associations were stronger at high BC levels (BC ≥ 3.7 µg/m³).

A randomized, double-blind crossover study among 44 healthy children also reported that reduced PM improved HRV, showing percent reductions in HRV indices per IQR increases in size-fractionated PM and BC over different moving averages (Liu et al. 2020). The greatest decrease in HF was 16.1% per IQR increase in PM_{0.5} (17.9 µg/m³) at 5-min moving average. The smaller the PM size, the stronger the effect observed. The greatest decreases were observed at 5-min moving averages for PM_{0.5} and PM_{1.0}, but 2-h moving averages for PM_{2.5}, PM₅, and PM₁₀. For BC, the greatest decrease in HF was 18.8% per IQR increase (3.6 µg/m³) at 3-h moving average. The association patterns of other indices including LF and SDNN were similar with HF. In addition, significant increases in V5_ST elevation were

associated with PM_{0.5} and PM_{1.0}. The greatest increase in V5_ST elevation was 0.022 mV per IQR increase in PM_{1.0} (22.2 µg/m³) (Dong et al. 2019).

However, some studies have not observed an association between indoor air pollution and HRV (Laumbach et al. 2014). A randomized, double-blind crossover intervention study among 40 nonsmoking older adults in a low-income senior residential building in Detroit, Michigan, did not find significant changes in HRV indices by period (Morishita et al. 2018). Another randomized crossover intervention trial in a panel of 35 nonsmoking senior participants conducted in China found an inverse association, although not statistically significant, between the use of portable air purifiers and HRV parameters (Shao et al. 2017).

Vascular Function

Vascular function is essential to assess cardiovascular health, and previous studies explored the associations between indoor air pollution and vascular function.

Reactive Hyperemia Index (RHI)

Reactive hyperemia index (RHI) is a promising cardiovascular risk predictor. Previous studies have validated its value in assessing coronary microvascular endothelial function and in predicting cardiovascular outcome in patients at risk, including those with chronic kidney disease (Liu et al. 2017). In a randomized crossover intervention study of the impact of particle exposures on endothelial function, 45 healthy adult residents of British Columbia, Canada, were randomized to receive consecutive 7-day periods of filtered and nonfiltered indoor air intervention (Allen et al. 2011). The results showed that indoor air purification was associated with a 9.4% (95% CI: 0.9, 18%) increase in RHI, implying improved endothelial function. However, two other studies did not find a significant increase of RHI associated with an indoor air purification intervention (Kajbafzadeh et al. 2015; Weichenthal et al. 2013).

Microvascular Function (MVF)

Measures of MVF have emerged as potential surrogate markers of cardiovascular outcomes. An air filtration-based intervention study including 21 nonsmoking and healthy elderly couples was conducted to explore the effects of indoor particles on the vascular function. In this crossover trial, the subjects were randomized to receive consecutive 48-hour particle-filtered or unfiltered indoor air. The results demonstrated that reduction of particle concentration in indoor air by filtration significantly improves MVF (Brauner et al. 2008). Similarly, a randomized, double-blind, crossover intervention study with a consecutive 2-week period of with or without air purification also found a significant association between decreased PM_{2.5} and improved MVF (Karottki et al. 2013).

Pulse Wave Velocity (PWV)

PWV is a simple and noninvasive indicator to assess stiffness of the arteries. PWV measures the performance of the arteries and has been established as a reliable prognostic parameter for cardiovascular morbidity and mortality in a variety of

adult populations including older adults, patients with end-stage renal disease, diabetes, and hypertension. An observational study monitored indoor levels of PM₁₀, PM_{2.5}, and BC in a Himalayan village (Pratali et al. 2019). The study found that average BC was correlated with PWV ($R = 0.589$, $P < 0.001$) especially in subjects older than 30 years. In a multiple variable analysis, BC remained an independent predictor of PWV ($\beta = 0.556$, $P = 0.001$).

Augmentation Index (AI)

The augmentation index (AI) is another indicator of arterial stiffness and has been shown to be elevated in those with hypercholesterolemia (Wilkinson et al. 2002). It is considered an early sign of vascular damage. It has been suggested that an increase in arterial stiffness is associated with increased systolic blood pressure (SBP) and diastolic blood pressure (DBP). Arterial stiffness is one of the major risk factors of cardiovascular disease (CVD) (Greenwald 2007). A randomized sham-controlled exposure study in 55 healthy adults investigated the effect of short-term exposure to indoor fine and ultrafine particles (UFP) on AI (Soppa et al. 2019). The study analyzed the association of particle emissions from several indoor sources, including candle burning, toasting bread, and frying sausages, with changes in pulse wave analysis indices. The study found that during candle burning, UFP concentrations were substantially increased, which was associated with a 9.5% (95% CI: 3.1%, 15.9%) increase in AI. During toasting bread, PM₁₀ and PM_{2.5} concentrations were increased significantly and were associated with 5.8% (95% CI: 3.2%, 8.4%) increase in AI 2 hours following the peak PM₁₀ exposure and 8.1% (95% CI: 2.5%, 13.7%) increase in AI immediately after PM_{2.5} peak exposure.

Blood Pressure

Blood pressure (BP) is one of the most widely used noninvasive indicators to assess vascular function and is the most significant risk factor for cardiovascular disease. A recent systematic review and meta-analysis of 65 epidemiological studies covering 16 countries reported that short-term exposures to four (PM₁₀, PM_{2.5}, SO₂, NO₂), two (PM_{2.5} and SO₂), and four air pollutants (PM₁₀, PM_{2.5}, SO₂, and NO₂) were significantly associated with hypertension, systolic blood pressure (SBP), and diastole blood pressure (DBP), respectively. The overall meta-analysis showed significant associations of long-term exposures to PM_{2.5} with hypertension as well as significant associations of PM₁₀, PM_{2.5}, NO₂, with DBP (Yang et al. 2018). Numerous studies have investigated the associations between indoor air pollution and BP (Allen et al. 2011; Brauner et al. 2008; Karottki et al. 2013; Kephart et al. 2020; Morishita et al. 2018; Padró-Martínez et al. 2015; Pratali et al. 2019; Weichenthal et al. 2013).

A randomized, double-blind crossover trial was conducted among 40 nonsmoking older adults in Detroit, Michigan. The participants experienced in their bedrooms and living rooms the following three conditions, each of 3-day duration, separated by 1-week washout periods: unfiltered air (sham filtration), low-efficiency (LE) HEPA filtration, and high-efficiency (HE) HEPA filtration, respectively. The results showed that personal PM_{2.5} exposures were significantly reduced by HEPA filtration from a

mean (SD) of 15.5 (10.9) $\mu\text{g}/\text{m}^3$ under the sham filtration to 10.9 (7.4) $\mu\text{g}/\text{m}^3$ under the LE filtration and 7.4 (3.3) $\mu\text{g}/\text{m}^3$ under the HE filtration. Compared with sham filtration, any HEPA filtration decreased SBP and DBP by 3.2 mm Hg (95% CI: -6.1 to -0.2 mm Hg) and 1.5 mm Hg (95% CI: -3.3 to 0.2 mm Hg), respectively. A continuous decrease occurred in SBP and DBP during the 3-day period of the LE filtration, with a mean of 3.4 mm Hg (95% CI: -6.8 to -0.1 mm Hg) and 2.2 mm Hg (95% CI: -4.2 to -0.3 mm Hg), respectively. Similarly, for the HE filtration, SBP and DBP decreased by 2.9 mm Hg (95% CI: -6.2 to 0.5 mm Hg) and 0.8 mm Hg (95% CI: -2.8 to 1.2 mm Hg), respectively (Morishita et al. 2018).

Thirty-five healthy college students in Shanghai, China, were recruited into a randomized, double-blind crossover trial and alternated the use of true or sham air purifiers for 48 hours with a 2-week washout interval (Chen et al. 2015b). The results showed that air purification resulted in a 57% reduction in PM_{2.5} concentration from 96.2 to 41.3 $\mu\text{g}/\text{m}^3$ within hours of operation; SBP, DBP, and pulse pressure decreased 2.7% (95% CI: -5.1%, -0.4%), 4.8% (95% CI: -8.5%, -1.2%), and 0.1% (95% CI: -8.5%, 7.7%), respectively, compared to the sham-purification. In this intervention study, an IQR increase (64 $\mu\text{g}/\text{m}^3$) in continuous indoor PM_{2.5} concentration was associated with an increase of 4.0% (95%CI: 0.9%, 7.2%) in DBP. In another randomized, double-blind crossover trial in 55 healthy college students in Shanghai, China, true and sham air purifiers were placed in subjects' dormitories randomly for 9 days with a 12-day washout interval (Li et al. 2017). The use of air purifiers reduced personal PM_{2.5} significantly from 53.1 $\mu\text{g}/\text{m}^3$ during the sham purification to 24.3 $\mu\text{g}/\text{m}^3$ during the real purification. Concomitantly, SBP was 2.61% (95% CI: 0.39%, 4.79%) higher during the sham purification than during the true purification. A 10 $\mu\text{g}/\text{m}^3$ increase in PM_{2.5} exposure was associated with 0.86% (95% CI: 0.10%, 1.62%) increase in SBP. Similar changes, although without a statistically significance, were observed for DBP and pulse pressure. Additionally, significant decreases in both SBP and DBP were observed following true purification from the prepurification values, while no significant changes were seen following sham purification. In another randomized crossover intervention study of short-term indoor air filtration intervention on cardiovascular health among 35 nonsmoking elderly participants living in Beijing in the winter of 2013, portable air filtration units were randomly allocated to active filtration for 2 weeks and sham filtration for 2 weeks in the households (Liu et al. 2018). Twelve-hour daytime ambulatory blood pressure (ABP) was measured during active and sham filtration, and real-time indoor and outdoor PM_{2.5} and indoor BC concentrations were measured. The study found that indoor PM_{2.5} and indoor BC decreased by 34.8% and 35.3% during active filtration. Indoor PM_{2.5} and BC exposures were significantly associated with increased ABP indices. Each 10 $\mu\text{g}/\text{m}^3$ increase in 8-hour moving average exposure of indoor PM_{2.5} was associated with increases of 0.39% (95% CI: 0.03%, 0.75%), 0.57% (95% CI: 0.05%, 1.10%), and 0.49% (95% CI: 0.07%, 0.92%) in SBP, DBP, and mean arterial pressure, respectively.

The aforementioned studies provide scientific evidence on cardiovascular health benefits reflected by reduced blood pressure of using air purifiers. The associations between indoor air pollutants and blood pressure, observed in these studies, support

the usefulness of blood pressure measures (SBP, DBP, and/or pulse pressure) as biomarkers of cardiovascular health in indoor air health studies.

Application of Biomarkers in Assessing Health Risks of the Hematologic System

The Structure and Function of the Hematologic System

The hematologic system consists of cells, tissues, and organs responsible for producing and maintaining blood and blood cells. Blood consists of plasma and blood cells (red blood cells, white blood cells, platelets, etc.) and is connected with all tissues and organs through the circulation system, involved in various physiological activities and maintaining the normal metabolism and homeostasis.

Indoor Air Pollution Affects Hematologic Health

The updated American Heart Association scientific statement in 2010 postulated that thrombosis and coagulation are among the mechanisms to explain the biological actions responsible for the adverse cardiovascular effects of PM (Brook et al. 2010). Indoor air pollution is also associated with thrombosis and blood coagulation. For example, chronic indoor pollution exposure to biomass cooking in rural India was associated with elevated circulating markers of platelet activation (Ray et al. 2006). The biomarkers of hematologic health effects of indoor air pollution were shown as below and in Table 3.

Biomarkers of Hematologic Health Effects of Indoor Air Pollution

Blood-Related Parameters

Hemoglobin (Hb)

A total of 41 nonsmoking elderly volunteers participated in a randomized, double-blind, crossover study with two consecutive 48-hour exposure scenarios of either particle-filtered or nonfiltered in their homes (Brauner et al. 2008). The results showed that hemoglobin (Hb) concentration was significantly improved by 0.9% (95% CI: 0.1%, 1.8%) during air filtration, as assessed in the mixed-effects model with inclusion of filtration as a categorical variable. A study conducted in rural north-east India investigated the levels of PM_{2.5} and PM₁₀ released during cooking with fuelwood and subsequent changes in hematological parameters (Rabha et al. 2018). The results showed the reduction of Hb concentration was significantly associated with higher PM_{2.5} and PM₁₀, respectively, after adjusting for confounding factors (e.g., age, height, weight, cooking index, and monthly income) in multiple linear regressions. One percent increases in the levels of PM_{2.5} and PM₁₀ resulted in 0.62%

Table 3 Biomarkers of the hematologic system used in assessing health risk of indoor air pollutants

Study site	Year	Study design	Pollutant	Participant, N	Biomarker	Reference
Copenhagen	2008	Randomized double-blind crossover trial	PM _{2.5} , PM _{10-2.5} ,	Healthy elderly, 42	Hb, RBC count, platelet count, plasma-selectin, and fibrinogen	Brauner et al. (2008)
Assam	2018	Cross-sectional study	PM _{2.5} , PM ₁₀	Healthy rural women, 200	Hb, WBC count, RBC count, and platelet count	Rabha et al. (2018)
Hungarian	2003	Cross-sectional study	NO ₂ , formaldehyde, benzene, xylene, and toluene	Asthmatic children, 176	RBC count, WBC count, and platelet count	Erdei et al. (2003)
Tehran	2017	Panel study	PM ₁₀ , PM _{2.5} , and PM ₁	Nonsmoking elderly, 44 Nonsmoking male high school students, 40	WBC count, vWF	Hassanvand et al. (2017)

Shanghai	2018	Randomized double-blind crossover trial	PM _{2.5} , PNC	Healthy adults, 70	vWF	Cui et al. (2018)

(continued)

Table 3 (continued)

Study site	Year	Study design	Pollutant	Participant, N	Biomarker	Reference
Shanghai	2015	Randomized double-blind crossover trial	PM _{2.5}	Healthy college students, 35	sCD40L	Chen et al. (2015b)
Beijing	2020	Randomized double-blind crossover trial	PM _{2.5}	Healthy college students, 29	sCD40L	Sun et al. (2020)

PM: particulate matter, PM_{2.5}: particulate matter with an aerodynamic diameter $\leq 2.5 \mu\text{m}$, PM_{0.5}: particulate matter with an aerodynamic diameter $\leq 0.5 \mu\text{m}$, PM₁: particulate matter with an aerodynamic diameter $\leq 1 \mu\text{m}$, PM₁₀: particulate matter with an aerodynamic diameter $\leq 10 \mu\text{m}$, NO₂: nitrogen dioxide, CO: carbon monoxide, TVOCs: total volatile organic compounds, PNC: particle number concentration, Hb: hemoglobin, RBC: red blood cell, WBC: white blood cell, vWF: von Willebrand factor, sP-selectin: soluble P-selectin, and sCD40L: soluble CD40 ligand

(95% CI: -0.057 , -0.003) and 0.54% (95% CI: -0.057 , -0.002) decrease in Hb concentration, respectively.

Red Blood Cells (RBC)

A cross-sectional study among Hungarian asthmatic school children aged 9–11 years reported a significant association between higher indoor nitrogen dioxide (NO_2) concentration and increased RBC count (Erdei et al. 2003). The authors speculated that the increase in RBC count associated with higher indoor NO_2 might have been a consequence of insufficient oxygen concentration indoors, because the indoor combustion source of NO_2 could have depleted oxygen indoors. Higher RBC levels may be used as a biomarker reflecting the negative effect of indoor air pollution on oxygenation in the blood.

White Blood Cells (WBC)

A study conducted in rural northeast India investigated the levels of $\text{PM}_{2.5}$ and PM_{10} released during cooking with fuelwood and subsequent changes in hematological parameters (Rabha et al. 2018). The study found that WBC had a positive and significant association with PM_{10} concentration, with 0.66% (95% CI: 0.019, 0.158) increase in WBC per 1% increase in PM_{10} concentration. A cross-sectional study among Hungarian asthmatic school children aged 9–11 years old also reported the significant association between high indoor NO_2 concentration and increased WBC count (Erdei et al. 2003).

A study involving a panel of 44 nonsmoking elderly subjects living in a retirement home and a panel of 40 healthy young adults living in a school dormitory in Tehran city, Iran, was conducted to clarify the effects of short-term exposure to size-fractionated PM (Hassanvand et al. 2017). The results showed that in the healthy young panel, exposure to PM_{10} , $\text{PM}_{2.5-10}$, and $\text{PM}_{1-2.5}$ was associated with increased WBC at different lag times, with the strongest association of 17.6% (95% CI: 10.5%, 25.2%) observed between WBC and $\text{PM}_{2.5}$ at lag 1. In the elderly population, exposure to PM_{10} , $\text{PM}_{2.5-10}$, $\text{PM}_{2.5}$, $\text{PM}_{1-2.5}$, and PM_1 was also strongly associated with increased WBC. Acute increases in WBC counts are associated with acute systemic inflammation.

Platelet Count

A study conducted in rural northeast India investigated the levels of $\text{PM}_{2.5}$ and PM_{10} released during cooking with wood and subsequent changes in hematological parameters (Rabha et al. 2018). The results showed that platelet counts were positively and significantly associated with both $\text{PM}_{2.5}$ and PM_{10} , with a 0.91% (95% CI: 0.105, 0.283) and 0.79% (95% CI: 0.095, 0.287) increase per 1% increase in the levels of $\text{PM}_{2.5}$ and PM_{10} , respectively. In a study of the health impacts of indoor air pollution from household cooking fuels, biomass fuel users were exposed to three times higher particulate pollution in kitchen and had significantly higher platelet aggregation than clean fuel users (23.2 versus 15.9 Ohm) (Dutta et al. 2011). An increase in platelet count is associated with an increased risk for blood coagulation or thrombosis.

Blood Coagulation Biomarkers

Fibrinogen

Fibrinogen, a soluble protein, is generated in the liver and mainly presents in the blood plasma. It is a key biomarker for blood coagulation. A panel of 300 healthy subjects from Taipei, aged 20 and over, were recruited to explore whether improving indoor air quality through air conditioning can improve cardiovascular health in human subjects (Lin et al. 2013). The results showed that the increase in fibrinogen was associated with increased levels of indoor particles and total VOCs in single-pollutant and two-pollutant models. In specific, in single-pollutant model, an IQR increase in PM_{2.5} and TVOC was associated with increases of 5.3% (95% CI: 1.5%, 15.2%) and 8.9% (95% CI: 4.2%, 13.6%) in fibrinogen concentration, respectively. In a two-pollutant models, an IQR increase in PM_{2.5} and TVOC was associated with increases of 3.4% (95% CI: 1.5%, 5.2%) and 1.6% (95% CI: 0.2%, 3.0%) in fibrinogen concentration, respectively.

Soluble P-Selectin (sP-Selectin)

The biomarker sP-selectin, also known as sCD62P, is derived predominantly from activated platelets and represents a circulating marker of platelet activation (De Pergola et al. 2008). Previous studies showed that elevated sP-selectin was observed in diseases associated with arterial thromboses, such as coronary artery disease and acute myocardial infarction (Ferroni et al. 2009; Polek et al. 2009).

A randomized crossover trial was conducted on 29 healthy young adults in Beijing, China. In the study, three waves of health measurements were conducted before, during, and after two typical PM_{2.5} pollution waves (PPWs), under filtered and sham indoor air purification with a washout interval of at least 2 weeks. The study found that sP-selectin concentration increased by 12.0% (95% CI: 3.8%, 20.8%) during-PPWs periods compared with pre-PPWs periods under sham purification, while the percentage change of 7.6% (95% CI: -1.9%, 18.1%) under the filtered condition was nonsignificant. The study further found that 24-h and 48-h personal PM_{2.5}-moving averages were significantly associated with sP-selectin, suggesting sP-selectin is a good biomarker for understanding the pathological process linking indoor air pollution and adverse health effects (Zhao et al. 2020). Consistently, in a panel study of 29 nonsmoking elderly subjects with a history of coronary artery disease, indoor PM_{0.25} and PM_{2.5–10} were positively and significantly associated with sP-selectin (Delfino et al. 2008).

Von Willebrand Factor (vWF)

Von Willebrand Factor (vWF) is a marker of blood coagulation process, an indicator of endothelial dysfunction, and has been linked to coronary events. A panel study of elderly subjects and healthy young adults was conducted to explore the short-term effects of size-fractionated PM on circulating biomarkers (Hassanvand et al. 2017). The results showed no associations between vWF and any PM size fractions in healthy young adults. However, vWF was positively

associated with PM_{1–2.5}, PM_{2.5}, PM_{2.5–10}, and PM₁₀ in the elderly subjects. In a double-blind, randomized crossover study among 70 healthy nonsmoking adults, compared to sham filtration, true HEPA filtration decreased indoor PM_{2.5} by 72.4% and particle number concentration by 59.2%, and concomitantly lowered vWF by 26.9% (95% CI: 7.3%, 46.4%) 24 h after the end of filtration, indicating reduced risk for thrombosis (Cui et al. 2018).

Soluble CD40 Ligand (sCD40L)

Soluble CD40 ligand (sCD40L) in blood is a surface adhesion molecule involved in both inflammatory and thrombogenic processes. A randomized, double-blind crossover trial among 35 healthy college students in Shanghai, China, reported that decreased in sCD40L of 64.9% (95% CI: -82.3%, 30.3%) was associated with the true-purification scenario compared to the sham-purification scenario (Chen et al. 2015b). The study also found that an IQR change (64 µg/m³) of continuous indoor PM_{2.5} concentration was associated with a 71.3% (95% CI: 29.8%, 126.1%) increase in sCD40L concentration. Similarly, another randomized, double-blind crossover trial of true or sham indoor air filtration among 29 healthy young adults in Beijing, China, reported that the increase in time-weighted personal PM_{2.5} was significantly associated with increased sCD40L (Sun et al. 2020).

Application of Biomarkers in Assessing Systemic Inflammation and Oxidative Stress

Inflammation and oxidative stress are common pathophysiological mechanisms underlying many diseases, including major chronic diseases such as cardiovascular diseases, cancer, chronic respiratory diseases, and diabetes. Air pollution exposure has been well linked to inflammatory and oxidative stress responses in both human and animal models. The biomarkers in assessing systemic inflammation and oxidative stress of indoor air pollution are shown below and in Table 4.

Biomarkers of Systemic Inflammation of Indoor Air Pollution

C-Reactive Protein (CRP) and High-Sensitivity CRP (hsCRP)

C-reactive protein (CRP) is a protein in the blood that signals acute inflammation. To determine the risk for heart disease, a more sensitive CRP test called high-sensitivity CRP (hsCRP) is available. A randomized crossover intervention study of 45 healthy adults exposed to consecutive 7-day periods of filtered and unfiltered air with portable air filters reported a 32.6% (95% CI: 4.4%, 60.9%) decrease in CRP associated with the filtration and a suggestive (without a statistical significance) association between indoor PM_{2.5} and CRP (Allen et al. 2011). A cross-sectional study assessed the relationship of indoor PM_{2.5} and CO with CRP, and the results showed that an IQR increase in PM_{2.5} and CO were associated with differences in CRP of -0.76 mg/L (95% CI: -1.64 to 0.11) and 0.36 mg/L (95% CI: -0.71 to

Table 4 Biomarkers of systemic inflammation and oxidative stress used in assessing health risk of indoor air pollutants

Study site	Year	Study design	Pollutant	Participant, N	Biomarker	Reference
West Bengal	2012	Case-control study	Indoor air pollution from biomass fuel use	142 women exposed to indoor air pollution from biomass burning and 126 age-matched control women	TNF- α , IL-6, IL-12, IL-8, MPO, and SOD	Banerjee et al. (2012)

Peru	2021	Cross-sectional study	PM _{2.5} , BC, CO, and NO ₂	Adult women, 180	CRP, IL-6, IL-10, IL-1 β , and TNF- α	Fandino-Del-Rio et al. (2021)
Copenhagen	2008	Randomized double-blind crossover trial	PM _{2.5} , PM _{10-2.5}	Healthy elderly, 42	CRP, IL-6, TNF- α , and 8-isoPGF2 α	Brauner et al. (2008)
British Columbia	2011	Randomized crossover trial	PM _{2.5}	Healthy adults, 45	CRP, IL-6, MDA, and 8-isoprostanate	Allen et al. (2011)
Shanghai	2017	Randomized double-blind crossover trial	PM _{2.5}	Healthy college students, 55	8-OHDG, MDA, 8-isoPGF2 α , SOD, hsCRP, IL-1 β , and IL-6	Li et al. (2017)
Taipei	2017	Randomized crossover trial	PM _{2.5} , TVOCs	Homemakers, 200	hsCRP, 8-OHDG	Chuang et al. (2017)
Eastern Massachusetts	2018	Panel study	BC	Patients with COPD, 85	CRP, IL-6	Garsick et al. (2018)
Taipei	2013	Panel study	PM _{2.5} , PM ₁₀ , TVOCs, and CO	Healthy adults, 300	hsCRP, 8-OHDG	Lin et al. (2013)
Shanghai	2015	Randomized double-blind crossover trial	PM _{2.5}	Healthy college students, 35	CRP, MCP-1, IL-1 β , TNF- α , IL-6, and MPO	Chen et al. (2015b)
Shanghai	2018	Randomized double-blind crossover trial	PM _{2.5}	Healthy college students, 55	IL-1, IL-6, and TNF- α	Chen et al. (2018)

Beijing	2017	Randomized crossover trial	PM _{2.5} , BC	Nonsmoking elderly, 35	IL-6, IL-8, and CRP	Shao et al. (2017)
Beijing	2020	Randomized crossover trial	PM _{2.5}	Healthy college students, 29	8-isopGF2 α , MDA, ox-LDL, GPx1, and EC-SOD	Han et al. (2020)
Boston	2018	Panel study	BC	Patients with COPD, 82	MDA, 8-OHdG	Grady et al. (2018)
West Bengal	2011	Case-control study	PM _{2.5} , PM ₁₀ ,	244 women using biomass fuels and 236 age-matched women using LPG	ox-LDL, ROS, and SOD	Dutta et al. (2011)

PM: particulate matter, PM_{2.5}: particulate matter with an aerodynamic diameter $\leq 2.5 \mu\text{m}$, PM₁₀: particulate matter with an aerodynamic diameter $\leq 10 \mu\text{m}$, BC: black carbon, CO: carbon monoxide, TVOCs: total volatile organic compounds, CRP: C-reactive protein, IL-6: interleukin-6, MDA: malondialdehyde, 8-isopGF2 α : Iso-prostaglandin F2 α , 8-OHdG: 8-hydroxy-2'-deoxyguanosine, SOD: superoxide dismutase, hsCRP: high-sensitivity C-reactive protein, IL-1 β : interleukin-1 β , IL-6: interleukin-6, TNF- α : tumor necrosis factor- α , MCP-1: monocyte chemoattractant protein-1, MPO: myeloperoxidase, IL-1: interleukin-1, IL-8: interleukin-8, ox-LDL: oxidized low-density lipoprotein, GPx1: glutathione peroxidase, and EC-SOD: extracellular superoxide dismutase

1.42), respectively (Kephart et al. 2020). In another randomized, double-blind crossover trial conducted in 55 healthy college students in Shanghai, a significant difference in hsCRP was observed following the intervention compared to following the control (Li et al. 2017). A randomized crossover intervention study recruited 200 homemakers from Taipei and randomly assigned 100 of them to air filtration or control intervention to explore the effect of long-term indoor air conditioner filtration on the association between air pollution and cardiovascular health (Chuang et al. 2017). The results of this study showed that increased levels of PM_{2.5} and TVOCs were associated with increased hs-CRP. An IQR increase in PM_{2.5} and TVOCs were associated with increases of 6.23% (95% CI: 2.82%, 9.64%) and 2.41% (95% CI: 1.63%, 3.19%) in hsCRP, respectively. In a study among 85 COPD patients, there was a 10.9% increase in CRP (95% CI: 0.7%, 22.2%) for each IQR increase in indoor BC concentration (Garshick et al. 2018).

In a panel of 300 healthy subjects aged 20 years old and over in Taipei, China, the increase in hsCRP was associated with increased levels of indoor particles and total VOCs in single and two-pollutant models (Lin et al. 2013). Specially, in the single-pollutant model, an IQR increase in PM_{2.5} and TVOC was associated with increases of 13.0% (95% CI: 6.4%, 19.7%) and 19.7% (95% CI: 10.2%, 29.1%) in hs-CRP, respectively. In the two-pollutant model, an IQR increase in PM_{2.5} and TVOC was associated with increases of 15.0% (95% CI: 9.7%, 20.3%) and 13.7% (95% CI: 8.7%, 18.6%) in hsCRP, respectively.

Inflammatory Cytokines

Cytokines are small-molecule proteins that are acutely synthesized and secreted by immune cells and nonimmune cells (e.g., endothelial cells, epithelial cells) in response to a stimulus. Cytokines can have either pro- or anti-inflammatory effects, and these effects can be contextual. Cytokines have been most commonly analyzed using enzyme-linked immunosorbent assays (ELISA) individually. Multiple cytokines can be measured simultaneously using so-called multiplex assays on a flow cytometer (Sun et al. 2020).

In 142 premenopausal, never-smoking women chronically exposed to indoor air pollution from biomass burning and 126 age-matched control women who cooked with a cleaner fuel, namely liquefied petroleum gas (LPG), a panel study showed that biomass users had 72%, 67%, and 54% higher plasma levels of the proinflammatory cytokines including tumor necrosis factor- α (TNF- α), IL-6, and IL-12, respectively, and doubled neutrophil chemoattractant IL-8 (Banerjee et al. 2012). A cross-sectional study among adult women in rural Peru reported that kitchen area black carbon (BC) concentrations were positively associated with proinflammatory cytokine TNF- α , while negatively associated with anti-inflammatory cytokine IL-10 (Fandiño-Del-Rio et al. 2021). In a randomized double-blind crossover trial, 35 healthy college students in Shanghai were measured for levels of proinflammatory cytokines including interleukin-1 β (IL-1 β), IL-6, and TNF- α (Chen et al. 2015b). Compared with the sham purification scenario, the true purification was associated with 68.1% (95% CI: 44.3%, 81.7%) decrease of IL-1 β , and an IQR

increase ($64 \mu\text{g}/\text{m}^3$) of continuous indoor $\text{PM}_{2.5}$ concentration was significantly associated with 69.7% (95% CI: 30.6%, 120.3%) increase in IL-1 β . In another randomized, double-blind crossover trial using true versus sham filtration, biomarkers of systemic inflammation, including IL-1 β , IL-6, and TNF- α , were measured in 55 healthy college students in Shanghai (Li et al. 2017). The study reported a significant between-treatment difference in IL-1 β .

In a similar double-blind, randomized crossover study in 55 healthy young adults in Shanghai, China, higher $\text{PM}_{2.5}$ exposure (mainly driven by indoor exposure) was positively associated with the expression of IL-1, IL-6, and TNF- α (Chen et al. 2018). A randomized crossover intervention trial in seniors living in Beijing also reported significant decreases in IL-8 of 58.59% (95% CI: -76.31%, -27.64%) in the total participants and 70.04% (95% CI: -83.05, -47.05) in the subset of COPD patients during the active-mode filtration period compared to the sham-mode filtration period (Shao et al. 2017). Taken together, the evidence is strong to indicate that biomarkers of proinflammatory cytokines such as IL-1, IL-6, IL-8, and TNF- α in the blood were associated with indoor air pollution exposure.

Myeloperoxidase (MPO)

Myeloperoxidase (MPO) is a lysosomal enzyme which presents in granulocytic and monocytic cells, and it is an established biomarker of inflammation. It has been suggested that MPO plays a significant role in the development of the atherosclerotic lesion and in rendering plaques unstable. An increase in MPO concentration in biological fluids is indicative of tissue or systemic inflammation. A randomized double-blind crossover trial found that a significant decrease of -17.5% (95% CI: -30.8%, -5.5%) in the concentration of plasma MPO was associated with true air purification compared with sham purification in 35 healthy college students living in Shanghai (Chen et al. 2015b). However, the evidence is limited on MPO responses to indoor air pollution exposure.

Monocyte Chemoattractant Protein-1 (MCP-1)

Monocyte chemoattractant protein-1 (MCP-1) is one of the key chemokines that regulate migration and infiltration of monocytes and macrophages in response to inflammation. The same study described above concerning MPO also reported a significant decrease in blood MCP-1 by -32.8% (95% CI: -67.5%, -5.3%) following the true filtration. This MCP-1 decrease indicated a reduced level of systemic inflammation.

Biomarkers of Oxidative Stress in Relation to Indoor Air Pollution

The imbalance between the generation of reactive oxygen species (ROS) and endogenous antioxidant capacity leads to oxidative stress when the balance shifts towards more ROS generation. Oxidative stress is a risk factor for many diseases and for accelerating aging of cells, tissue, and human.

Iso-Prostaglandin F2 α (8-isoPGF2 α)

Iso-prostaglandin F2 α (8-isoPGF2 α) is a major metabolite from the peroxidation of arachidonic acid. This compound, often simply called 8-isoprostanate, is among most commonly used biomarkers of lipid peroxidation. This compound has been considered as a potent vasoconstrictor of lung and has been identified to be associated with asthma, lung diseases, and atherosclerosis. A study showed significant associations of both 24-h and 48-h personal PM_{2.5} moving averages with 8-isoPGF2 α in 29 healthy young adults living in Beijing (Zhao et al. 2020), indicating that increased indoor PM exposure was associated with increased oxidative stress measured as lipid peroxidation. When indoor PM levels were reduced via the use of air filtration, a significant reduction in 8-isoPGF2 α level was observed in 55 healthy college students living in Shanghai (Li et al. 2017). A randomized double-blind crossover trial among 21 couples reported a borderline significant association between number concentration of particles (10–700 nm) and 8-isoPGF2 α (Brauner et al. 2008).

Malondialdehyde (MDA)

Malondialdehyde (MDA) is generated by the peroxidation of polyunsaturated fatty acids in cell membranes. It is also produced in the process of prostaglandin synthesis. MDA is a frequently used biomarker of oxidative damage. MDA can be measured in biological fluids (e.g., urine, blood, nasal mucus, and exhaled breath condensate) in two forms: MDA free from conjugation and MDA conjugated with proteins or other biomolecules. A study recruiting 82 COPD patients assessed the relationships between indoor BC exposure and urinary oxidative stress biomarkers (Grady et al. 2018). The study found a positive association between BC exposure and MDA. Specifically, 0.8% (95% CI: -5.4%, 7.4%) increase in free MDA and 5.4% (95% CI: -2.4%, 14.0%) increase in total MDA (free and conjugated) were associated with per IQR increase in multiday-integrated BC. Additionally, effects on total MDA were statistically significant with averaged 1–4 days BC exposure before urine collection (8.3% increase; 95% CI: 0.03%, 17.3%). The previously mentioned intervention study in 55 healthy Shanghai college students reported significantly lowered MDA concentrations using true purification than sham filtration (Li et al. 2017).

Oxidized Low-Density Lipoprotein (Ox-LDL)

Reactive oxygen species (ROS) can oxidize low-density lipoprotein (LDL). The product (ox-LDL) is shown to cause proatherogenic effects through endothelial activation (Kattoor et al. 2019). In 29 healthy young adults in Beijing, a significant increase of 9.2% (95% CI: 0.3%, 18.0%) in ox-LDL was associated with an IQR increase in 24-h personal PM_{2.5} moving average, and the personal PM_{2.5} exposure was principally from indoor exposure in this air-purification intervention study (Zhao et al. 2020). A case-control study assessing the health impacts of indoor air pollution reported that women using biomass fuels had three times more particulate pollution in kitchen, as well as elevated ox-LDL (170.6 vs. 45.9 U/l; $P < 0.001$), compared to women using liquified petroleum gas (LPG) (Dutta et al. 2011).

Superoxide Dismutase (SOD) and Glutathione Peroxidase 1 (GPx1)

Superoxide dismutase (SOD) and glutathione peroxidase 1 (GPx1) are cellular antioxidant enzymes, which play a central role in the control of ROS. SOD is represented by three different ubiquitously expressed enzymes that convert superoxide anion to hydrogen peroxide. GPx1 is the ubiquitous intracellular form and a key antioxidant enzyme within most cells, including the endothelium (Blankenberg et al. 2003). These biomarkers of oxidative stress have been widely used in *in vitro* and in *vivo* animal studies of particle toxicity (Deng et al. 2013; Guan et al. 2019; Wang et al. 2019). Several studies have explored the associations between the two antioxidation enzymes and indoor air pollutants, but no significant associations were observed (Zhao et al. 2020). The aforementioned case-control study in biomass versus LPG users showed that women exposed to biomass smoke had a 13% lower SOD level than the controls (Dutta et al. 2011).

Application of Biomarkers in Assessing Health Risks of the Immune System

Composition and Function of the Immune System

The immune system is complex, consisting of cells, tissues, and molecules that mediate unique reactions resisting pathogens and noninfectious substances, including harmless environmental molecules, tumors, and unaltered host components. The most important physiologic function of the immune system is to prevent or eradicate infections. The immune system plays a vital role in defending against tumors, controlling tissue regeneration and scarring, injuring cells, and inducing pathologic inflammation, recognizing and responding to tissue grafts and newly introduced proteins.

The immune system is formed from two main parts: innate immunity and adaptive immunity. Innate immunity, also called natural immunity or native immunity, is always present in healthy individuals and provides immediate protection against microbial invasion. Adaptive immunity, also called specific immunity or acquired immunity, consists of two types of humoral immunity and cell-mediated immunity and requires proliferation and differentiation of lymphocytes in response to microbes before it can provide adequate defense, namely the complex mechanism allows it to perform comprehensive and powerful function compared with innate immunity that is the critical first barrier to outside harmful factors (Abbas et al. 2019). The human immune system is involved in responding and defending against the insult from air pollution exposure. Hence, immunological biomarkers are used in studying the health effects or assessing the health risk of air pollution exposure.

Health Effect on the Immune System of Indoor Air Pollution

Among the diseases that have been related to indoor air pollution, asthma may have the strongest link to immunologic responses to a variety of indoor pollutants

including dust mites, microbes, tobacco smoke, phthalates, endotoxin, and nitrogen dioxide (Kanchongkittiphon et al. 2014). Other diseases that have been linked to immunologic effects of indoor air pollutants include allergic diseases such as wheeze, rhinitis, and eczema, as well as other respiratory systems and illnesses (e.g., bronchitis, persistent cough, and chronic obstructive pulmonary disease) (Bolling et al. 2020; Braun et al. 2020).

Children are susceptible population to immunology diseases due to their developing immune systems. Recently, there has been an increasing interest in the potential role of prenatal exposure to indoor air pollution in the development of immunologic disorders. Taking the developing immune system may be especially susceptible to low-dose exposure to indoor air pollutants into consideration, early-life exposures are more likely to produce persistent, irreversible changes to immunological development, consequently increasing the risk for an allergic phenotype for the life time. The biomarkers in assessing immune system health of indoor air pollution were shown as below and in Table 5.

Biomarkers in Assessing Health Risks of the Immune System

Immune Cells

Lymphocytes

The development of lymphocytes, including T lymphocytes ($CD3^+$, $CD4^+$, and $CD8^+$), B lymphocytes ($CD19^+$, $CD20^+$, $CD21^+$, and $CD22^+$), and natural killer (NK) cells, starts during the earlier weeks of gestation. Significant associations have been observed between polycyclic aromatic hydrocarbons (PAH) or $PM_{2.5}$ during early gestation and increases in $CD3^+$ and $CD4^+$ lymphocytes percentages and decreases in $CD19^+$ and NK cells percentages in cord blood. In contrast, exposures during late gestation were associated with decreases in $CD3^+$ and $CD4^+$ fractions and increases in $CD19^+$ and NK cells fractions (Herr et al. 2010).

Dendritic Cells

Dendritic cells (DC) play a crucial role as antigen-presenting cells to initiate an appropriate immune response to inhaled antigens. Mature dendritic cells are differentiated from monocytes and can recognize antigens via different pathways. A study found that simultaneous exposure of crushed whole-body house dust mite (HDM) extract, instead of allergen Der p1 and hexabromocyclododecane (HBCD), can enhance the antigen presentation and maturation/activation of DC (Canbaz et al. 2016).

Immunoglobulin

Immunoglobulins (Igs) are bifunctional molecules, binding to antigens with high specificity and initiating other biologic functions. Ig binding directly neutralizes toxins. A main function of Igs is the opsonization, which is the promotion of the target (e.g., particle, spore, and microbe cell) to the phagocyte. IgG is the main effector

Table 5 Biomarkers of the immune system used in assessing health risk of indoor air pollutants

Study site	Year	Study design	Pollutant	Participant, N	Biomarker	Reference

Table 5 (continued)

Study site	Year	Study design	Pollutant	Participant, N	Biomarker	Reference
Shanghai, China	2019	Randomized crossover study	PM _{2.5}	Preschool children, 43	Salivary lysozyme	Gao et al. (2019)
Liverpool, England	2011	Prospective descriptive study	Passive smoking	Children, 39	MMP-9	De et al. (2011)

PAH: polycyclic aromatic hydrocarbons, PM_{2.5}: fine particles less than 2.5 microns in diameter, NK cells: natural killer cells, HBCD: hexabromocyclododecane, HDM: house dust mite, DC: dendritic cells, IgG: immunoglobulins G, NO₂: nitrogen dioxide, IL-33: interleukin-33, TSILP: thymic stromal lymphopoietin, TNF- α : tumor necrosis factor- α , miR: MicroRNA, MMP-9: Matrix metalloproteinase 9

in serum, and the IgA response is directed toward the mucosa. A published study found that compared to individuals living in the control reference buildings, those residing in microbe-dense buildings had higher levels of spore-specific IgG, IgG1, and IgG3 serum antibody (Atosuo et al. 2020). Immunoglobulin E (IgE) plays a vital role in the development of allergic diseases. Serum IgE are significant for the diagnosis of allergies. Cord blood IgE levels have been previously used to assess the immunotoxin effects of in utero environmental contaminant exposure (Ashley-Martin et al. 2016).

Cytokines

Inflammatory cytokines are described above under Biomarkers of Systemic Inflammation. Cytokines play an important role in immune responses to a stimulus, especially given that cytokines, including interleukins (ILs), interferons (IFNs), and tumor necrosis factor-alpha (TNF- α), are mainly produced by immune cells. Cytokines are a unique class of regulatory proteins that play an essential role in maintaining and regulating immune system functions. An imbalance in cytokines and/or cytokine receptors can lead to different pathological disorders, such as asthma, allergy, etc. (Ramani et al. 2015). Prenatal tobacco smoke exposure has been associated with an increase in IL-8 levels among neonates (Chahal et al. 2017). For children exposure to parental tobacco smoke, significant increases in IL-13 were observed compared with those nonexposed children (Feleszko et al. 2006).

IL-33 and thymic stromal lymphopoietin (TSLP) are two epithelial cell-derived cytokines that participate in allergic disease and type 2 inflammation. These mediators have a critical role in the etiology of atopic dermatitis, often the first manifestation of allergic disease in childhood. Ashley-Martin et al. (2016) reported elevated cord blood concentrations of IL-33 and TSLP were associated with maternal NO₂ exposure for newborn girls but not boys.

DNA Methylation as Epigenetic Biomarkers

Tobacco smoke is a potent environmental factor for DNA methylation. Parental tobacco smoke (PTS) exposure can induce epigenetic changes in the fetus with sequelae in later life, altering risks for allergic diseases. For example, PTS exposure can accelerate CpG methylation in the gene loci of FOXP3 and IFN γ , and lead to lower promoter methylation in the neuropeptide S receptor 1 (NPSR1) and higher expression of AXL gene methylation at birth (Braun et al. 2020). These abnormal DNA methylations were associated with the higher risk of asthma or bronchus symptoms. In addition, the increased risk of asthma caused by exposure to phthalate may also be mediated through alterations in DNA methylation of TNF- α (Wang et al. 2015).

MicroRNA

MicroRNAs (miRNAs) are small RNA molecules with about 22 nucleotides that regulate posttranscriptional gene expression. Placental miRNAs are coresponsible for the development of the maternal placenta and for the development of fetus. An upregulation of miR-223 in maternal and cord blood by PTS exposure has been associated with lower T regulatory cells (Treg) cell numbers in cord blood, subsequently increasing the risk for allergies (Herberth et al. 2014). A recent study showed

positive associations between higher serum levels of miR-155 and asthma in children exposed to indoor air pollution (Liu et al. 2019).

Salivary Lysozyme

Salivary lysozyme, an antibacterial protein, is part of the innate defensive mechanism. It is a noninvasive biomarker and activates immunity responses through the hydrolysis of β -1,4-glycosidic bonds of bacterial cell wall peptidoglycan. A recent study found that salivary lysozyme was significantly and inversely associated with indoor PM_{2.5} and that certain nasal bacteria might play critical roles in mediating PM_{2.5} exposure and children's lysozyme levels (Gao et al. 2019).

Matrix Metalloproteinase-9

Matrix metalloproteinase-9 (MMP-9) is thought to contribute partly to the pathogenesis of allergy, regulating the activity of certain soluble proteins and responsible for the degradation of extracellular matrix components. Increasing levels of MMP-9 has been reported to increase acute allergic responses in the nose, lung, and skin, respectively. In children exposed to secondhand smoke, the MMP-9 activity and concentrations in nasal secretions were higher than in children without secondhand smoke exposure (De et al. 2011).

Application of Biomarkers in Assessing Health Risks of the Reproductive System

The Structure and Function of the Reproductive System

The structure of the reproductive system is different between male and female. The reproductive system in male consists of a pair of testes, delivery channels, seminal vesicles, the prostate, the bulbourethral glands, and the penis. In female, this system includes the ovaries, fallopian tubes, uterus, vagina, accessory glands, and external genital organs. Within the context of producing offspring, the main function of the reproductive system includes producing eggs and sperm cells and secreting hormones, which are responsible by primary productive organs consisting of testes and ovaries; transporting and sustaining these cells; and nurturing the developing offspring (Abbas et al. 2019).

Health Effect on the Reproductive System of Indoor Air Pollution

Partial indoor air pollutants such as phthalates, bisphenol A, and flame retardants are endocrine disruptors chemicals (EDCs), which refer to compounds with the endocrine-disrupting mechanism of action that seriously affect human reproduction. In this context, indoor air pollution could lead to adverse health effects on the reproductive system including infertility, cryptorchidism, decreased semen quality, and hypospadias (Sifakis et al. 2017). Tobacco smoke with high exposure, occurring

mainly indoors, has been associated with reproductive hormone system dysfunction and impaired sperm development in males (Dai et al. 2015), and ovarian toxicity in females (Budani and Tiboni 2017). The biomarkers of reproductive health effects of indoor air pollution were shown as below and in Table 6.

Biomarkers in Assessing Health Risks of the Reproductive System

Semen Parameter

Male reproductive health is usually related to the process of spermatogenesis, and semen parameters are thought to be the most sensitive marker of adverse environmental exposures. The following 6 semen parameters are typically used to characterize semen quality: semen concentration, sperm volume, total sperm number, progressive motility, morphology, and acrosin activity. Acrosin activity levels are related to sperm morphology and in vitro fertilization rate. Pan et al. (2015) found that acrosin activity was negatively associated with mono-*n*-butyl phthalate (MBP), mono-isobutyl phthalate (MiBP), MEHP, and that %MEHP in total phthalates, MBP, and MiBP were also negatively associated with sperm morphology.

Oocyte

The oocyte is the primary determinant of embryo developmental competence in women and delivers half the chromosomal complement to the embryo. Mok-Lin et al. (2010) found that urinary bisphenol A (BPA) concentrations were inversely associated with the number of oocytes retrieved per cycle referring to female fertility, with an average decrease of 12% for each log unit increase in SG-BPA. BPA is a high-volume chemical that has been widely used to make hard plastic items such as baby bottles, food containers, and storage containers.

Reproductive Hormones

Reproductive hormones play an essential role in the development of the reproductive system. They consist of follicle-stimulating hormone (FSH), luteinizing hormone (LH), estradiol (E2), testosterone (TEST), prolactin (PROL), anti-Müllerian hormone (AMH), insulin like-factor 3 (INSL3), etc. Both males and females produce and secrete reproductive hormones, but the quantity and function of reproductive hormones are different for males and for females.

In the male, FSH usually reflects the status of spermatogenesis as a result of feedback between the testis and hypothalamus/pituitary glands. An elevated level of FSH indicates abnormal sperm production. LH is an essential hormone that stimulates TEST production by the Leydig cells, and, together with FSH, regulates spermatogenesis. Low TEST levels are associated with abnormal sexual differentiation and decreased fertility (Radke et al. 2018). INSL3, a primary secretory product of Leydig cells, plays a crucial role in testicular descent and germ cell survival and is associated with spermatogenesis and sperm morphology in adult men. In a study of the effect of phthalates on reproductive hormones in 599 men, urinary metabolites of phthalates were measured, including mono-isobutyl phthalate (MiBP), monomethyl phthalate

Table 6 Biomarkers of the reproductive system used in assessing health risk of indoor air pollutants

Study site	Year	Study design	Pollutant	Participant, N	Biomarker	Reference
Nanjing, China	2015	Cross-sectional study	Phthalate	Men of reproductive age, 1066	Acrosin activity, sperm morphology, and INSL3, DFI	Pan et al. (2015)
Massachusetts, America	2010	Prospective cohort study	BPA	Women undergoing in vitro fertilization, 84	Oocytes; E ₂	Moh-Lin et al. (2010)
Saudi Arabia	2019	Cross-sectional study	Phthalate	Men who were part of couples undergoing IVF or intracytoplasmic sperm injection, 599	TEST; PROL; E ₂ ; LH; FSH; and sperm concentration	Al-Saleh et al. (2019)
America	2016	Cross-sectional study	Tobacco smoke, indoor heating/cooking sources (wood, artificial firelogs)	Premenopausal women, 913	AMH	White et al. (2016)
Massachusetts, America	2007	Cross-sectional study	Phthalate	Men from an infertility clinic, 379	CE; tail%; TDM	Hauser et al. (2007)
Hungary	2005	Cohort study	Tobacco smoke	Females who had received in vitro fertilization, 40	Cumulus cells	Sinko et al. (2005)
Chongqing, China	2019	Cross-sectional study	Phthalate	Volunteers, 118	LINE-1 DNA methylation	Tian et al. (2019)
California, America	2017	Cohort study	Phthalate	Mother-child pairs, 336	DMRs	Solomon et al. (2017)

INSL3: insulin like-factor 3, DFI: DNA fragmentation index, BPA: Bisphenol A, E₂: estradiol, IVF: in vitro fertilization, TEST: testosterone, PROL: prolactin, LH: luteinizing hormone, FSH: follicle-stimulating hormone, AMH: anti-Müllerian hormone, CE: comet extent, Tail%: percentage of DNA in tail, TDM: tail distributed moment, LINE-1: long interspersed nuclear element-1, and DMRs: differentially methylated regions

(MEP), mono-(2-ethylhexyl) phthalate (MEHP), mono-(2-ethyl-5-hydroxyhexyl) phthalate (MEHHP), and mono-(2-ethyl-5-oxohexyl) phthalate (MEOHP); and % MEHP represents the urinary level of the primary metabolite MEHP as a proportion of total DEHP metabolites (Al-Saleh et al. 2019). This study found negative associations between TEST and MiBP, between FSH and MEHHP, and between PROL and MEOHP, respectively. The study also found positive associations between E₂ and MEP, %MEHP and LH, respectively. The study further found that FSH mediated significantly and up to 60% of the positive relationship between sperm concentration and MEHHP, while FSH and LH, respectively, mediated 15% and 12% of the negative association between sperm concentration and %MEHP (Al-Saleh et al. 2019). In another study, serum levels of INSL3 were negatively associated with urinary MEHP and %MEHP, respectively (Pan et al. 2015).

In the female, estrogens are female hormones responsible for the onset and progression of female reproductive cycles, of which E₂ is the most important hormone. Serum anti-Müllerian hormone (AMH) is a common biomarker of ovarian reserve, and lower AMH levels (e.g., <1 ng/mL) may indicate a woman with diminished ovarian reserve and, hence, with an increased risk for infertility. Mok-Lin et al. (2010) found that the number of oocytes retrieved was strongly correlated with peak serum E₂ concentrations, and both of oocyte count and serum E₂ were negatively associated with increasing urinary BPA concentrations. Serum AMH levels have been found to be lower in current heavy smokers and have been negatively associated with long-term exposure to environmental tobacco smoke (active and passive smoking) and indoor burning of wood or artificial fire logs, respectively (White et al. 2016). Therefore, serum AMH can serve as a biomarker of female reproductive effects (specifically ovarian reserve or infertility risk) of indoor air pollutants emitted from combusting biomass (tobacco and wood).

DNA Damage

Sperm DNA Fragmentation Index (DFI) represents sperm DNA damage levels. DFI has been positively associated with phthalate (MBP and MiBP) exposures (Pan et al. 2015). Sperm DNA damage levels can also be measured as comet extent (CE), percentage of DNA in tail (Tail%), and tail distributed moment (TDM). These biomarkers of sperm DNA damage are typically assayed using the neutral comet assay (Hauser et al. 2007).

In developing follicles, cumulus cells are coupled to the growing oocyte through gap junctions as a functional syncytium that facilitates the transfer of signals as well as nutrients into and out of the oocyte and between follicle cells. Thus, cumulus cells play a pivotal role in oocyte maturation and maintenance. Sinko et al. (2005) found that smoking was associated with significantly elevated DNA damage levels in cumulus cells in women who were scheduled for in vitro fertilization.

DNA Methylation

DNA methylation plays a vital role in sperm maturation. Abnormal epigenetic modification may result in impaired spermatogenesis and compromised sperm function. The global DNA methylation surrogate (long interspersed nuclear

element-1, LINE-1) hypermethylation has been related to decreased sperm motility, reduced sperm quality, and lower sperm morphology. Tian et al. (2019) reported sperm LINE-1 DNA methylation was negatively associated with exposure to total DEHP isomers and sperm quality, respectively. They further found that LINE-1 DNA methylation mediated 20.7% of the association between DEHP exposure and sperm motility.

Differentially methylated regions (DMRs) utilizing co-correlation patterns between nearby CpG sites, taking advantage of the epigenomic structure, may be more informative than methylation in individual CpG sites in predicting disease or health status. Solomon et al. (2017) examined the effects of prenatal (in utero) phthalate exposure and on cord blood DNA methylation. Concentrations of 11 phthalate metabolites were analyzed in maternal urine samples, and DNA methylation was assessed and adjusted for cord blood cell composition. They identified 27 DMRs, the majority of which were associated with multiple phthalate metabolites. Furthermore, 51% of the significant DMRs were associated with the di-(2-ethylhexyl) phthalate metabolites. In addition, five individual CpG sites, showing hypermethylation, were associated with phthalate metabolite concentrations. Solomon et al. (2017) also identified specific genes in the DMRs related to male fertility including IFT140, TESC, and PRDM8. This study provides a good example for DNA methylation at specific CpG sites and at specific regions of the epigenetic structure to serve as biomarkers of early-life (e.g., during fetal development) exposure to environmental chemicals such as phthalates.

Application of Biomarkers in Assessing Health Risks of Other Physiologic Systems

Kidneys

The kidney is the primary organ of the urinary system, filtering the blood, removing wastes, and excreting the urine. Serum uric acid, estimated glomerular filtration rate (eGFR) estimated with serum creatinine, and urinary albumin to creatinine ratio (ACR) are common measures of renal impairment. Farzan et al. (2016) found that PAH metabolites were positively associated with uric acid and negatively associated with eGFR in adolescents (each 100% increase in 2-hydroxyphenanthrene and 3-hydroxyphenanthrene was associated with a 3.36% increase (95% CI: 0.338–6.372; $p=0.032$) in uric acid and a 2.66% decrease (95% CI: –4.979 to –0.331; $p=0.028$) in eGFR, respectively). Kidney injury molecule-1 (KIM-1) and neutrophil gelatinase-associated lipocalin (NGAL) are biomarkers of proximal tubule injury and distal tubule damage. Jacobson et al. (2020) found that urinary concentrations of bisphenol A (BPA), phthalic acid, and phthalate metabolites, respectively, were associated with increased NGAL and KIM-1 concentrations over time, indicating that exposure to these chemicals (mostly occurring indoors) affected renal function biomarkers in the long term.

Thyroid

The thyroid is an essential organ of the endocrine system located in the neck. Thyroid hormones secretion is vital for fetal and child growth and brain development, for the control of metabolism and energy balance, and many aspects of normal physiology, including nervous, cardiovascular, pulmonary, and reproductive systems. About 95% of active thyroid hormones is thyroxine (T4), and most of the remaining 5% is triiodothyronine (T3). Thyroid hormone secretion is regulated by a negative feedback mechanism about thyrotropin (TSH) and itself. Thyroglobulin antibody and thyroid peroxidase antibody are common autoantibodies that could cause thyroid autoimmunity. Wang et al. (2013) found that smoking during pregnancy was associated with higher free T3 levels and lower free T4 levels in euthyroid women (Mannisto et al. 2012). Another study found associations of urinary BPA with thyroid measures and increased thyroid function were independent of thyroglobulin antibody and thyroid peroxidase antibodies in Chinese adults ().

Metabolic System

Two major metabolic disorders have been linked to indoor air pollution: diabetes and obesity.

Diabetes is a metabolic disease closely related to cardiovascular diseases. Fasting glucose and glycated hemoglobin (HbA1c) are common biomarkers of diabetes. HbA1c, reflecting average plasma glucose concentration over the past 3 months, has been used as one of the indicators for defining prediabetes (HbA1c between 5.7% and 6.4%) and diabetes (HbA1c >6.4%). A meta-analysis of prospective cohort studies showed that long-time exposure to high levels of PM_{2.5} and NO₂ was significantly associated with elevated risk of type 2 diabetes mellitus (Wang et al. 2014). Rajkumar et al. (2018) found a higher prevalence of prediabetes and diabetes in women with higher exposure to household air pollution and suggestive evidence for a stronger effect in women ≥40 years of age in Honduras. In a case-control study conducted in China, Duan et al. (2019) found a significant positive association between urinary mono (2-ethylhexyl) phthalate and fasting glucose (Duan et al. 2019).

Epigenetic regulation of miRNAs, specifically miR-9-5p, miR-16-5p, miR-29a-3p, and miR-330-3p, has been associated with gestational diabetes mellitus (GDM). For instance, miR-16-5p was mainly associated with MAPK, insulin, TGF-β, and Mtor-signaling pathways (Zhu et al. 2015). A study reported that adjusted urinary mono-benzyl phthalate (adjusted for dilution by urinary creatinine value) levels and adjusted MEHP concentrations were positively associated with miR-16-5p expression levels and miR-29a-3p expression levels, respectively, while MBP concentrations and unadjusted MiBP levels were negatively in relation to miR-29a-3p expression levels (Martinez-Ibarra et al. 2019).

The prevalence of overweight and obesity has increased steadily around the globe since 1980 (Stevens et al. 2012). A hypothesized contributor to the increasing prevalence is exposure to phthalates and BPA, as these compounds may operate through complex causal pathways starting from in utero development to childhood and adult obesity. Insight into the susceptibility of fetal development to the potential adverse effects of phthalates and BPA can be obtained by examining biomarkers of fetal metabolic function such as leptin and adiponectin. Elevated leptin levels are associated with increased body mass index (BMI) in adults and large for gestational age infants. High cord blood leptin levels have been positively correlated with birth weight and insulin resistance, whereas low cord blood leptin levels have been associated with small for gestational age. Ashley-Martin et al. (2014) found that BPA was negatively associated with adiponectin levels, and mono-(3-carboxypropyl) (MCPP) was associated with increased odds of high leptin among males. Metabolomics, using unbiased and data-driven approaches to measure the relative concentrations of endogenous low-molecular weight metabolites in biofluids, has been recently applied to explore in vivo pathologic alterations associated with phthalate exposure. For example, it was found that in Chinese children among the metabolic markers related to MnBP exposure, 1-methylhydantoin, pyrrole-2-carboxylic acid, and monostearin were positively associated with obesity indices (Xia et al. 2018). Simultaneously, hydroxyproline, l-ornithine, and lactate were negatively associated with overweight and obesity in children (Xia et al. 2018).

Cognitive Function

In recent years, several major epidemiologic studies have reported significant associations between air pollutants and cognitive function in cross-sectional and cohort studies. Cognitive function was assessed through direct clinical exams of study subjects or through the retrieval of a medical record database (Paul et al. 2019). Questionnaires, scales, and tests such as Mini-Mental State Examination (MMSE), immediate word recall, delayed word recall and verbal fluency, the Benton Visual Retention Test, and Trail Making Test were commonly used to assess cognitive function (Falck et al. 2017). In addition to these assessments, emerging biomarkers were also used in recent studies.

A series of studies have used magnetic resonance imaging (MRI) scans of brain to assess cognitive function. Using the MRI technique, for example, Wilker et al. measured total cerebral brain volume (TCBV), hippocampal volume (HV), white matter hyperintensity volume (WMHV), and covert brain infarcts (CBI) in subjects participating the Framingham Offspring Study. By associating these brain image measures with PM_{2.5} exposure, the authors reported that a 2 µg/m³ increase in PM_{2.5} exposure was associated with 0.32% (95%CI: 0.59, 0.05) smaller TCBV (Wilker et al. 2015). A prospective study of 1403 older women enrolled in the Women's Health Initiative

Memory Study (WHIMS) reported that for each IQR increment change ($3.49 \mu\text{g}/\text{m}^3$) of cumulative PM_{2.5} exposure, the average WM volume (95% CI) was 6.23 (3.72 – 8.74) cm³ lower in the total brain and 4.47 (2.27 – 6.67) cm³ lower in the association areas, equivalent to 1–2 years of brain aging (Chen et al. 2015a). Similar studies provide important evidence that air pollution influences brain function and brain structure (Casanova et al. 2016; Power et al. 2018; Wilker et al. 2016).

The pathological hallmarks of Alzheimer's disease (AD) include the extracellular accumulation of amyloid- β (A β) and intracellular aggregates of hyperphosphorylated tau (Frisoni et al. 2017). In a population of cognitively unimpaired adults, greater exposure to NO₂ and PM_{2.5} was associated with higher levels of brain A β deposition, while a greater exposure to PM₁₀ and PM_{2.5} was associated with higher levels of CSF NfL (Alemany et al. 2021). A cross-sectional study including 18,178 US participants with cognitive impairment who received an amyloid PET scan reported that greater PM_{2.5} exposures were significantly associated with brain A β plaques, after adjusting for demographic, lifestyle, and socioeconomic factors as well as medical comorbidities (Iaccarino et al. 2021). Although biomarkers of cognitive function related to ambient air pollution have been assessed recently, few studies apply these biomarkers in the assessment of cognitive function in relation to indoor air pollution. Considering personal exposure to air pollution can be dominated by indoor exposures, it is promising to use A β , tau, and MRI as early and sensitive biomarkers to assess cognitive function associated with indoor air pollution.

The biomarkers of other systems of indoor air pollution were summarized in Table 7.

Conclusion

This chapter provides a summary of biomarkers that can reflect changes in concentrations or expression levels in molecular patterns (e.g., DNA methylation) associated with exposure to indoor air pollutants. These biomarkers can be measured in bodily fluids (e.g., blood, urine, exhaled breath, saliva, and nasal mucus) from human participants. Given that these biomarkers are specific to the pathophysiology of the respiratory system, cardiovascular system, hematologic system, immune system, reproductive system, and other systems, application of these biomarkers would provide insight into the health risk of indoor air pollutants exposure. Furthermore, considering these biomarkers reflect subclinical or preclinical changes, and are typically more sensitive than clinical outcomes, they are particularly useful to understand the potential biological mechanisms through which indoor air pollutants would affect human health. The mechanistic insights would strengthen the causal inference of the health effects, thereby reducing the uncertainty in the estimation of health risks attributable to specific indoor air pollutants or sources.

Table 7 Biomarkers of other physiologic systems used in assessing health risk of indoor air pollutants

Study site	Year	Study design	Pollutant	Participant, N	Biomarker	Reference
America	2016	Cross-sectional study	PAH	Adolescents, 660	Uric acid, eGFR, and ACR	Farzan et al. (2016)
America and Canada	2020	Cohort study	BPA, phthalates	Children and adolescents, 618	KIM-1, NGAL	Jacobson et al. (2020)
Finland	2012	Cohort study	Tobacco smoke	Euthyroid mothers, 4837	T3, T4	Mannisto et al. (2012)
Shanghai, China	2013	Cross-sectional study	BPA	People age 40 years or older, 3394	T3, TSH	Wang et al. (2013)
Honduras	2018	Cross-sectional study	PM _{2.5} , BC	Women in rural, 142	HbA1c	Rajkumar et al. (2018)
Tianjin, China	2019	Case-control study	Phthalate	T2DM cases and controls, 500	Fasting glucose	Duan et al. (2019)
Mexico	2019	Case-control study	Phthalates	Women with GDM and nondiabetics, 40	miR-16-5p, miR-29a-3p	Martinez-Ibarra et al. (2019)
10 Canadian sites	2014	Cohort study	Phthalate, BPA	Pregnant women, 2001	Adiponectin, Leptin	Ashley-Martin et al. (2014)
China	2018	Case-control study	Phthalate	Overweight/obese children and normal weight children, 149	Metabolic markers	Xia et al. (2018)
New England Region	2015	Cross-sectional study	PM _{2.5}	Healthy elderly, 943	MRI (TCBV, HV, WMHV, and CBI)	Wilker et al. (2015)
United States	2015	Cohort study	PM _{2.5}	Older women, 1403	MRI (GM, WM)	Chen et al. (2015a)
Barcelona	2021	Cross-sectional study	NO ₂ , PM _{2.5} , and PM ₁₀	Cognitively unimpaired adults, 156	Aβ42, Aβ40, p-Tau, t-Tau, and NfL	Alemany et al. (2021)
United States	2020	Cross-sectional study	PM _{2.5} , O ₃	Cognitively impaired adults, 18,178	PET Aβ	Iaccarino et al. (2021)

PAH: polycyclic aromatic hydrocarbons, eGFR: estimated glomerular filtration rate, ACR: albumin to creatinine ratio, BPA: Bisphenol A, KIM-1: kidney injury molecule-1, NGAL: neutrophil gelatinase-associated lipocalin, T3: triiodothyronine, T4: thyroxine, TSH: thyroid-stimulating hormone, BC: black carbon, HbA1c: glycated hemoglobin, T2DM: type 2 diabetes mellitus, GDM: gestational diabetes mellitus, miR: MicroRNA, TVBC: total cerebral brain volume, HV: hippocampal volume, WMHV: white matter hyperintensity volume, CBI: covert brain infarcts, and NfL: neurofilament light

Abstract

There is an increasing concern for health risks from exposure to chemical emissions in indoor environments where we spend a lot of time. A chain of complex relationships connects emission sources, exposure, and health effects. For some indoor contaminants, we know a lot about the separate relationships. However, linking specific sources and environmental exposure pathways to

hazardous effects is challenging, with a lack of evidence that is needed for risk assessment as a result.

This chapter presents the full chain model that follows chemicals and maps the relationships from sources to potential health effects. It is a tool to establish relevant scientific knowledge regarding chemical exposure. The model consists of three overlapping sections: environmental exposure, human exposure, and health effects, and includes relationships between emission sources, environmental pathways, human uptake, and effects on health and development.

As a demonstration, results from the Swedish Environmental Longitudinal Mother and child Asthma and allergy (SELMA) study were applied to the full chain model. Phthalates, a group of abundant indoor contaminants, and airway disorders were used as an example. Starting with polyvinyl chloride (PVC) flooring as an emission source, connections were made between indoor dust levels, exposure and uptake among pregnant women, and airway symptoms in young children. By using the full chain model, not only separate relationships were identified. Butylbenzyl phthalate could be followed from a source to elevated environmental exposure and human uptake to associations with a higher risk for airway outcomes in children.

Biomarkers · Dust · Human intake · Indoor exposure · Phthalates

Introduction

In modern society, we used to consider hazardous chemical exposure to mainly originate from industrial emissions and occupational environments. Increasingly, this framework has been replaced by concerns over the diffuse chemical emissions that we are all exposed to from our everyday activities and indoor spaces. In general, people spend 85% or more of their time indoors (Schweizer et al. 2007). A large number of chemicals can leach from building materials and consumer goods to indoor dust and air. This process means that we are almost continuously exposed to diffuse chemical mixtures in our homes, schools, offices, and hospitals (Salthammer et al. 2018).

To prevent hazardous exposure, we must determine the risk for effects on human health. Many scientific studies have investigated chemical exposure and its associations with adverse health effects. Their results provide valuable information. However, research tends to investigate separate relationships. Human exposure and resulting health effects depend on a chain of complex relationships, starting at the source from where the contaminant originated. Therefore, we lack evidence that allows us to predict what risk indoor sources and chemical emissions pose. Such information is vital for an adequate risk assessment.

This chapter presents the full chain model as an approach to establishing relevant scientific knowledge that addresses this knowledge gap. The model follows contaminants from source, over environmental exposure and human exposure, to health

effects (Preece 2021; Shu 2017). As a demonstration, results from the Swedish Environmental Longitudinal Mother and child Asthma and allergy (SELMA) study are applied to the full chain model. The example illustrates how phthalates can be followed from polyvinyl chloride (PVC) flooring through a chain of relationships connected to airway symptoms in young children.

The Full Chain Model

The full chain model (Fig. 1) depicts human chemical exposure by mapping relevant factors and their relationship. It can be employed to establish information on environmental contaminants that are needed for risk assessment (Preece 2021; Shu 2017) by facilitating the collection and evaluation of exposure data. It consists of three overlapping triangular sections that describe

- Environmental exposure
- Human exposure
- Health effects

The first section, environmental exposure is explained by the sources from where the contaminants originate and how they are released to the environment. Emitted contaminants can adhere to particles or evaporate into the air (Weschler et al. 2008). Indoor particles are either dust that is generally made up of particles that may become airborne but will eventually settle, or fine particles that remain airborne, so-called particulate matter (Weschler et al. 2008; WHO 1999). The emission

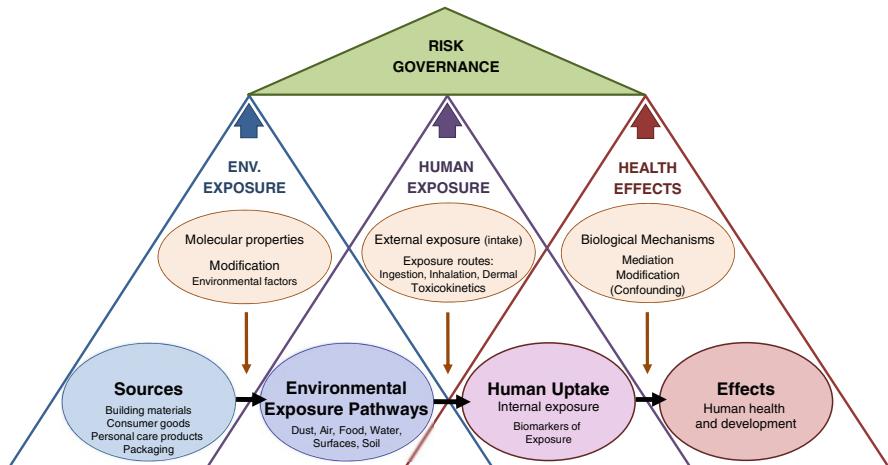

Fig. 1 The full chain model follows human chemical exposure from sources to potential health effects. The model is divided into three overlapping sections that describe relevant relationships for environmental exposure, human exposure, and health effects

process and environmental fate of a contaminant are affected by its molecular properties, such as molecular weight, volatility, and degree of water solubility (Weschler et al. 2008). Indoor physical conditions can also modify environmental exposure, such as temperature, humidity, and air exchange rate (Wei et al. 2018). The age and life cycle of the emission sources may also be relevant to consider. In the indoor environment, settled dust and air can become exposure pathways through which contaminants expose humans. Other exposure pathways include food, drink, personal care products, surfaces we touch, and soil.

The middle section of the full chain model is human exposure. It describes the interface between the environment and humans by linking environmental exposure to human uptake (internal exposure). Biomonitoring is frequently used to quantify chemical uptake in humans. It involves chemical analysis of biosamples such as blood or urine to detect the contaminant itself or markers of exposure (e.g., metabolites). These samples provide indirect information on the total uptake at a specific time point for the individual that provided the sample (Koch et al. 2012; Wittassek and Angerer 2008). The biomonitoring data represents the combined uptake from multiple sources and all pathways (such as diet, dust, air, and sometimes medical devices leaching directly to the blood) that the person was exposed to (Salthammer et al. 2018).

To understand how different sources and exposure pathways contribute to the total uptake of an indoor contaminant, we must have knowledge of the processes that result in human uptake. For uptake to occur, it must first have made contact with human tissue. In an indoor space, we are exposed through the routes of ingestion, inhalation, or dermal absorption, i.e., a person is exposed through the nose, mouth, or skin. This combination of processes is referred to as external exposure or intake (Zartarian et al. 2005). However, inhaling contaminated air or unintentionally ingesting contaminated dust may not always lead to absorption and uptake. Instead, a fraction of the contaminant is likely to be exhaled or excreted without being absorbed into the human tissue. Hence, external exposure (intake) may or may not result in the uptake of an indoor contaminant (Zartarian et al. 2005).

The processes that determine whether external exposure results in uptake depend on many parameters (Salthammer et al. 2018) that are summarized as exposure routes and toxicokinetics in the full chain model. Ingestion of dust particles is an exposure route that results in unintentional oral intake, where the contaminant is exposed to digestive processes and may be absorbed via the digestive tract. Inhalation results in the intake of contaminants in two forms, either in gas phase or adsorbed to airborne particles, i.e., the particulate phase. Gas-phase compounds and very small particles ($<5\text{ }\mu\text{m}$) can generally travel through the airways deep into the lung alveoli. There, contaminants may expose the lung tissue and contribute to uptake (Bølling et al. 2013; Salthammer et al. 2018). Our skin is in constant contact with the surrounding air, dust, and clothing and is permeable to various compounds. Toxicokinetics describes processes such as disposition, interactions, metabolism, and excretion of toxic compounds over time (Koch et al. 2012). A contaminant may be absorbed and distributed in tissues differently depending on whether the intake is oral, respiratory, or skin contact (Salthammer et al. 2018).

Bølling et al. (2013) suggest that tissues that serve as a barrier between environment and body, such as the airways, lungs, or skin, may be exposed to considerably higher concentrations of a contaminant than the exposure that can be detected in biomonitoring studies. Dust ingestion rates, inhalation rates, and dermal absorption rates can vary between infants, children, adults, pregnant women, and the elderly. Hence, individuals that spend the same time in the same indoor environment may be exposed differently to indoor contaminants (US Environmental Protection Agency [EPA] 2017).

The third section, health effects, associate chemical exposure to human health and developmental outcomes. Such relationships are generally deemed as noncausal because of the risk of confounding. However, if potential mediators or effect modifiers are included the observational data can be interpreted more toward causality.

The SELMA Study

The SELMA study is designed to investigate the importance of early life exposure to environmental factors during pregnancy and infancy, and their significance for health and development in children. The prospective pregnancy cohort follows approximately 2,000 mother-child pairs from early pregnancy over birth through childhood. Women were enrolled during early pregnancy (median tenth week of pregnancy) from 2007–2010. Data has been collected through questionnaires, environmental samples collected in the participant's homes, and biosampling of blood and urine from the participants. In brief, data on participant background information, home characteristics including flooring material, and health outcomes were acquired through self-administered questionnaires. Chemical exposure was assessed in dust samples collected in the participant's home and in blood and urine collected from the pregnant mothers and from the children. Serum was also analyzed for biomarkers of nicotine/tobacco use (cotinine) and urine for creatinine to allow for urine dilution adjustment. More details regarding the recruitment process, study design, and data collection can be found in Bornehag et al. (2012).

Chemical Exposure

Phthalates make up a group of inexpensive and versatile synthetic chemicals that are added to many building materials and large numbers of consumer goods. The leading use of phthalates is as plasticizers in plastic materials such as PVC, also known as vinyl (SCA 2015). Other uses include solvents, lubricants, thinners, and stabilizers (SCA 2015). Materials that may contain phthalates include plastics, rubber, synthetic leather, and textiles. The products include packaging, food containers, construction materials, sports and leisure equipment, toys, fabrics, footwear, clothes, carpets, electronics, paints, cleaning agents, personal care products, cosmetics, and fragrances (European Chemicals Agency [ECHA] 2021). Phthalates are

among the most well-studied group of semi-volatile indoor contaminants (Weschler et al. 2008). They do not bioaccumulate, instead phthalates are excreted and their half-lives in the human body range from a few hours to a few days, (Andersen et al. 2018; Koch et al. 2012). Still, the extensive use of phthalates results in continuous human exposure.

Concern for phthalate exposure to human health has been raised for over 40 years (Colborn et al. 1993). Experimental studies in cell and animal models and population-based epidemiological studies have provided evidence that links exposure to several phthalates to effects on human reproduction, neuro-development, and endocrine disruption (Bergman et al. 2013; Engel et al. 2021; Radke et al. 2018). Because of these concerns, restrictions have been imposed on several phthalates. However, not all use is regulated and new phthalates are continuously introduced as replacements (Bui et al. 2016). Environmental exposure to phthalates is mainly an indoor concern since the amounts in outdoor dust and air are magnitudes lower than indoors (Guo and Kannan 2011).

In SELMA, seven phthalates were analyzed in bedroom dust from 500 families. Dust samples collected twice; around week 25 of pregnancy (prenatally) and during infancy when the child was 6 months old (postnatally). Corresponding phthalate metabolites were quantified in urine samples collected from the pregnant mothers at enrolment. Phthalates and corresponding metabolites that were included in the chemical analysis are listed in Table 1.

Airway Outcomes

In the SELMA study we have studied wheeze and croup in the children. These outcomes were chosen as indicators of inflammatory responses in early age since asthma cannot be diagnosed in young children (Herzog and Cunningham-Rundles 2011). Wheeze is characterized by a high-pitched continuous sound caused by airway constriction. Wheeze is mainly caused by viral infections or asthma (Ducharme et al. 2014). Many children with early wheeze grow out of symptoms and have no further respiratory problems. However, early childhood wheeze is a risk factor for asthma development (Herzog and Cunningham-Rundles 2011). Croup (acute subglottic laryngitis) is characterized by airway inflammation and swelling of the upper airways that cause acute breathing difficulties and a barking cough. It mainly affects young children between 6 months and 3 years old (Mazurek et al. 2019). There may be a relationship between croup and asthma, but no clear link has been established (Bjornson and Johnson 2008; Mazurek et al. 2019; Pruijkken et al. 2009).

Environmental exposures including indoor contaminants and cleaning products have been suggested as contributing risk factors for respiratory outcomes such as asthma (Dallongeville et al. 2016; Parks and Takaro 2020; Stern et al. 2020). There are epidemiological reports of associations between phthalate exposure and asthma and other airway conditions. However, the results are not conclusive as reviewed by, e.g., Bølling et al. (2020) and Casas and Gascon (2020). Associations that separately link

Table 1 Names and CAS numbers of phthalates and corresponding metabolites included in chemical analysis of bedroom dust and pregnant mother's urine in the SELMA study

Dust analysis			Urine analysis		
Phthalate	Common name	CAS	Metabolite	Common name	CAS

^aMetabolites of DnBP and DiBP are difficult to distinguish in the chemical analysis. Therefore, their results are reported as MBP (Σ DBP)

^bSummary concentrations of DEHP and DiNP were calculated from the molar sum of the metabolites and the molecular weight of the corresponding parent phthalate (Σ DEHP and Σ DiNP, respectively)

^cNot included in chemical analysis of dust

^dMetabolite of both DiDP and DPHP

phthalate sources to environmental exposure, phthalates in dust and air to human uptake, or phthalates in dust and their metabolites in urine to airway outcomes are frequently reported. Despite this result, we still lack enough evidence to predict how phthalate exposure may affect children's airway health, and to what extent indoor phthalate sources and exposure contribute to the observed health effects.

Applying SELMA Data to the Full Chain Model

We now apply results from the SELMA study to the full chain model (Fig. 1). More specifically, we are demonstrating connections between PVC flooring as a source of indoor phthalate emission, exposure via dust, uptake, and the relationship to airway symptoms in young children.

Environmental Exposure

Sources of indoor phthalate emission include a great number of materials and consumer goods, where PVC plastics is dominant (SCA 2015). In the SELMA study, 25% of the families reported having PVC flooring in the parent's bedroom (Shu et al. 2019). Only wood and parquet were the more common flooring materials (43%), while laminate flooring was the third most common type of flooring (18%).

In the SELMA study, phthalates were analyzed in bedroom dust samples collected in 496 homes before and after birth of the child. Phthalates were abundant, with detection rates $\geq 90\%$. DEHP was dominant with geometric mean (GM) levels 102–131 $\mu\text{g/g}$ dust. Levels of diethyl phthalate (DEP) and di-2-propylheptyl phthalate (DPHP) were the lowest with GM levels between 1.3 and 1.9 $\mu\text{g/g}$ (Preece et al. 2022). The SELMA results are within the range of phthalate levels in residential indoor dust that have been reported by numerous other studies. DEHP is generally the most abundant phthalate detected in indoor dust from all countries, which reflects its domination of global plasticizer production and wide use in PVC plastic (Gao et al. 2018; SCA 2015). In dust collected in homes, median levels of DEHP ranged from around 100 $\mu\text{g/g}$ up to 1200 $\mu\text{g/g}$ as presented by a review of 94 studies that analyzed phthalate levels in indoor dust and/or air samples (Bu et al. 2020). For other phthalates, the results vary more between regions. For example, butylbenzyl phthalate (BBzP) is often the second most dominant phthalate in North American studies, while the abundance of BBzP varies in European countries, and the levels are low in most studies from Asia. Levels of DEP in dust are generally low in all countries, while it is more abundant in the air (Bu et al. 2020).

Dust is a frequently chosen matrix to estimate environmental contamination (Bu et al. 2020; Lucattini et al. 2018). Although it is a complex matrix, contaminants detected in dust provides an approximation of emissions to all available sources in a particular indoor space (Weschler et al. 2008). Phthalate concentrations in dust are strongly related to the available phthalate emission sources (Lucattini et al. 2018) and the total amount of emitted phthalates (Salthammer et al. 2018; Weschler et al. 2008). PVC flooring reported by the SELMA families was associated with higher levels of di-*n*-butyl phthalate (DnBP), BBzP, and diethylhexyl phthalate (DEHP) compared to other flooring materials (Fig. 2). Reports from other studies have linked PVC flooring to higher levels of several phthalates in homes, preschools, and offices (Bi et al. 2018; Christia et al. 2019; Larsson et al. 2017). The number of rooms with PVC flooring in a home has been reported to correlate with the levels of BBzP and DEHP in the dust (Bornehag et al. 2005).

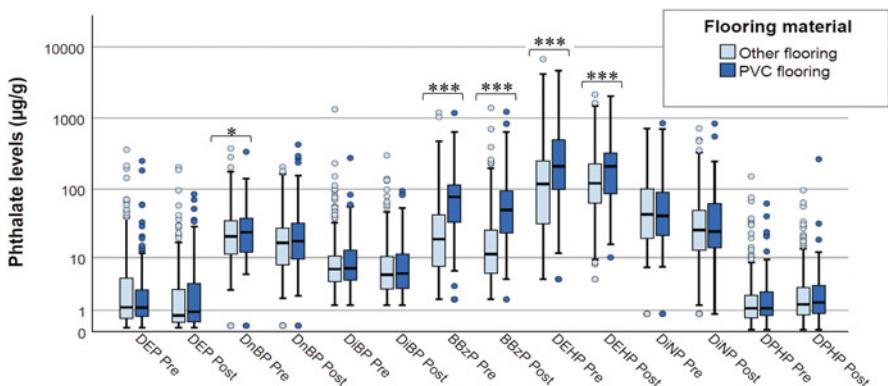

Fig. 2 Phthalate levels in dust ($\mu\text{g/g}$) collected during pregnancy (pre) or 6 months after birth (post) stratified for flooring material, shown on a \log_{10} scale. The flooring materials were categorized as “other than PVC” ($n = 378$) or “PVC” ($n = 118$). Levels below the limit of detection (LOD) were assigned a replacement value of $\text{LOD}/\sqrt{2}$. * $P < 0.05$, *** $P < 0.001$ for the difference between flooring materials

The results from the SELMA study show that phthalates are common contaminants in bedroom dust, and that PVC flooring acts as a source for phthalates in dust. Other published research results confirm these findings.

Human Exposure

Phthalates are metabolized fairly rapidly in the human body and measuring the resulting metabolites in urine serves as a method to quantify phthalate uptake (Wang et al. 2019; Wittassek and Angerer 2008). In SELMA, phthalate metabolite concentrations were also used to estimate the total phthalate intake followed by comparisons to phthalate intake from indoor dust.

Phthalate Metabolites in Urine

All pregnant SELMA mothers had detectable urinary levels of several phthalate metabolites, and in more than 98% of mothers all 13 analyzed metabolites were detectable (Shu et al. 2019). The DnBP and DiBP metabolites are difficult to distinguish in chemical analysis. Therefore, their results are reported as a sum denoted DBP. Crude- and creatinine-adjusted results revealed that GM concentrations of metabolites of DEP and DBP were dominant (37 and 33 nmol/mmol creatinine, respectively) and two orders of magnitude higher than two metabolites originating from either di-iso-decyl phthalate (DiDP) or DPHP which were the least abundant (0.41 and 0.21 nmol/mmol creatinine, respectively). In between, the GM concentration of the BBzP metabolite monobenzyl phthalate (MBzP) was 6.8 nmol/mmol creatinine (Shu et al. 2019). The data also reveals increasing or decreasing exposure trends over time, indicating that phthalate restrictions and replacement can make an impact on human uptake (Shu et al. 2018a).

A large number of biomonitoring studies reveal a ubiquitous phthalate exposure among all tested populations and age groups. However, exposure profiles vary a lot both within and between populations, as reviewed by, e.g., Lioy et al. (2015) and Wang et al. (2019). Pregnancy is a time when women might make changes to lifestyle and diet that could also affect their phthalate exposure. However, biomonitoring data suggest that exposure among pregnant women does not show any substantial difference compared to women in general (Lioy et al. 2015; Wang et al. 2019). The SELMA results are comparable to other studies that collected urine around the same time period (2007–2010). However, the concentration of BBzP in SELMA is higher than most other reports (Lioy et al. 2015; Preece et al. 2021a; Shu et al. 2019). One possible explanation is that PVC materials in the indoor environment may contribute to the BBzP exposure among these women.

Phthalate Metabolites in Urine and PVC Flooring

In the SELMA study, the relationship between urinary metabolite concentrations and PVC flooring was studied using general linear regression models adjusted for the mother's age, education, smoking, and urine creatinine (Shu et al. 2019). The results show that three metabolite concentrations from the parent compounds DBP ($P < 0.001$), BBzP ($P < 0.001$), and DEHP ($P < 0.05$) are higher in urine from women with PVC flooring in their homes when compared with women with other flooring materials. An increasing number of rooms with PVC flooring was associated with increasing concentrations of the metabolites. Hence, the results indicate that PVC flooring in the home makes a relevant contribution to BBzP uptake in pregnant women. Support for this finding can be found for pregnant women (Sugeng et al. 2020) and infants (Carlstedt et al. 2013).

Phthalates in Urine and Dust

When cross-sectional phthalate metabolites in urine and phthalate levels in dust were compared in SELMA ($n = 455$), a positive relationship was found for DEP, DnBP, di-iso-butyl phthalate (DiBP), and BBzP ($P < 0.001$). The relationship was strongest for BBzP (Pearson correlation coefficient $r = 0.37$). For DEHP, no significant correlation was found. The results indicate that dust and the home indoor environment is a relevant contributor to the total intake of phthalates, BBzP in particular. However, the intake of DEHP is more strongly influenced by other exposure routes (e.g., diet or other indoor environments than the home) (Preece et al. 2021b). Data on phthalates in urine and dust samples can be used further to estimate the total phthalate intake and the contribution to intake from the indoor environment.

Total Daily External Phthalate Exposure (Intake)

In SELMA, estimations of each woman's total daily external phthalate exposure (intake) were back-calculated from metabolite concentrations of five phthalates. Complete data on matched phthalates in dust, metabolites in urine, flooring material, and personal characteristics were available for 455 women (Preece et al. 2021b). The greatest total daily median intake was found for DEHP with 2.95 µg/kg body weight/day. It was of similar magnitude for DEP (2.16 µg/kg/day) and DBP (2.36 µg/kg/day).

For BBzP, it was an order of magnitude lower (0.54 µg/kg/day). For each phthalate, the total intake among the participants showed substantial variability (two to three orders of magnitude) although the interquartile range was within the same magnitude for all phthalates (Preece et al. 2021b). The SELMA intake estimations did not include di-isobutyl phthalate (DiNP) or DPHP due to less available experimental data to determine the parameters needed for intake modeling. The DPHP levels in dust were also very low which combined with its lower volatility would result in a low indoor-related intake.

Based on phthalate metabolite concentrations, several studies have estimated the total daily phthalate intake among adults in general and pregnant women (Wang et al. 2019). These estimations vary between different populations, as can be expected from the variation in phthalate metabolite concentrations. Reported total daily intakes of DEHP among women of reproductive age (including pregnant women) range between 1.5 and 4.1 µg/kg body weight/day (Ait Bamai et al. 2015; Liou et al. 2015; Sugeng et al. 2020). The result for the pregnant women in SELMA was within this range. The median total intakes are generally one or two orders of magnitude lower than authority guidance values (Wang et al. 2019). In the EU the tolerable daily intake (TDI) for DEHP is 50 µg/kg/day (Silano et al. 2019). However, individuals with exposure levels exceeding the 95th percentile of the population generally exceeded the tolerable daily phthalate intake (Wang et al. 2019). This exceedance was also the case in SELMA, where the TDI was exceeded for DBP and DEHP among the seven (1.5%) most highly exposed women (Preece et al. 2021b). The total phthalate intake can be compared to the intake explained by phthalates in the dust.

Intake from Dust and Contribution to Total Intake

Phthalate levels detected in the SELMA bedroom dust were used to estimate the phthalate intake through dust ingestion, inhalation, and dermal absorption at home using steady-state models based on the method described by Bekö et al. (2013). The SELMA study focused on phthalate intake over 13 h during which the pregnant women were expected to be at home (Schweizer et al. 2007). Phthalate intake from dust ingestion was estimated for 5 h only, during which the pregnant women were expected to be awake in their homes during the day. No dust ingestion was presumed to take place during sleep (EPA 2017). The results show that median indoor intake is the highest for DBP (640 ng/kg/day), followed by DEP (210 ng/kg/day), DEHP (200 ng/kg/day), and lowest for BBzP (12 ng/kg/day). Dermal absorption was the main indoor exposure route for DEP and DBP, dust ingestion and inhalation were most important for BBzP, and dust ingestion was the most relevant indoor exposure route for DEHP.

Compared to the total daily intakes (24 h), the indoor related intakes during 13 h at home are equivalent to relative contributions of 12% for DEP, 28% for DBP, 2.1% for BBzP, and 0.7% for DEHP (medians). For the most highly exposed that exceeded the TDI limit for DBP, the indoor-related intake in their homes made a meaningful contribution to this concerning intake (Preece et al. 2021b). The intake differences between women with PVC flooring or other flooring materials are shown in Fig. 3.

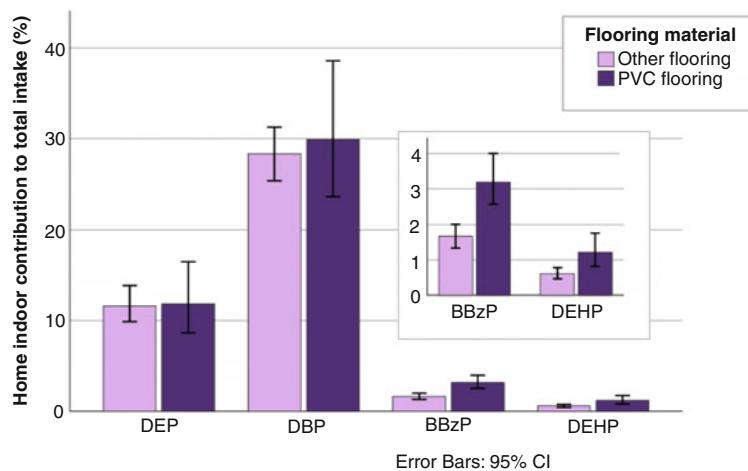

Fig. 3 Median intake contribution (%) to the total daily phthalate intake from dust ingestion, inhalation, and dermal absorption from the air during 13 h at home among 455 pregnant women with or without PVC flooring

For women with PVC bedroom flooring, the indoor contribution to intake of BBzP and DEHP was around twice as high compared to women with other flooring materials. However, the contribution to the total intake was marginal (1–2%). The flooring material had only minor effect on the intake contribution for DEP and ΣDBP (Preece et al. 2021b).

Previously, phthalate intake has been estimated from phthalate levels in residential dust, air, or both dust and air among adults in several studies. Phthalate intake from dust ingestion or air inhalation are generally estimated in these studies. A limited number of studies estimate dermal absorption of phthalates including Dodson et al. (2015); Li et al. (2021); Pelletier et al. (2017); Wang et al. (2014); and Zhu et al. (2019). Studies that estimate intake and include both measurements of environmental exposure and biomonitoring data are also limited. We identified four studies that estimated total daily phthalate intake and contributions from indoor exposure. One study included the exposure route dust ingestion only (Shi et al. 2021), while the other two also included inhalation and dermal absorption (Giovanoulis et al. 2018; Guo and Kannan 2011). Guo and Kannan (2011) compared the intake in China and the USA based on dust and urine measurements that were not collected from the same study populations (dust sample sizes were N = 33 and N = 75). The intake estimations were calculated from theoretical reference values for adults. Shi et al. (2021) compared dust ingestion to total daily intake based on dust, urine, and person-by-person data collected in the same study population of mothers to children aged 0–7 years (N = 47). Finally, Giovanoulis et al. (2018) used dust, air, urine, and person-by-person data that was collected in the same study population of adults (N = 61). A meta-analysis was conducted by Bu et al. (2020) where intake from the three exposure routes were estimated based on phthalate levels

in dust from 35 previous studies. SELMA is a relatively large cohort compared to other studies that analyze phthalate exposure in data from both dust and urine samples.

Generally, intakes are estimated over 24 h in other studies while the SELMA results are based on 13 h spent at home. Despite this, the SELMA results were generally close to or within the range of intakes reported elsewhere as results vary between one or two orders of magnitude for most phthalates and intake routes.

The current intake estimations performed in SELMA and other studies suggest that dermal absorption of DEP and DBP is dominant compared to dust ingestion and inhalation (Bu et al. 2020; Giovanoulis et al. 2018; Preece et al. 2021b). However, experimental studies on human subjects conclude that inhalation is comparable to or greater than the uptake from dermal absorption (Weschler et al. 2015; Andersen et al. 2018). Therefore, the dermal absorption of phthalates from the air might be overestimated and/or the inhalation intake underestimated by theoretical methods. Estimating intake requires knowledge of behavior in circulation, distribution in various tissues, metabolic pathways, and elimination/clearance processes (Koch et al. 2012; Salthammer et al. 2018). So far, the models are used to predict exposures as averages in larger populations, they are not precise enough to accurately predict intakes for individuals (Weschler et al. 2008). Increasing knowledge about these parameters will result in more precise estimations.

The results from the SELMA study show that dust can explain a relevant intake of DEP and DBP from the indoor environment. Analysis suggests that the indoor environment also makes a relevant contribution to the total uptake of some phthalates, particularly BBzP. Women with PVC flooring have a higher intake of BBzP and DEHP while analysis of uptake suggests DBP uptake can also be higher among women with PVC flooring. This result confirms the relationship between human exposure from indoor environment and human uptake. It also links a source of phthalate emission to human exposure.

Health Effects

Associations between phthalate exposure during pregnancy or phthalate levels in dust and two airway symptoms in young children were investigated in SELMA. The outcomes were wheeze or croup at 12 or 24 months of age.

Prenatal Phthalate Exposure

Three analyses explored associations between 13 metabolites from 8 parent phthalates (Table 1) in prenatal maternal urine and airway symptoms in their children. First, wheeze at 12 months of age was investigated. The prevalence of ever wheeze was 30% (23% of girls and 35% of boys). Some associations between metabolites of DiNP and ever wheeze were found, which were stronger among girls than boys (Shu et al. 2018b).

Second, one year later at 24 months of age, the prevalence of ever wheeze was 34% (27% of girls and 41% of boys). Associations and indications of a dose-

response relationships were found between metabolites of more high molecular weight DiDP and DPHP and wheeze (Preece et al. 2021a). No significant associations between DiNP metabolites and wheeze were found when the full study population was considered. In subgroup analyses, the associations between DiDP and DPHP metabolites and wheeze were stronger for boys than girls. Effects on wheeze among children whose parents reported not having (54%) or having (46%) asthma and/or rhinitis were also investigated. Wheeze was more common if parents did have asthma/rhinitis than if not (41% and 29%, respectively). Associations between metabolite concentrations and wheeze were stronger among the children whose parents did not suffer from asthma/rhinitis (Fig. 4). In this subgroup, there were further associations between wheeze and metabolites of BBzP and DiNP, with indications of dose-response relationships (Preece et al. 2021a).

Third, croup and associations with maternal metabolite concentrations were investigated at 12 months of age. The prevalence of ever croup was 10% (7% of girls and 12% of boys). Associations were found between ever croup and metabolites of BBzP and DEHP. The associations were stronger among boys (Shu et al. 2018b).

Other biomonitoring studies have also assessed associations between phthalate exposure of pregnant women and effects on children's health and development. Relating to airway conditions, metabolites of DBP, BBzP, and/or DEHP have been associated with asthma and wheeze in children aged 0–9 years in several studies with 145–1489 participants from Spain (Gascon et al. 2015), Germany (Jahreis et al. 2018), Taiwan (Ku et al. 2015), Poland (Podlecka et al. 2020), Ukraine, Greenland (Smit et al. 2015), and the USA (Whyatt et al. 2014). Adgent et al. (2020) found an adverse mixture effect among US children whose mothers did not have asthma, and Ait Bamai et al. (2018) found an association between DEHP and wheeze among Japanese girls but not boys. No effect on asthma was found among Danish children (Jøhnk et al. 2020). The number of reports including DiNP, DiDP, and DPHP in the

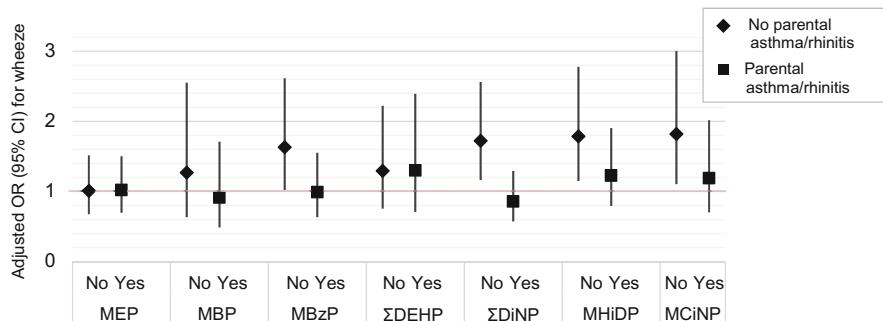

Fig. 4 Associations between prenatal phthalate exposure and infant wheeze (odds ratios with 95% CIs), stratified for parental asthma and/or rhinitis (N = 1148). Logistic regression models were adjusted for sex of the child, and mother's education, smoking, and creatinine in urine. Summary concentrations of DEHP and DiNP were calculated from the molar sum of the metabolites and the molecular weight of the corresponding parent phthalate

analysis were more limited. Prenatal concentrations of DiNP and DiDP metabolites were associated with decreasing lung function and increased risk of probable asthma among 5- to 7-year-olds (Berger et al. 2019; Vernet et al. 2017). However, contrasting results showing protective effects from higher concentrations of DiDP metabolites on asthma and wheeze among US children were reported by Adgent et al. (2020).

Differences in time points when prenatal exposure and the airway outcome were assessed may contribute to the contradictory results. Most studies analyzed urine collected during the third trimester of pregnancy. The first trimester of pregnancy represents the initial development of the fetal respiratory system and immune system, while the third trimester is characterized by tissue maturation (Nikolic et al. 2018; Pinkerton and Joad 2006). Today, our understanding of the distinct stages of early human development and possible critical exposure time windows is limited (Pinkerton and Joad 2006). The chosen outcome assessment time point is also relevant to consider. Effects from prenatal exposure combined with interaction from the postnatal environment and airway infections may influence the maturation of the airways that continue after birth (Driscoll et al. 2020; Nikolic et al. 2018; Pinkerton and Joad 2006). The effect of environmental phthalate exposure during early childhood is another question to investigate.

Phthalates in Dust

The relationship between environmental monitoring data and human health outcomes can be investigated; hence, linking the left and right sections of the full chain model. In SELMA, associations between seven phthalates in bedroom dust (Table 1) and the airway outcome croup were explored at 12 months of age. The prevalence of ever croup was 10% (6% of girls and 13% of boys). The results showed that higher levels of DEP and DEHP in dust were associated with croup. The associations were stronger for boys among which BBzP levels were also associated with croup (Preece et al. 2021c).

Phthalates in indoor dust and airway outcomes have been investigated in several other studies. Croup has not been used as an outcome, but wheeze and asthma have been associated with levels of DBP, BBzP, and/or DEHP among children aged 1–14 years in studies from North America and Europe (Bekö et al. 2015; Bornehag et al. 2004; Kolarik et al. 2008; Navaranjan et al. 2021). BBzP was associated with rhinitis and eczema but not asthma in children aged 3–9 years from Taiwan (Hsu et al. 2012). Two Japanese studies associated DnBP and DEHP with rhinoconjunctivitis, DiBP and BBzP with eczema, and DiBP and BBzP with atopic dermatitis but not to asthma in 0- to 14-year-old children (Ait Bamai et al. 2016; Ait Bamai et al. 2014). High molecular weight phthalates in the dust were associated with asthma and wheeze in Chinese children aged around 7 years (Zhang et al. 2021). Plastic wall materials or PVC flooring have been associated with wheeze and/or asthma in Finnish, Russian, and Swedish children aged 1–13 years (Jaakkola et al. 2004; Jaakkola et al. 2000; Larsson et al. 2010; Shu et al. 2014).

Hence, the associations between BBzP and DEHP in dust and an airway outcome in children found in SELMA have support in previous literature. However, an

association between DEP in dust and croup was also identified (Preece et al. 2021c). This finding has no substantial support since croup is not frequently used as an outcome to investigate phthalate exposure effects and associations between DEP and other airway conditions have not been reported by other studies.

Relevance of the Results

We have used the example of phthalates and airway symptoms, but we believe this model is a useful tool for collecting evidence of exposure from source to health effect for other indoor contaminants and health outcomes. There are many sources of other semi-volatile compounds in our indoor environments of relevance for human health, including brominated flame retardants, perfluorinated compounds, and organophosphates (Salthammer et al. 2018).

The SELMA results applied in the full chain model showed that an indoor source of phthalate emission, PVC flooring, makes a difference on the phthalate levels in the dust. In turn, this result has an effect on human uptake and children's airway symptoms. This approach allowed us to not only investigate separate associations, but to connect a number of relationships that are necessary to understand human exposure and its effects. One phthalate, BBzP, could be followed over the full chain of relationships, from source to association with airway outcomes in children. As previously described, support for these results of the separate links in the full chain model has been found in the scientific literature.

We analyzed one source, PVC flooring. This source was chosen as it has previously been linked to higher phthalate levels in indoor dust (Bornehag et al. 2005). PVC flooring materials are relevant to investigate since they are durable and may remain in use in people's homes for a considerable time, hence acting as a permanent emission source throughout their long use (Swedish Chemical Agency [SCA] 2015; Wormuth et al. 2006). The current results suggest that the indoor environment makes a relevant, but not dominating, contribution to the total phthalate intake among pregnant women. The intake is fairly low for the majority, but for the most highly exposed, the contribution was concerning. Introducing measures to reduce exposure for this group is particularly important. Collecting more data on parameters that modify environmental exposure will provide more robust results. They include temperature, phthalate degradation, relative humidity, air exchange rate, and composition of dust (Bope et al. 2019; Salthammer et al. 2018; Wei et al. 2018; Weiss et al. 2018; Weschler et al. 2008).

Assessing chemical exposure in early life is relevant, since early development modulation may persist and contribute to adverse health effects later in life (DeWitt and Patil 2018; Grandjean et al. 2019). We still need to learn more about how the observed early childhood effects relate to long-term airway health and asthma development. The airway outcomes wheeze, croup, and asthma can rarely be explained by one simple cause. Instead, genetic and environmental factors interact during disease development (Herzog and Cunningham-Rundles 2011). As there are no cures, prevention is vital to reduce suffering and societal cost (Mukherjee et al. 2016).

Identifying and reducing exposure to modifiable environmental risk factors could make a meaningful contribution to preventive strategies (Beasley et al. 2015). Factors to consider that are not explicitly mentioned in the full chain model include the time points of exposure and health outcome assessment. Also, chemical mixture effects can influence associations between exposure and outcomes.

Reducing airway disease is part of the work to ensure health and well-being for all, the third of the 17 sustainable development goals in Agenda 2030 of the United Nations (UN) (United Nations [UN] 2015). The results from SELMA suggest that the risk for airway conditions associated with phthalates in dust and air is quite low for the individual child. However, airway disease is common, so limiting indoor phthalate sources and exposure during early human development may reduce a harmful exposure and benefit overall public health. Gaining a more complete picture of chemical exposure, as proposed in the full chain model, will also contribute to achieve the 12th sustainable development goal on consumption and production patterns. Specifically, subgoal 12.4 states that we must achieve an environmentally sound management of chemicals and reduce release in order to minimize impacts on human health (UN 2015). Competence in various fields such as chemistry, engineering, toxicology, epidemiology, biostatistics, medicine, etc. is needed to understand human exposure to indoor contaminants (Salthammer et al. 2018). To provide relevant input for risk assessment, establishment of strong interdisciplinary approaches are necessary. The full chain model is a tool that can facilitate such work. It may also be used to connect existing results from different studies and to identify research gaps.

Conclusions

In this chapter, we applied results from one cohort study to the full chain model. This example allowed us to link indoor exposure from source to health effects. We found that one source, PVC flooring, made an impact on the levels of several phthalates in indoor dust, which was linked to a higher phthalate uptake among pregnant women, which was further associated with wheeze in young children. Phthalates in dust were also associated with croup during infancy.

These results are concordant with results from other studies. However, more knowledge and a better understanding of various environmental and biological modifying factors would make the results more robust. The full chain model approach can facilitate the acquiring of evidence that is necessary for adequate risk governance and the development of strategies to reduce hazardous chemical exposure in our indoor environments.

Abstract

The highest environmentally related health benefits can be expected from policies that effectively target environmental exposures having high contributions to the population burden of disease (BoD). Such policies are demonstrated, for example, by the smoking bans in public places that have shown significant population health improvements in many countries. The health impacts of environmental exposures range from mild effects like annoyance to effects on chronic morbidity such as asthma, cardiovascular diseases, cancer, and even premature mortality, challenging the quantitative comparison of alternative policy options.

The environmental burden of disease provides a useful quantitative indicator of environmental health impacts, including chemical pollutants and noise. It allows quantitative comparisons of public health impacts associated with a wide range of environmental risk factors and targeting research and especially risk management to the major issues. This chapter gives an overview of the methods and presents five studies to demonstrate the use of the concepts.

Keywords

Burden of disease · Health risk characterization · Population attributable fraction (PAF) · Disability adjusted life years (DALY) · Incidence · Intake-daly

Introduction

The objectives of applying burden of disease tools to indoor air include (i) identification of pollutants and exposures relevant for indoor environments, (ii) demonstrating application of a harmonized environmental methodology on reducing burden of disease (EBD), and (iii) making the methods available for further applications and refinement. The factors to be considered for stressor selections should include (i) public health relevance, potential for (ii) high individual risks, (iii) public concerns, and (iv) large economic impacts.

Burden of disease methods have been widely accepted on global scale for assessing the health status of nations and identifying health losses caused by wide range of risk factors such as pollution, behavior, infectious diseases, nutrition, and violence (Fig. 1). The results highlight the global significance of environmental pollution, while indoor environments are largely missing as the air pollution component includes only unvented indoor use of solid fuels, typical of the developing countries.

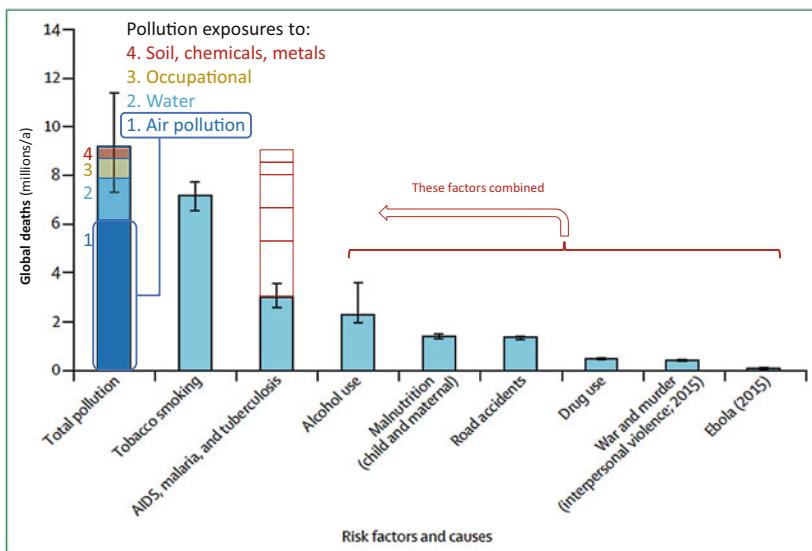

Fig. 1 Global estimated premature deaths by major risk factors and causes in 2015 using data from the GBD 2016 Study. (Modified from Landrigan et al. 2018)

Nevertheless, over the past decade there is emerging activity applying BoD methods focusing on indoor specific exposures (Table 1). This chapter introduces these methods and approaches.

Health risk characterization involves three nested assessment levels: (i) underlying health burden caused by diseases and corresponding causes (burden of disease, BoD); (ii) fractions of these burdens than can be attributed to risk factors (environmental burden of disease (EBD)); and (iii) impact of policies on these environmental burdens, assessed in the health impact assessment (HIA) process (Table 2).

The focus of most environmental risk assessments is on level (ii), overall impact associated with a given environmental exposure. However, a large part of the methodological literature quite correctly suggests that assessments should focus on the preventable fraction. This section introduces these approaches.

Global Burden of Disease Studies (GBD)

Burden of disease methods were proposed in 1990 by the collaborative work of World Bank, Harvard University, and World Health Organization (WHO) as an improvement to the earlier state of the art in characterizing health status of populations (Murray and Lopez 1996). A consistent and comparative description of the burden of diseases and injuries and the risk factors that cause them is an important input to health decision-making and planning processes. Information that is available on mortality, morbidity, and health status of populations in all regions of the world is fragmentary and sometimes inconsistent. Thus, a framework for integrating, validating, analyzing, and disseminating such information is needed to

assess the comparative importance of diseases, injuries and risk factors in causing premature death, loss of health and disability in different populations. Countries can combine this type of evidence along with information about policies and costs to decide how to set their health agenda.

The first GBD study quantified the health effects of more than 100 diseases and injuries for eight regions of the world in 1990. It generated comprehensive and internally consistent estimates of mortality and morbidity by age, sex and region. The study also introduced a new metric, the disability-adjusted life-year (DALY), as a single measure to quantify the burden of diseases, injuries and risk factors. The DALY estimate is based on years of life lost from premature death and years of life lived in less than full health. GBD 1990 study was subsequently updated by WHO for the target years 2000–2002–2004 and included a more extensive analysis of the mortality and burden of disease attributable to 26 global risk factors using a consistent analytic framework known as comparative risk factor assessment (CRA).

The burden of disease was originally calculated from estimated or registered incidence data of various diseases, using disease specific disability weights defined

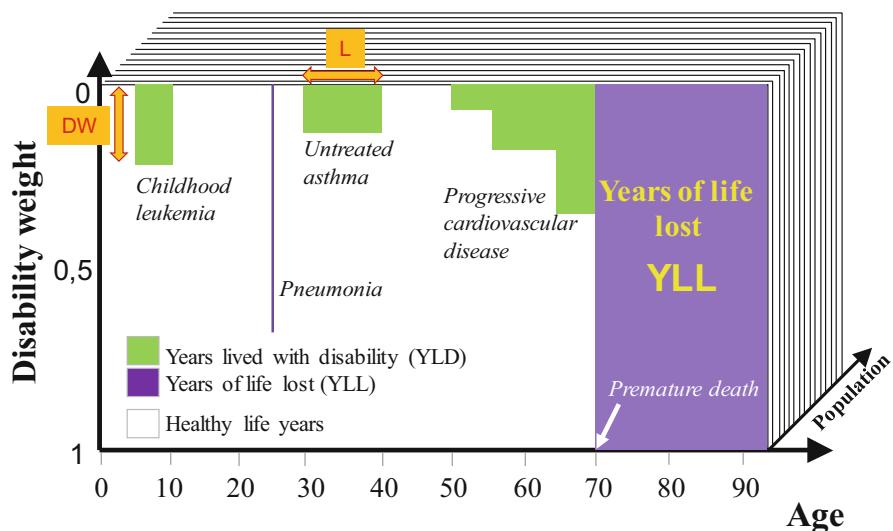

Fig. 2 Burden of disease concepts: premature mortality leads to years of life lost (YLL). Disability weight (DW) are used together with the disease duration (L) to calculate comparable estimate of years lived with disability (YLD). (Adopted from Hollander et al. 1999)

by expert panels, estimated disease specific durations, and accounting for years of life lost due to premature mortality (Fig. 2). The original studies used the longest living Japanese and South Korean populations for determining the life expectancy for calculation of years of life lost.

Since 2010 the Institute for Health Metrics and Evaluation (IHME), located at University of Washington, USA, and other academic partners have collaborated on the GBD 2010 global burden of disease study, published on 14 December 2012. Regional estimates of deaths and DALYs using a new method for calculation of DALYs for the years 1990, 2005, and 2010 were reported. Subsequently, over the past decade several updates and improvements were prepared and published. Most comprehensive global study – analyzing 286 causes of death, 369 diseases and injuries, and 87 risk factors in 204 countries and territories – until now is the GBD 2019 study (GBD 2021a; Vos et al. 2020).

National burden of disease estimates from both IHME and WHO are readily available and have been actively used as a key input to top-down assessment of indoor air burdens.

Risk Assessment (RA)

Health risk assessment (HRA) was largely developed prior to the GBD work by the US Environmental Protection Agency (US EPA) in the 1980s to quantitatively or semi-quantitatively inform decision-makers on the types and probability of environmental risks. As of today, it still remains the most comprehensive theoretical

framework for health risk assessments through the evolution of risk characterization and quantification, including the environmental burden of disease (Fig. 3).

The nature and probability of adverse potential health effects in humans who may be exposed to hazardous chemicals in contaminated environmental media in the past, now or in the future were characterized (US EPA 1989). HRA as defined by the US EPA consisted of three input elements, used to characterize the risk (Table 3). It is noteworthy, that the components do not include the target population characteristics such as age and health profiles that actually may substantially modify the risk characteristics.

The role of target population at risk with age, sex, and health characteristics has become obvious through the adaptation of the burden of disease methods and moving from hazard indexes and quotients toward more quantitative risk characterization based on epidemiological evidence from real human populations as will be presented below.

The risk characterization provided a useful and flexible framework for how in practice the risks should be presented. Based on the toxicological evidence in the 1980s, two major lines of analyses emerged (see Xiong et al. 2018 for a review),

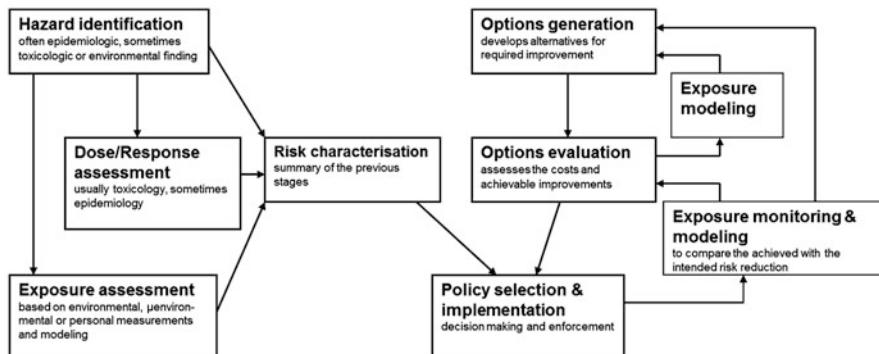

Fig. 3 Components of risk assessment and management processes (based on NRC 1983)

Table 3 Components of the US-EPA risk assessment process (based on NRC 1983)

Level	Assessment
I	Hazard Identification scientific information on the hazardous properties of environmental agents;
II	Dose-response quantitative relationship between exposure and effects
III	Exposures the extent of human exposure to those agents
IV	Risk characterization the product of the risk assessment is a statement regarding the probability and nature of harm in populations or exposed individuals

presented below shortly to provide the background on which burden of disease methods were developed for a good reason. The first approach focused on non-carcinogenic risks and health outcomes, remaining totally ignorant on the types of non-carcinogenic health outcome: the risk was quantified by comparing exposures (pollutant concentrations in the contact medium such as air) or doses (amount of substances entering the body or target organs) with the available health or toxicology based reference values for that chemical and presenting the single chemical or exposure value as hazard quotient:

$$HQ_i = \frac{E}{Rf} \quad (1)$$

where HQ : hazard quotient, E : exposure or dose, Rf : selected reference toxicological level (derived from, e.g., no observed effect level (NOEL)).

Further, regardless of the potentially widely varying differences in types of health outcomes and toxicological mechanisms associated with the exposure in question, aggregation of the hazard quotients was done by defining hazard index as a cumulative sum over hazard quotients:

$$HI = \sum_i HQ_i \quad (2)$$

where HI : hazard index, HQ : hazard quotient.

Thus the hazard index seemingly provided additivity, while remaining semi-quantitative at best as a characterization of risk.

Better quantification was already possible for carcinogenic risks at that time. The selected cancer model assumed linear no-threshold risk probabilities of developing cancer as function of the exposures:

$$p = E \times CSF \quad (3)$$

where p : probability, E : exposure or dose, CSF : cancer slope factor (ratio of cancer probability to dose).

At that time, no safe level was assumed for carcinogenic exposures and use of simple linear relationship allowed for estimation of the cancer slope from basically single-dose tests or ecological data sets. As can be seen from this short introduction, risks were estimated separately for two different types of complex disease groups and there was no possibility to quantitatively compare them for prioritization, setting the scene for the development of new approaches in the 1990s.

Environmental Burden of Disease (EBD)

Environmental exposures are associated with a large variety of human diseases ranging from milder effects like headaches and annoyance to severe diseases such as cancer, and premature deaths. Therefore, quantitative comparison of such risks

and prioritization of preventive measures cannot be based on merely incidence or prevalence rates. The environmental burden of disease methodology accounts for both years of life lost due to mortality as well as years lived with various disabilities. The latter are quantified using, besides the duration of the condition, condition specific severity weights. Such weights inherently contain a value component, but in practice, the resulting environmental burden of disease estimates have been found quite useful.

Improved population health registries and harmonization of disease codes together with statistical methods such as population attributable fraction that can be estimated from epidemiological data, allow for rapid and comparable international assessments.

In the first global burden of disease study by Murray and Lopez (1997), two environmental risk factor groups were considered: (i) poor water, sanitation, and hygiene and (ii) air pollution. In the updates of the global burden of disease project for 2002 and 2004, additional environmental risk factors were included: (iii) lead, (iv) indoor air pollution from solid fuel combustion, and (v) climate change.

One of the first more comprehensive analyses of environmental burden of diseases from a number of risk factors was conducted by de Hollander et al. (1999) in the Netherlands. A total of 19 environmental risk factors were covered.

The World Health Organization then took the lead to harmonize the EBD methods (Prüss-Ustün et al. 2003) and published a series of reports on environmental burden of disease quantifying the amount of disease caused by selected environmental risks factors including chemicals and mixtures as well as physical exposures such as noise and radiation.

Similar to the overall population health status, disease burden attributable to the environment can be expressed in deaths and in disability-adjusted life years (DALYs). The latter measure combines the burden due to death and disability in a single index. Using such an index permits the comparison of the burden due to various environmental risk factors with other risk factors or diseases.

The environmental burden of disease quantifies the amount of disease caused by environmental risks. In 2016, as much as 24% of all deaths worldwide were attributable to the environment (Prüss-Ustün et al. 2016). The realization of how much disease and ill health can be attributed to modifiable environmental risks may contribute to identifying prevention opportunities and should add impetus to global efforts encouraging sound preventive measures through available policies, strategies, interventions, technologies and knowledge.

Additional information required for the rational development of policies by the health sector and activities of other sectors which directly manage or influence the determinants of health includes the effectiveness and cost-effectiveness of interventions, the availability of resources, and the type of policy environment.

Due to background exposures from natural sources and practical limitations in removing anthropogenic pollution, the total attributable burden of disease cannot be directly interpreted as reduction potential. In many cases natural background prevents from completely removing the exposures, natural ionizing radiation or atmospheric particulate matter being examples. Nevertheless, EBD estimates can be used

to identify areas of high disease burden for more detailed analysis of the reduction potential by targeted policies. The use of quantitative methods like EBD and health impact assessment should be promoted to inform policymakers about the health benefits of specific policy measures.

Health Impact Assessment (HIA)

According to WHO, health impact assessment (HIA) is a practical approach used to judge the potential health effects of a policy, program or project on a population, particularly on vulnerable or disadvantaged groups. Recommendations are produced for decision-makers and stakeholders, with the aim of maximizing the proposal's positive health effects and minimizing its negative health effects. The approach can be applied in diverse economic sectors and uses quantitative, qualitative, and participatory techniques (WHO 2021).

HIA provides a way to engage with members of the public affected by a particular proposal. It also helps decision-makers make choices about alternatives and improvements to prevent disease or injury and to actively promote health. It is based on the four interlinked values of democracy (promoting stakeholder participation), equity (considering the impact on the whole population), sustainable development and the ethical use of evidence.

US Centers for Disease Control and Prevention (US-CDC 2021) has identified six steps in conducting an HIA:

1. Screening (identifying plan, project, or policy decisions for which an HIA would be useful).
2. Scoping (planning the HIA and identifying what health risks and benefits to consider).
3. Assessment (identifying affected populations and quantifying health impacts of the decision).
4. Recommendations (suggesting practical actions to promote positive health effects and minimize negative health effects).
5. Reporting (presenting results to decision-makers, affected communities, and other stakeholders).
6. Monitoring and evaluation (determining the HIA's impact on the decision and health status).

There is a significant conceptual difference between the overall environmental burden of disease associated with a selected exposure and the target of health impact assessment. While HIA may aggregate over several pollutants and exposures associated with the policy under scrutiny, the HIA, by definition, focuses on the change in health effects, i.e., the impact of the policy in question. Typically, the impact of a single policy is rather small on overall environmental exposures. Thus, it is critical to keep the overall burden attributable to a given exposure conceptually separate from the estimated health impact of a selected policy or decision.

Building on the previous concepts of BOD, RA (HRA; CRA), EBD, and HIA, details of applying burden of disease methodology on selected exposures are provided and discussed hereafter.

Methods

Burden of disease is a measure of sickness and death in a population. The burden of disease methodology is based on making years lived with a disability (*YLD*) comparable with years of life lost (*YLL*) due to premature mortality. Summing these two components produces disability adjusted life years (DALY) as the quantitative measure of burden of disease (Murray and Lopez 1997):

$$BoD = YLL + YLD \quad (4)$$

where years of life lost (*YLL*) in a case of premature mortality are calculated as the age-specific remaining life expectancy (*LE*) at the age at death (*AD*):

$$YLL = LE - AD \quad (5)$$

The value of the time lived in non-fatal health states, in comparison with life lost due to premature mortality, is estimated using health state weights reflecting social preferences for different states of health. Incidences of acute and chronic diseases and corresponding mean durations available in health registries are supplemented with disability weights to calculate corresponding estimate of years lived with disability (*YLD*) accounting for the duration of the disease (*L*) and the disease severity expressed as a disease specific disability weight (*DW*):

$$YLD = DW \times L \quad (6)$$

Some disability weights used in DALY calculations quantify societal preferences for different health states. Others are based on medical expert panel assessments of the conditions, taking into account for the potential need for hospitalization, medication, and differences in disease progression in patients. Both WHO and IHME have published their own disability weights.

It is noteworthy that the questionnaire-based weights do not typically represent the lived experience of a disability or health state. Neither do they imply any societal value for the person in a disability or health state. Nevertheless, they may quantify societal preferences for health states in relation to the societal ideal of good health. The term “disability” is used broadly to refer to departures from good or ideal health in any of the important domains of health. These include mobility, self-care, participation in usual activities, pain and discomfort, anxiety and depression, and cognitive impairment (Prüss-Ustün et al. 2003). Examples of disability weight values, collected from dedicated questionnaire panels, are shown in Table 4. Treatment of diseases further modifies the diseases and thus the disabilities. In many cases a

Table 4 Examples of early disability weights. (Adopted from Murray and Lopez 1996) compared with GBD 2019 sequelae. The early approach considered disabilities by disease treatment status. Since then several rounds of international and various national updates have been conducted. Here as an example the corresponding number of sequelae from the GBD 2019 study are shown for comparison. Details of the conditions can be found from the GBD documentation (GBD 2021a)

treated disease is substantially less disabling than a non-treated disease. These differences are highlighted in the table, too.

A unit risk model for attributable incidence (AI, or estimated number of cases) can be calculated using similar probability-based approach as was developed originally for the cancer slope method described earlier, supplemented merely by the population size (see, e.g., Xiong et al. 2018 for more details):

$$AI = E \times UR \times N \quad (7)$$

where AI : attributable incidence (No. of cases), E : exposure, UR : unit risk (e.g., cancer slope; probability of the outcome per exposure), N : population size (persons).

Excess risk approach has been applied also estimation of attributable incidence when epidemiological estimate of relative risk has been available (Xiong et al. 2018). This method is a simplification of the full population attributable fraction calculation that will be explained next:

$$AI = (RR_E - 1) \times B \quad (8)$$

where AI : attributable incidence, RR : relative risk to the exposed population, B : background incidence.

Equation (8) is the first equation introducing a key variable based on epidemiological methods. It has been suggested that human-based evidence from real populations represents the most relevant and reliable evidence on exposure-response relationships (e.g., Klaassen, 2008). Such data accounts for actual levels of exposure and avoids the use of extrapolation methods inherently typical for toxicological in vitro and in vivo estimates from cell and animal studies, and most importantly, the use of theoretical safety and sensitivity scaling factors.

Population Attributable Fraction (PAF)

The burden of disease estimates describe the overall burden in a population and generally only a small fraction of the adverse outcomes can be attributed to the given environmental and other risk factors.

The burden of disease can be estimated using a bottom-up approach described in Eqs. 4, 5, and 6. However, the mathematical properties of relative risks offer an operational way to estimate the fraction of disease burden associated with a given risk factor when epidemiological data are available. In 1953, Levin first proposed the concept of the population attributable fraction. Since then, the phrases “population attributable risk,” “population attributable risk proportion,” “excess fraction,” and “etiological fraction” have been used interchangeably to refer to the proportion of disease risk in a population that can be attributed to the causal effects of a risk factor or set of factors (Rockhill et al. 1998).

In this context, the environmental burden of disease associated with a given risk factor can be calculated simply from the overall population burden of a given disease by multiplying it by the epidemiological estimate of the population attributable fraction. National background burden of disease estimates are directly available from both the World Health Organization and Institute of Health Metrics and Evaluation.

Attributable burden EBD is calculated from background burden (BoD) using the population attributable fraction (PAF) as

$$EBD = PAF \times BoD \quad (9)$$

The population attributable fraction (PAF) can be derived from relative risk (*RR*) as described in more detail, e.g., in Hänninen and Knol (2011):

$$PAF = \frac{f \times (RR - 1)}{f \times (RR - 1) + 1} \quad (10)$$

where *f* is the fraction of population exposed to a given factor and *RR* is the relative risk of the exposed population.

In the case of environmental exposures, the relative risk is commonly expressed per a standard increment of exposures, e.g., $10 \mu\text{g m}^{-3}$ as in the case of fine particles. Simplified approaches for most practical purposes use linear scaling; in this case, exposure to, e.g., $15 \mu\text{g m}^{-3}$ would be expressed as $E = 1.5$. Also, many non-linear exposure response functions have been proposed and even becoming the standard approach. The log-linear association, simply derived mathematically from the group-level definition of relative risk, leads to supra exposure response relationship and relative risk at prevailing exposure level:

$$RR = e^{(E \ln RR^o)} = RR^o E \quad (11)$$

One of the early non-linear approaches for particulate matter was suggested by Ostro and applied, e.g., by WHO (Ostro 2004). More recently many empirical and parametric sublinear associations have been proposed based on meta-analysis of especially particulate matter exposures such as versions of integrated exposure response function (IER; Burnett et al. 2014; Cohen et al. 2017), global exposure mortality model (GEMM; Burnett et al. 2018) and GBD 2021b. Debate on linearity

versus supra- and sub-linearity and existence of a safe level (biological or toxicological threshold) versus use of uncertainty cut-off levels at low exposures continues. In the absence of solid evidence on deviance from linearity it would seem reasonable to use linear estimation as a simplification and including low-end extrapolation even in lack of observational data at extremely low concentrations. Nevertheless, there is no wide consensus on any preferred approach.

Linking with Toxicological Databases

Epidemiological data from large populations is currently available for population attributable fraction-based, top-down estimation of environmental burden of disease only for a relatively small number of risk factors (see, e.g., Table 1). In the context of life cycle assessments, Mark Huijbregts and colleagues proposed a human toxicological effect model for carcinogenic and non-carcinogenic chemicals (Huijbregts et al. 2005). They presented a methodology to derive human damage and effect factors of toxic pollutants, starting from a lognormal dose-response function and applied the method to calculate combined human damage and effect factors for a total of 1,192 substances, including a subdivision into carcinogenic and non-carcinogenic compounds. Uncertainties in the damage and effect factors were also estimated.

Logue et al. (2012) applied this method for 69 + 2 indoor air exposures in the United States. The strengths of the approach include (i) top-down approach from established estimates of non-communicable diseases; (ii) use of disability adjusted life years as a comparable and harmonized metric; and (iii) availability of the method for many chemical substances. On the uncertainties side, it must be taken into account that the toxicological evidence is extrapolated to burden of disease without any specific understanding or justification of biological mechanisms beyond processing carcinogens separately, or considerations of interspecies scaling, sensitive subpopulations, temporal exposure patterns over developmental stages, etc. Liu et al. continued with similar estimates for China to be discussed in more detail in corresponding section later in this chapter. and used the results of Logue et al. for comparison.

In the next subchapter, we look in detail how the presented methods have been applied in estimation of indoor air attributable burden of disease in selected international and national studies and give an overview of the results reported.

Current Estimates of Indoor Air Burden of Disease

This section presents the state of art in applying the burden of disease methods to indoor exposures by presenting the key elements of a few selected international and national studies. It is expected that the field of applying burden of disease concepts for estimating the health effects of indoor exposures will continue to rapidly expand

and the reader is advised to supplement the material here with new studies reported in the scientific literature.

European EBoDE Study

One of the first European projects applying burden of disease methodology for selected exposures also including indoor air characteristics was the multinational Environmental Burden of Disease in European Countries (EBoDE) study. Six countries, each with national funding and a research team, participated the project supported by World Health Organization. Several meetings were organized at the Bonn office of WHO European Centre of Environment and Health and representative from the Environmental Burden of Disease Programme, Geneva, actively took part in the work in 2010–2011. The results were first published as a project report (Hänninen and Knol 2011) and then the key results as a peer reviewed journal article (Hänninen et al. 2014). The report remains a useful source of the assessment methods that are partly reproduced in this handbook chapter.

EBoDE remains the only study that proposed the use of a lag time between exposures and effect, which is significant for, e.g., the initiation of a cancer but also for development of cardiovascular and other chronic diseases. EBoDE was also one of the first studies that compared discounting, the standard approach in 2010, with non-discounted estimates. Discounting downscals health effects, mortality in particular, of children and thus counteracted the strategical objectives of Children's Environment and Health Action Plan (CEHAPE). Since then both IHME and WHO have chosen to drop discounting.

Stressor Selection

Four criteria were defined for the selection of environmental stressors to be included in the study:

1. Public health impact
2. High individual risk
3. High political or public concern
4. Economic significance

In addition, the selection was affected by the feasibility of the calculation. Therefore, we also considered the availabilities of:

- Exposure data
- Evidence-based exposure response function(s)
- Baseline health statistics

A total of nine stressors were selected: benzene, dioxins, fine particulate matter ($PM_{2.5}$) formaldehyde, lead, radon, second-hand smoke (SHS), and traffic noise. Formaldehyde, radon and SHS directly represented indoor dominant exposures.

Transportation noise effects also dominantly occurs in indoor spaces such as bedrooms and offices. Fine particles have significant indoor sources, but in the EBoDE study, only outdoor concentrations were used (see follow-up improvements in this respect in the next section on HealthVent study).

Exposure Assessment

Exposure data were primarily collected from international harmonized and validated sources, supplemented with national studies data and from other sources. Population representative exposures were targeted, accounting for potential differences in the urban and rural exposures, different age groups, gender, and other relevant sub-groups.

International exposure data were available for SHS, transport noise, ozone, PM and radon. National data were used for benzene, dioxins, formaldehyde, and lead, with complementary information from (non-comprehensive) international data sources such as AirBase ambient data for benzene; several international multiple center studies for indoor concentrations of benzene and formaldehyde covering some of the participating countries, and WHO Mother's milk database for dioxins.

The study also attempted assessment of exposure trends, relevant for harmonizing the target year exposures, accounting for health effect lag, with limited success. For several stressors (e.g., lead, dioxins) not enough data were available to make sensible trend estimates. For other stressors (PM, ozone, benzene), temporal and/or spatial variability was so large that reliable evaluations of the trend on the basis of these data were not possible. In these cases, expert judgment was used to estimate trends and corresponding confidence intervals. Due to the large uncertainties, no national trend estimates were created.

Exposure-Response Relationship Modelling

For each combination of environmental stressors and health endpoint, exposure-response functions were selected from:

- Recent international meta-analyses or WHO guidelines
- If not available, then from individual high-quality studies

Recent active and unstable evolution of concentration-response relationships for ambient particles in the GBD studies effectively demonstrates the challenges even for PM_{2.5}, which represents the most studied exposures with epidemiological data from the largest cohorts. Particles were modelled in EBoDE study using relative risks from earlier studies (Pope et al. 2002, 2004).

Formaldehyde and lead response models included an estimated safe threshold level at 100 µg m⁻³ and 24 µg l⁻¹, respectively. Further, a lead model for lower intelligence quotient and hypertensive disease were quantified by step functions over the diagnostic threshold of 70 pt. and 140 mm Hg, respectively. Transportation noise modelling applied polynomial prevalence response for both sleep disturbance and annoyance. For all other exposures, a linear (unit risk models) or log-linear (relative risk models) were applied as summarized in Table 5.

Table 5 Summary of EBoDE health endpoints, exposure units and exposure/response-relationships for the indoor relevant exposures

Stressor	Health endpoint	Population	Exposure estimate	Unit of exposure	Type of ERF	Point estimate	LCL (95%)	UCL (95%)	Reference (s) for ERF	Method
SHS	Tracheas, bronchus and lung cancers ^{c)}	Adult non-smokers	% of people exposed (=yes)	yes/no	RR	1.21	1.13	1.30	US S.G. 2006	PAF
	Ischemic heart disease	Adult non-smokers		yes/no	RR	1.27	1.19	1.36	US S.G. 2006	PAF
	Asthma induction	Adult non-smokers		yes/no	RR	1.97	1.19	3.25	Jaakkola et al. 2003	PAF
	Asthma induction	Children (<14 yr)		parental y/n	RR	1.32	1.24	1.41	Cal-EPA 2005	PAF
	Lower respiratory infections	Infants (<2 yr)		parental y/n	RR	1.55	1.42	1.69	US S.G. 2006	PAF
	Otitis media	Toddlers (<3 yr)		parental y/n	RR	1.38	1.21	1.56	Eitzel et al. 1992; Cal-EPA 2005	PAF
Formaldehyde	Asthma aggravation (children) (morbidity only)	Toddlers (<3 yr)	Annual mean residential indoor concentration	$\mu\text{g m}^{-3}$	RR	1.017	1.004	1.025	Rumchev et al. 2002	PAF
Road traffic noise	High sleep disturbance (HSD) (morbidity only)	All	Persons exposed to predefined exposure categories	Lnight (dB)	UR	function	function	Miedema and Vos 2007	n × DW × L	
	Ischemic heart disease (IHD)	All		Lday16h (dB)	OR	function	function	Babisch 2006	PAF	

Railway noise	High sleep disturbance (HSD) (morbidity only)	All		Lnight (dB)	UR	function	function	Miedema and Vos 2007	n × DW × L
Aircraft noise	High sleep disturbance (HSD) (morbidity only)	All		Lnight (dB)	UR	function	function	Miedema and Vos 2007	n × DW × L
PM _{2.5} ^a	Cardiopulmonary disease	Adults (>30 yr)	Population weighted ambient level	µg m ⁻³	RR	1.0077	1.0020	Pope et al. 2002; WHO 2006	PAF
Lung cancer	Adults (>30 yr)			µg m ⁻³	RR	1.012	1.004	Pope et al. 2002; WHO 2006	PAF
Chronic bronchitis (new cases)	Adults (>27 yr)			µg m ⁻³	UR	5.33 × 10 ⁻⁵	1.70 × 10 ⁻⁶	Hurley et al. 2005; WHO 2006	n × DW × L
Restricted activity days (RAD)	15–64 yr			µg m ⁻³	UR	0.0902	0.0792	Hurley et al. 2005; WHO 2006	n × DW × L

^a PM_{2.5} exposures were collected for ambient air and indoor sources not accounted for

^b Ozone mortality estimated with relative risk based PAF model, was set to cause loss of exactly 1 year of life

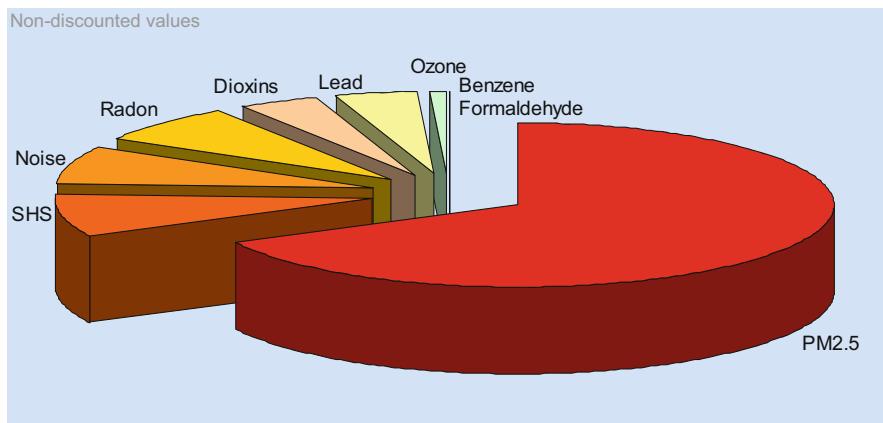

Fig. 4 EBoDE estimates of the relative burden attributable to the chosen nine stressors in six European countries (Hänninen and Knol 2011)

While the nine chosen stressors do not represent a comprehensive list of toxicants causing measurable public health impacts in European countries, the dominant role of ambient particles (PM_{2.5}) was obvious (Fig. 4). The health impacts of second-hand smoke, traffic noise, and radon were similar. Radon was more important in Finland than in the other participating countries due to the geological characteristics. The results suggested that 3–7% of the national burden of disease in the participating six countries is associated with the selected nine environmental stressors. Particulate matter (PM) is estimated to be associated with the highest disease burden (6.000 to 10.000 DALYs per million people), followed by traffic noise, second-hand smoke, and radon.

Ranking of environmental health impacts was elaborated with caution. However, even while “discounting” affected some of the estimates (especially radon, and SHS and particles) quite substantially, the ranking remained consistent. Only among the runner-up group of SHS, noise, and radon did the order change since noise effects are to a large extent immediate and not affected by discounting.

Long tradition prevails in assessing parametric uncertainties in environmental epidemiology and subsequent extrapolations in risk characterization. Exposure estimates already contain uncertainties that are difficult to be quantified. In an ideal world, unbiased random sampling could be used, reducing the exposure uncertainty to normal statistical uncertainty. In reality, exposure data is always available from geographically, socioeconomically, and temporally limited or chosen cohorts or panels, thus limiting and potentially, even likely to bias, representativity.

Further, it remains much more challenging to include model uncertainties in the overall uncertainty assessment. The EBoDE study applied expert judgment to categorize overall uncertainties in the estimates as presented in Fig. 5. It was suggested that the most reliable estimates were those for particles, second-hand smoke, radon, and benzene and the most uncertain ones were for dioxins and

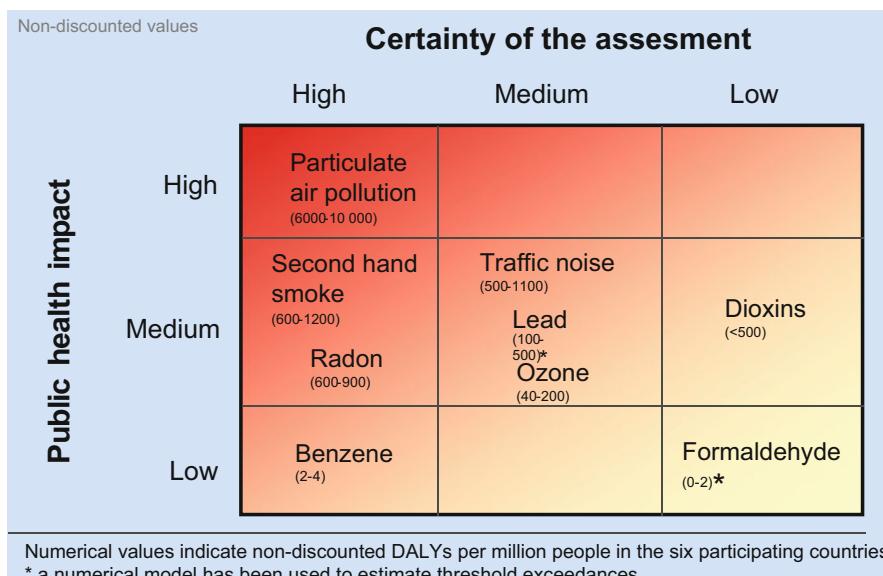

Fig. 5 Expert judgment estimates of relative uncertainty in the nine stressor estimates of environmental burden of disease in six European countries (Hänninen and Knol 2011)

formaldehyde. For the latter, even the types of endpoints and causality were considered uncertain.

The EBoDE estimates suggested that fine particles ($PM_{2.5}$) were the leading environmental health risk in European countries in 2010 by causing up to ten thousand non-discounted lost years of health per million people annually in the EU. The next most important public health impacts were associated with second-hand smoke and radon, both representing indoor exposures. The benzene estimate was also considered scientifically robust, but remained lower than 1% of the previous discussed stressors. Traffic noise, lead, and ozone estimates ranged from 40 to 1100 DALY/million, including relatively large uncertainties. The lowest certainties were warranted for dioxin and formaldehyde effects.

Indoor Specific Follow-Up in the HealthVent Study

While the earlier EBoDE study covered selected population exposures, it did not specifically consider indoor exposures. The EU-funded HealthVent project did that by adding physical exposure modelling related to infiltration of ambient air pollutants as part of building ventilation as well as estimates of indoor generated exposures to fine particles and volatile organic compounds. Further, mortality due to acute carbon monoxide poisoning and exposures to dampness and mold were added using register data and simplified yes/no exposure characterization,

respectively. Moreover, allergic reactions due to ambient bioaerosol exposures such as pollens was added by using expert judgment PAF.

While the EBoDE study covered only six selected countries, the HealthVent model was developed for 26 EU countries omitting only Malta of the member states at that time due to lack of national data from this small island state. On the other hand, while in EBoDE support from the World Health Organization made it possible to compare discounted and non-discounted approaches, in HealthVent, it was necessary to revert back to publicly available data sources, which meant that only discounted burden of disease models could be evaluated.

Stressor selection and indoor exposure modelling was conducted to exposures adjusted for their indoor air relevance:

- EBoDE pollutants included: ambient PM_{2.5}, radon, SHS
- Pollutants added to EBoDE: bioaerosols, CO, indoor generated PM_{2.5}, total VOCs
- Pollutants excluded: benzene, dioxins, formaldehyde, lead, ozone, traffic noise

The indoor and outdoor generated components of the indoor concentrations were derived using the single compartment, complete mixing, mass-balance model as suggested by Wilson et al. (2000) and applied later, e.g., by Hänninen et al. 2004, 2011, 2013 and Diapouli et al. 2013. Using the complete mass-balance equation (see Hänninen and Asikainen 2013, for more details):

$$\overline{C}_i = \frac{Pa}{a+k} \overline{C}_a + \frac{G}{V(a+k)} - \frac{\Delta C_i}{\Delta t(a+k)} \quad (12)$$

the ambient originated, i.e., infiltrated concentration was solved, after omitting the transient delta-component, as

$$C_{ai} = \frac{pa}{a+k} C_a = F_{INF} \times C_a \quad (13)$$

This equation was also used in ventilation scenarios, where the air exchange rate was adjusted. The simplified aerosol model parameters shown in Table 6 were used. Accordingly, the indoor generated concentration would then be

Table 6 Mass-balance parameters for the ambient air pollutants included in the model

Pollutant	Mass balance parameters				
	Dp(eff) μm	Penetration (P) [fraction]	Density g cm ⁻³	Decay (k) h ⁻¹	Finf [fraction]
PM _{2.5}	<2	90%	1.5	0.14	0.55
Pollen	10	80%	1.0	5.41	0.07
VOC	n/a	100%	n/a	0.10	0.69

Dp(eff) = effective particle diameter; Finf = resulting infiltration factor at a=0.22 h⁻¹; in the model the actual Finf values are calculated according to the used ventilation rates.

$$C_{ig} = \frac{G}{V} \times \frac{1}{(a \times k)} \quad (14)$$

but could also be calculated from the observed indoor concentration by subtracting the infiltrated component

$$C_{ig} = C_i - C_{ai} \quad (15)$$

Exposure-response relationship modelling and results

Fine particles, radon, and second-hand smoke were modelled using the same response models as in EBoDE. Also, dampness and mold estimates were calculated using the PAF approach, but the exposure indicator was merely a fraction of affected homes based on yes/no questionnaires. However, simplified exposure-response relationships were used for the remaining exposures. Carbon monoxide poisoning fatalities were obtained from national registers and WHO and a loss of 20 years was assumed for all cases. This approach may be an underestimation, certainly it is for children and teenagers. Pollen and VOC related allergies were estimated by expert judgment PAF values and concentration-ratio adjusted PAF, respectively.

In the baseline results, the main addition to the EBoDE outcome was the estimate for indoor generated fine particles, representing 16% of the disease burden of the included pollutants in 26 EU countries (Fig. 6). All HealthVent estimates were calculated using discounted values and thus, produced lower estimates for all significant sources of premature mortality, such as particles, carbon monoxide, radon, and second-hand smoke. Alternatively, for dampness and mold, bioaerosols, and VOCs the application of discounting played no significant role.

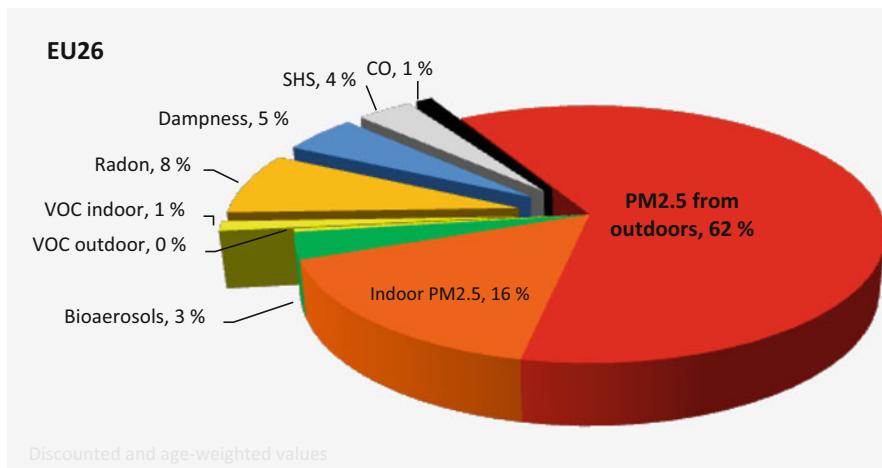

Fig. 6 Overall HealthVent results for the 26 EU countries in 2010. Total disease burden estimated at 2.1 million DALY (Hänninen and Asikainen 2013; Asikainen et al. 2016)

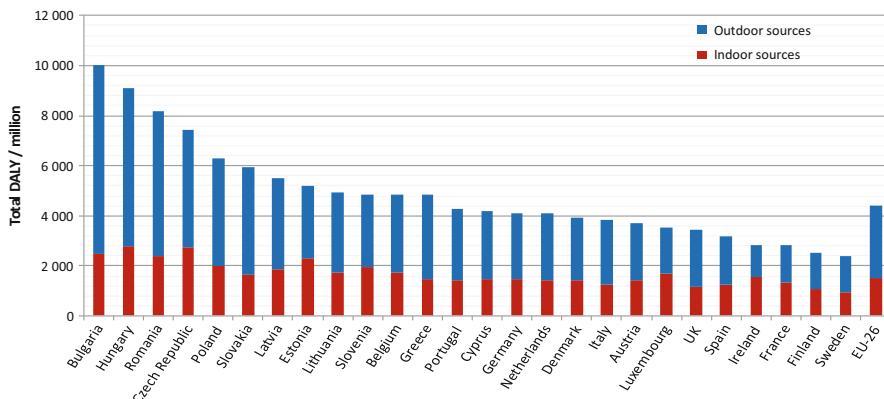

Fig. 7 National discounted disease burdens divided to indoor and outdoor source contributions (Hänninen and Asikainen 2013)

The HealthVent approach allowed to utilize high quality European Environmental Agency data for the population weighted ambient particle concentrations and thus comparing the disease burden of indoor and outdoor sources on national levels (Fig. 7). Differences between the indoor source burden are substantially more modest than the variability attributed to ambient component. Eastern European countries represented the worst ambient air quality in 2010.

Using estimates for Germany as an example, it can be shown that cardiovascular diseases are dominant, representing over 50% of the total burden (Fig. 8), followed by lung cancer, asthma, and COPD. Fine particles were the most significant exposures also in Germany in 2010.

HealthVent quantified the balance of indoor and outdoor air sources on the burden of disease for health optimization of ventilation rates as shown in Fig. 9. Interestingly the lowest burden occurs for ventilation rates of around 4 lps per person.

To date, HealthVent remains the only study that was able to conduct health impact assessment, i.e., calculate the quantitative health benefits that could be expected from implementation of defined ventilation guidelines. To support the development of European health-based ventilation guidelines, three scenarios were modelled (Fig. 10). Optimization of ventilation rates only or filtration of air intake only were less effective than targeted source control and optimized ventilation together.

The maximum reduction of the disease burden was almost 50%. Figure 11 shows the reduction potential of various diseases attributed to indoor (red) and outdoor (blue) sources. Cardiovascular diseases also dominated at the EU26 level. The largest reductions were projected for lung cancer from indoor sources and asthma from outdoor sources.

Indoor source concentrations of fine particles were estimated from relatively old EXPOLIS data, only available for four cities. While these cities (Athens, Basel, Prague, Helsinki) cover all the climatological regions of Europe, they do have limited geographical and national representativity, and thus, the exposure estimates

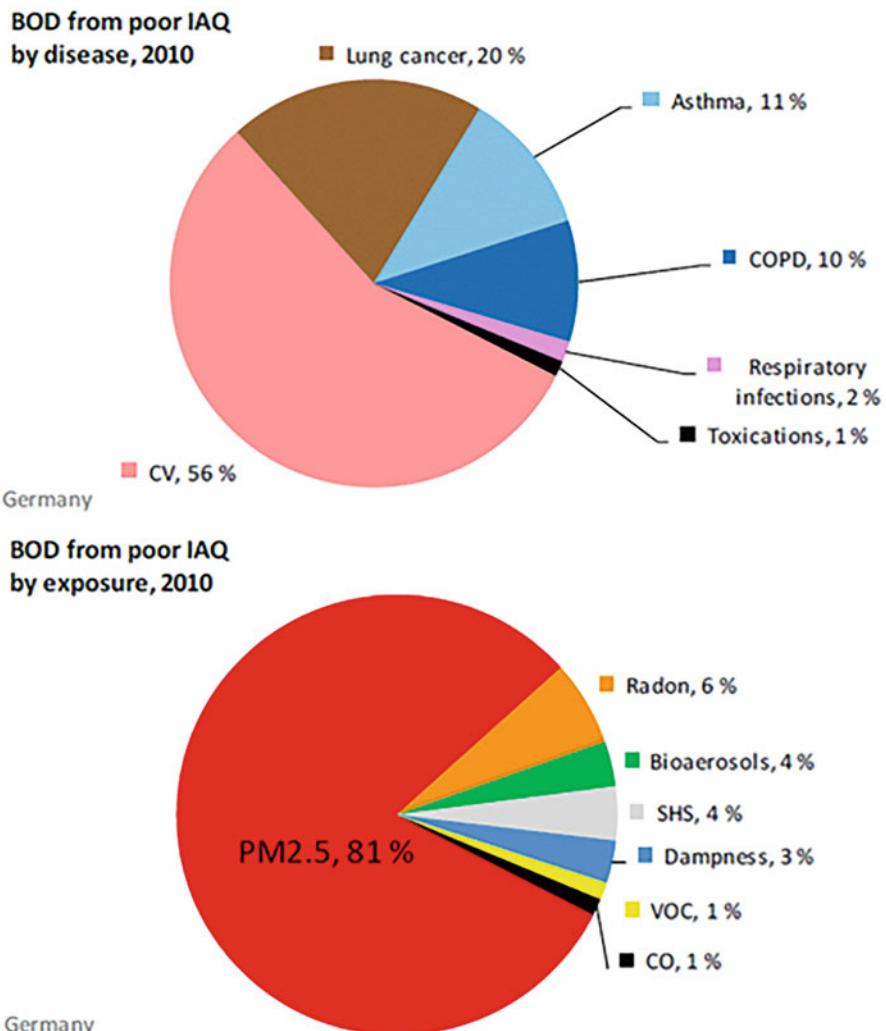

Fig. 8 Diseases attributed to indoor exposures in Germany in 2010 according to the HealthVent study (Hänninen and Asikainen 2013)

can be expected to be relatively uncertain. It remains a critical issue to update European estimates of population exposures to indoor generated particles as well as globally to consider methods to improve the corresponding concentration-response functions. Significant amounts of work have been conducted over the past decade for creating new models for ambient particles, but practically nothing has been proposed for the indoor generated ones.

The overall discounted health effect was substantially lower at 2.1 million DALY in EU26 (ca. 4200 DALY/million) than the non-discounted six-country estimates in

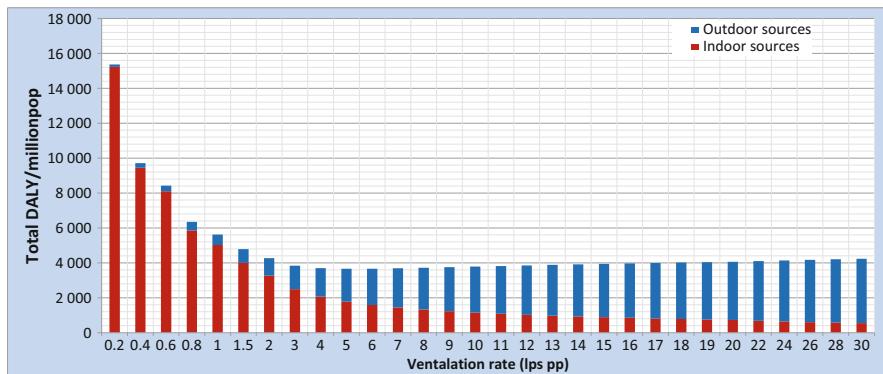

Fig. 9 Burden of diseases due to indoor air exposures as function of modified ventilation level. At low ventilation rates the indoor source contribution peak; as ventilation rate increases the indoor emissions are effectively diluted and the infiltration of ambient air pollution gradually increases (Hänninen and Asikainen 2013)

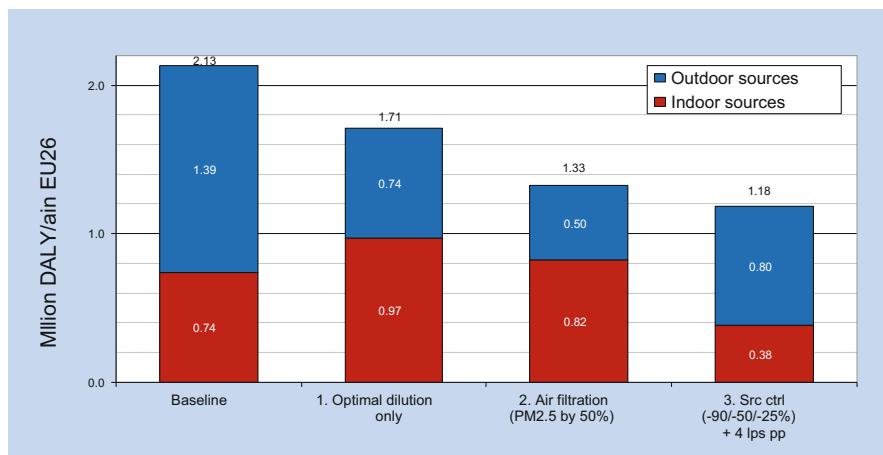

Fig. 10 Baseline burden was compared with three alternative reduction scenarios (Hänninen and Asikainen 2013; Carrer et al. 2018)

the EBoDE study (e.g., ca. 8000 DALY/million for ambient particles only), even though a relatively large component from indoor generated particles was added. Alternatively, traffic noise and other non-indoor pollution related exposures were excluded, but the main reasons for the reduction are that discounting was used, and the indoor exposure-related burden was calculated using the same exposure response relationship after accounting for the infiltration. Lack of personal exposure or even personal dose based health risk estimation remains a challenge.

The overall picture of the dominant role of fine particles was also confirmed in the HealthVent study. It was estimated that reduction of unnecessary ventilation could

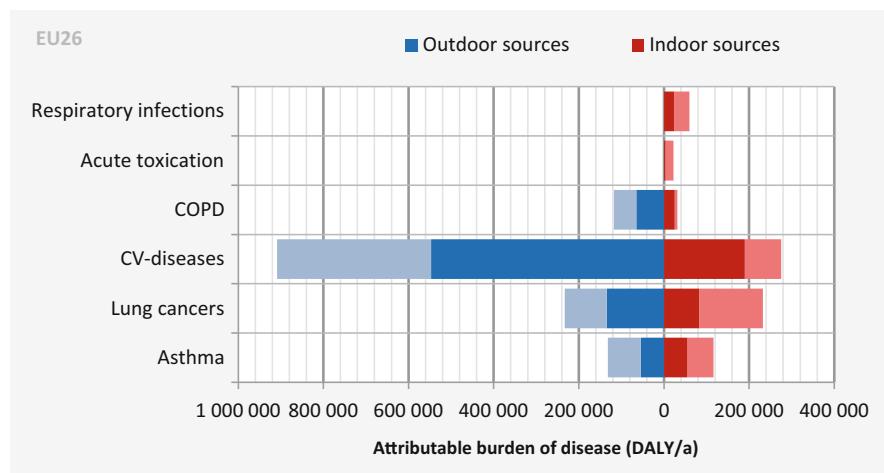

Fig. 11 Contribution of main disease categories to the burden of disease in EU26 caused by indoor air exposures to pollutants originating from outdoor (blue) and indoor (red) air (Hänninen and Asikainen 2013). The estimated maximum reduction is shown in the lighter shade by disease category. (COPD = chronic obstructive pulmonary disease, CV = cardiovascular diseases) (Hänninen and Asikainen 2013)

reduce disease burden by 15% and filtration of ambient intake air up to 30%, but most efficient controls involved a combination of indoor source control with optimized ventilation, allowing the annual saving of ca. 0.9 million DALYs in EU.

Indoor Air Pollution and Associated Socio-economic Costs in France

In 2001, the French government set in place a permanent research program on indoor air quality called the French Indoor Air Quality Observatory. Over time, with increasing knowledge on indoor pollution, i.e., increasing number of pollutants to be considered and rising evidence of health effects, it appeared necessary to the policymakers supporting the IAQ Observatory to have quantitative values expressing the impact of this environmental pollution at the national scale. Such evaluations of the socio-economic costs are useful to hierarchize the public health priorities and facilitate the development of appropriate policies. In 2014, the health impacts in terms of mortality and morbidity, as well as the economic impact, associated with indoor air pollution in France were assessed (Boulanger et al. 2017).

Pollutants Considered for the Evaluation

The target pollutants were selected based on: (i) existing data already documenting the health impact, i.e., attributable diseases and deaths, for the population in France, (ii) published dose-response relationships, and (iii) existing data on exposure in indoor environments at the national scale allowing for health impact calculations to be performed as needed.

Benzene, trichloroethylene, radon, carbon monoxide (CO), fine particles ($PM_{2.5}$), and second-hand smoke (SHS) were included:

- Annual deaths due to exposure to radon were already available (Catelinois et al. 2007)
- Mortality and hospitalization due to CO poisoning are monitored every year by the French Institute for Public Health Surveillance
- Number of deaths per year due to passive smoking was available (ERS 2006)
- For benzene, trichloroethylene, and $PM_{2.5}$, it was possible to calculate the yearly mortality associated with indoor exposure because both dose-response relationships and indoor concentrations in French dwellings were available.

Evaluation of Yearly Mortality

When not already available, i.e., for benzene, trichloroethylene, and $PM_{2.5}$, the yearly mortality was calculated through two approaches depending on the nature of the available data. The first method follows the principles of quantitative health risk assessment based on the NRC (1983) method, and the second is based on concepts and methods relating to the health impact assessment approach. For both of these approaches, toxicological data and indoor concentrations related to each target pollutant were needed:

- Toxicological data were retrieved from existing reviews and monographs. The health endpoints of each target pollutant are presented in Table 7;
- Indoor concentrations were those measured in dwellings at the national scale by the French Indoor Air Quality Observatory (Langer et al. 2016). Since the measurements were conducted between 2003 and 2005, the reference year for this evaluation was set at 2004. In the absence of monitoring surveys in other indoor environments in France at the time of the evaluation, the concentrations measured in the housing stock were considered to represent the indoor air concentrations in all indoor environments. The median indoor concentrations were considered to be the exposure concentration of the whole population for the target pollutants. The time spent indoors by the French population was considered to constitute 90% of the lifetime.

The excess collective risk resulting from benzene and trichloroethylene indoor exposure, respectively, was calculated based on the principles of quantitative health

Table 7 Summary of health endpoints considered for the six target pollutants

Radon	Second-hand smoke	Carbon monoxide	Benzene	Trichloroethylene	$PM_{2.5}$
Lung cancer	Lung cancer Heart attack Stroke COPD	Asphyxia	Leukemia	Kidney cancer	Lung cancer Cardiovascular disease COPD

COPD: Chronic Obstructive Pulmonary Disease

risk assessment, using Eq. (7) introduced in the Methods section of this chapter. The unit risk proposed by WHO (2000) for acute leukemia associated with benzene exposure through inhalation was used. For trichloroethylene, the inhalation unit risk proposed by the USSG (2006) for kidney cancer was used. PM_{2.5} health impacts were determined based on Eq. (10). To avoid any double counting since the impact of second-hand smoke, which includes particles emitted through smoking, is evaluated separately, the median concentration of PM_{2.5} was the one measured in non-smoker dwellings. The background concentration was the 5th percentile of the PM_{2.5} concentration distribution in non-smoker dwellings. The RR used were derived from Pope et al. (2002, 2004).

For each disease, the difference between the average age of death and the life expectancy of the general population, considered to be 80 years of age, was needed to determine the number of life-years lost. The average age of death for each studied disease was obtained from the French Center for Epidemiology on Medical Causes of Death.

The number of deaths of each disease in the reference year (2004) and the number of life-years lost used to calculate the external cost of mortality are presented in Table 8. For the target pollutants, indoor air pollution was estimated to be annually associated with about 20,000 deaths in France.

Evaluation of Yearly Morbidity

When not already available, the morbidity of each studied health effect, i.e., the new cases of the disease attributed to the indoor exposure, was estimated from the

Table 8 Estimates of the yearly health impacts associated with indoor exposure to each of the six target pollutants and external costs in France

	Radon	Second-hand smoke	Carbon monoxide	Benzene	Trichloroethylene	PM _{2.5}
Cases per year in France (2004)						
Number of deaths (n _d)	2,074	1,114	98	342	15	16,236
Number of life-years lost per death	11	15	47	15	15	15
Number of new cases (n _c)	2,388	2,836	—	385	41	22,784
Number of life-years with the disease per case	1.5	37.5	—	15	1.5	26.5
Costs (M€, 2004)						
Costs of premature deaths	2,089	322	237	453	19.6	5,760
Costs due to loss of life quality	309	837	0	383	6.7	7,350
Costs due to loss of productivity	282	85	72	38	1.5	1,102
Total external costs	2,680	1,244	309	874	27.8	14,212

mortality/morbidity ratio for this disease multiplied by the calculated (or available) mortality rate of the French population for the given disease. The mortality/morbidity ratio was obtained using data provided by the National Institute for Cancer, the French Ministry of Health and the French Institute for Public Health Surveillance. Moreover, the number of life-years with each studied disease was needed: data provided by the National Institute for Cancer and by WHO on the survival times for each studied disease were used.

The number of new cases of each disease in the reference year (2004) and the number of life-years with the disease used to calculate the external cost of morbidity are reported in Table 8. For the target pollutants, indoor air pollution was estimated to be annually associated with about 28,000 new cases of a disease in France.

Socio-economic Cost Evaluation

The socio-economic impacts of indoor air pollution were defined as the monetary value of the negative consequences of indoor air pollution, i.e., the quantity of resources lost by society as a result of exposure to this pollution. Since the objective was to assess the socio-economic costs to society, only public costs were calculated; costs supported by private companies or by individuals were not assessed. In this context, there are two types of socio-economic costs to be considered: external costs and impacts on public finances, whose respective calculation is described hereafter.

From an economic perspective, indoor air pollution is a negative externality, i.e., a consequence whereby no monetary compensation is initially planned, leading to external costs. To calculate these costs, the value of a statistical life year (VOLY) is needed. The VOLY is derived from the value of a statistical life (VSL). Different methods exist to assess the VSL, among them the “willingness to pay” approach. In France, following this approach, a VSL was set for all the socio-economic analyses and the VOLY was estimated to €115,000. Since the costs are increasing in the future relative to the reference year, an adjustment rate of 4% per year was applied in the calculations. For each pollutant and each disease associated with indoor exposure to this pollutant, the number of life years lost between the average age at death and the life expectancy was multiplied by the adjusted value of life year to calculate the total cost due to the premature deaths according to Eq. (16).

$$\text{External cost of premature deaths} = n_d \times \sum_i \frac{\text{VOLY}}{(1+r)^i} \quad (16)$$

where, n_d = number of premature deaths associated with a disease generated by one pollutant, VOLY = value of a statistical life year, €115,000, r = adjustment rate, 4%, and i = number of life – years lost because of the disease.

The external costs also include the costs associated with morbidity, i.e., quality of life loss and productivity loss. The socio-economic costs in terms of the loss of quality of life were derived from the calculated morbidity value and from the average disability weight defined by WHO for each disease. Similar to the costs of mortality, quality of life costs were adjusted over the number of years of life with a given disease prior to death, with the adjustment rate of 4% per year. Each adjusted cost

was then multiplied by the number of new cases for each disease associated with indoor exposure to a studied pollutant to obtain the total cost of quality of life loss for each disease according to Eq. (17).

$$\text{External cost of loss of quality of life} = n_c \times \sum_j \frac{\delta \times VOLY}{(1+r)^j} \quad (17)$$

where n_c = number of new cases associated with a disease generated by one pollutant, δ = loss of quality of life, i.e., average disability weight defined by the WHO for the disease, $VOLY$ = value of a statistical life year, €115,000, r = adjustment rate, 4%, j = number of years of life with a given disease prior to death.

Finally, to estimate production loss, the “discounted income stream” approach, proposed by the National Institute for Cancer, was used to assess the production value that an individual would have generated if he had not died from cancer or another disease.

Regarding public finances (i.e., the second type of costs to be considered), indoor air pollution involves expenses that are supported by public finances. First, the different diseases associated with indoor air pollution generate a demand for healthcare which represents a cost to public finances. Second, to reduce indoor air pollution, the State invests in public research. Lastly, when deaths occur between age 60, i.e., the start of retirement, and 80, the life expectancy, savings resulting from the non-payment of full or partial retirement pensions were calculated. The average annual retirement pension value in 2004 (€15,000) was adjusted by 4% over the number of years of retirement lost.

The external costs per pollutant and disease are reported in Table 8. Overall, the external costs were estimated to M€19,347 in the reference year (2004). Besides, the costs for public finances in the reference year were estimated to M€96. In total, for the target pollutants, indoor air pollution was estimated to cost M€19,443 in France in 2004.

The external costs represent nearly all of the total cost, and the impacts on public finances represent less than 1% of the total cost. Overall, mortality and morbidity have the same effect, i.e., 46% of the external costs. However, it varies depending on the pollutant. Particles contribute the most to the total cost (approximately €14 billion). Radon also has a significant health cost (€2.68 billion). The pollutants’ relative contributions to costs are ranked as follows: particles > radon > SHS > benzene > carbon monoxide > trichloroethylene.

Limitations and Conclusions

The limitations of this evaluation include the limited number of indoor pollutants, due to lack of dose-response relationships and/or to indoor exposures that are not comprehensively characterized in France compared, e.g., to China, as described in the next section. The indoor concentrations measured in dwellings were extrapolated to other indoor environments. The health effects identified for a given pollutant were not exhaustive. Moreover, health effects associated with exposure to mixtures of pollutants were not assessed. The health impact estimation method used was based

on quantitative health risk assessment and health impact calculation principles. Other approaches exist, such as the ones described in the other sections of this chapter based on the DALY. There are uncertainties regarding the average age at death or the ratio of morbidity to mortality. From an economic point of view, the valuation of €115,000 per year of life lost is debatable. The discount rate was considered to be the same regardless of the time horizon or the severity of the disease.

Despite these limitations, such an evaluation provides an order of magnitude of the impact of indoor air pollution and confirms that it is imperative for researchers and policymakers to continue addressing indoor air quality issues. Moreover, such figures can now serve as a baseline for cost-benefit analyses on possible strategies used to reduce indoor air pollution, with the objective to identify the most efficient strategy.

Disease Burden of Indoor Air Pollutants in China

To comprehensively have a good knowledge of health impacts of indoor air pollutants (IAPs) in different kinds of buildings in China, the Burden of Disease for Indoor Air Pollutants (IAP-BD) study was launched in China, using the updated methods from the GBD study (Murray et al., 2012) and studies for burden of diseases due to indoor pollutants in other countries or regions (Hänninen et al. 2014, Logue et al. 2012).

Indoor Exposure Assessment

The list of dominant indoor air pollutants in China was summarized based on the national standards for indoor air quality GB/T 18883 (National Health Commission of China 2002), WHO air quality guideline (WHO 2006, 2010), and the study on cancer risk of IAPs in China (Du et al. 2014). Additionally, several rounds of seminars were held and experts from multidisciplinary backgrounds provided advice on this list. The final list of IAPs in China in this study contained five types of pollutants, particulate matters, inorganic chemical pollutants, volatile organic compounds (VOCs), semi-volatile organic compounds (SVOCs), and microbial pollutants, and 31 IAPs in total.

For PM_{2.5}, SO₂, NO₂, and O₃, that predominantly come from outdoors, the infiltration factor method (Hu et al. 2020; Xiang et al. 2019) was applied to estimate the indoor exposure concentrations. For the other 27 indoor air pollutants that come primarily from indoor sources, systematic reviews were conducted to summarize and estimate the concentration distributions of these indoor air pollutants in China. (Zhang et al. 2021; Guo et al. 2020; Sun et al. 2021; Su et al. 2021) After the data collection, the Monte Carlo method was employed to estimate the concentration distributions of these 27 IAPs in China (Bu et al. 2019). Finally, the concentration distributions of each IAP across China were generated for residences, offices, and schools, weighted by population of all provinces in China. To differentiate the exposure concentrations of these IAPs in adults and children, the average concentration distributions were calculated for adults weighted by the time allocation in

residences and offices, and for children weighted by the time spent in residences and schools.

The PM_{2.5} concentrations and related inorganic chemical pollutants in China are shown in Fig. 12. The concentrations of nine kinds of VOCs are shown in Fig. 13. Additionally, Fig. 14 summarized the exposure values of microbial pollutants and dust-phase SVOCs in China. Clearly, most of the IAPs in China had higher concentrations than those in Europe and USA.

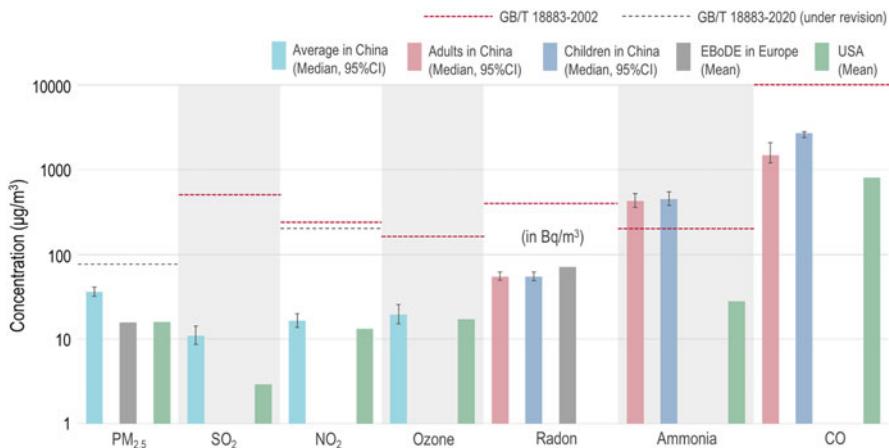

Fig. 12 The concentration of PM_{2.5} and inorganic chemical pollutants in China, Europe and USA. The colorful bar represents the point estimate, and the line represents the 95% confidence interval

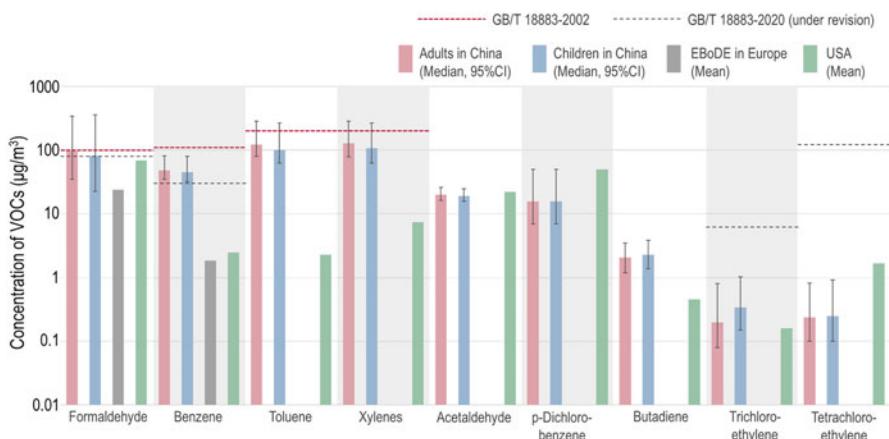

Fig. 13 The concentration of VOCs in China, Europe and USA. The column bars represent the point estimates, and the error bars the 95% confidence interval. Xylenes include m-, p-, o-xylenes

Fig. 14 The concentration of microbial pollutants and dust-phase SVOCs in China, Europe and USA. The column bars represent the point estimates, and the error bars the 95% confidence interval. In the 13 SVOCs, the first 5 pollutants belong to phthalates and the latter 8 pollutants belong to PAHs

Associations Between IAPs and Health Outcomes

For PM_{2.5}, the integrated exposure-response (IER) model was directly applied to describe the associations between the PM_{2.5} concentration and several health outcomes. (Burnett et al. 2014) For other indoor air pollutants, systematic reviews were conducted to summarize available concentration-response (C-R) relationships for various health outcomes from epidemiological studies. Finally, the information on location, year, sample size, study type, effect size, and exposure concentrations were collected from eligible studies for the meta-analysis. The results of the meta-analysis have been shown in Figs. 15, 16, and 17.

Disease Burden Attributable to Indoor Air Pollutants in China

Using concentrations and associations between IAPs and health outcomes, the disease burden attributable to IAPs can be estimated according to the PAF method mentioned in the section of methods above. In this section, only significant C-R relationships between IAPs and outcomes (underlined in Figs. 15, 16, and 17) were included. The insignificant C-R relationships were excluded in this analysis, such as the relationship between benzene and asthma, which required further evidence. When the concentration was higher than the maximum reported in the available epidemiological studies, the RR was assumed to behave as a horizontal level instead of a simple nonlinear extrapolation by the equation in the methods section.

Estimation of IAP-BD in China

The total DALY rate due to exposure to indoor air pollutants in China was ca. 33,000 per million, accounting for 12.5% of total DALY rate that rose to 263,000 per million in 2017 in China. (GBD 2021c) Among all the selected indoor air pollutants, PM_{2.5}, benzene, NO₂, butadiene, and ozone ranked in the top five DALY losses, all of which were all over 1000 per million (Fig. 18). In particular, PM_{2.5} led to 17,600 DALY

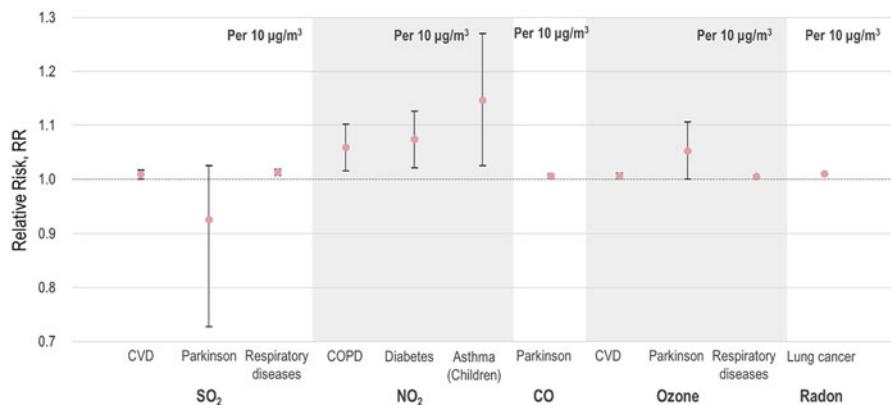

Fig. 15 The associations between health outcomes and inorganic chemical pollutants through meta-analysis (relative risk and 95% confidence interval)

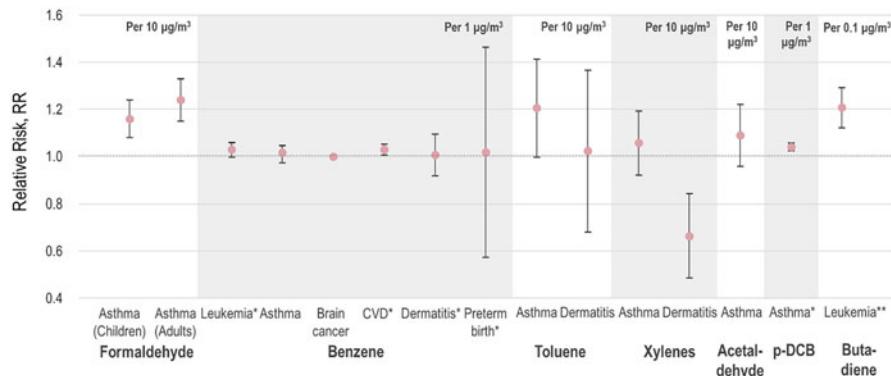

Fig. 16 The associations between health outcomes and VOCs through meta-analysis (relative risk and 95% confidence interval)

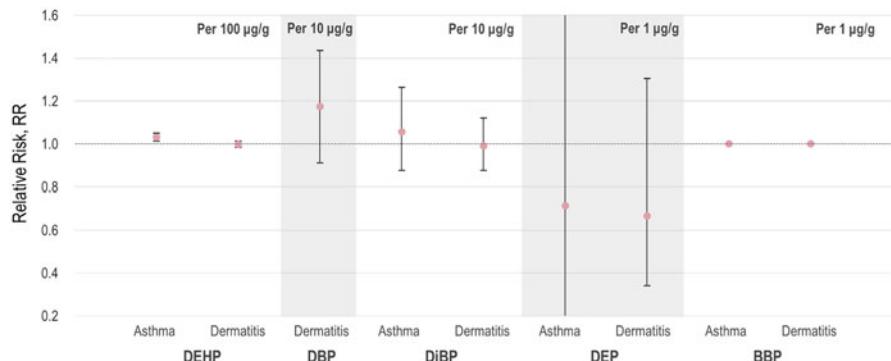

Fig. 17 The associations between health outcomes and SVOCs through meta-analysis (relative risk and 95% confidence interval)

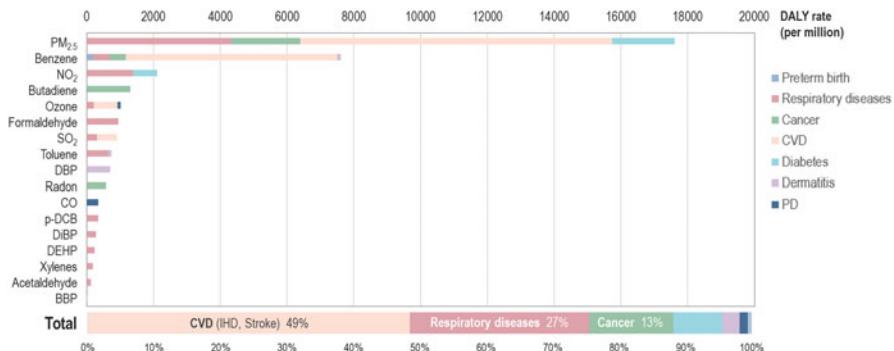

Fig. 18 The composition of DALY rate attributable to indoor air pollutants in China according to various health outcomes

losses per million, approximately 50% of the disease burden due to all indoor air pollutants. Additionally, butadiene exposure (1300 DALY losses per million) has not been considered in the related standard but ranked 4th, suggesting to requires greater attention given its importance. The other three pollutants, benzene, NO₂, and ozone, were controlled by the current national standard in China, but still contributed to over 30% of attributable DALY losses, suggesting that the standards in the future should be tightened to decrease the disease burden of these three IAPs. Formaldehyde, which ranked 6th, produced nearly the same disease burden as ozone, so formaldehyde is also worth focusing on. From the perspective of the type of IAPs, the disease burden of IAPs other than PM_{2.5} accounted for nearly 50% but had been previously neglected. Additionally, many VOCs and SVOCs did not have sufficient evidence to support associations with various health outcomes, suggesting that they may cause more disease burden in reality than the estimation in this study. All these results imply that the health effects caused by VOCs and SVOCs have to be the focal point in future studies. From Fig. 18, it can be also seen that cardiovascular diseases, COPD, respiratory diseases, lung cancer, and diabetes accounted for the majority ($\approx 90\%$) in the DALY losses attributable to IAPs. The largest proportion of disease burden owing to IAP exposure was concerned with cardiovascular diseases (including ischemic heart disease and stroke), which accounted for nearly 52%, followed by COPD.

Comparison of IAP-BD Among Countries

As previously mentioned, the concentrations of many indoor air pollutants in China were higher than those in Europe and USA, thus inducing higher disease burdens attributable to IAPs (Hänninen et al. 2014; Logue et al. 2012). To ensure fair and valid comparisons, the disease burden of IAPs in Europe and USA was estimated by combining the concentrations reported in the study of six European countries and USA (Hänninen et al. 2014; Logue et al. 2012) and the C-R relationship summarized in this study. The IAP-BD in China (32,900 DALY losses per million) is significantly

Fig. 19 The ranking of indoor air pollutants according to attributable disease burden in China, Europe (EBoDE, 6 countries), and USA

higher than that in USA (24,500 DALY losses per million), followed by the six European countries. The IAP-BD in the Netherlands was the smallest, only 16,300 DALY losses per million, nearly half of that in China. From the view of the proportion of IAP-BD, China also ranked the highest, where the IAP-BD reached 12.5% of the total DALY losses in 2017. Instead, the IAP-BD in European countries and USA ranged from 5.8% to 7.9%, suggesting that it is essential to address the problems of indoor air pollution in China in the near-term future. The ranking of IAPs in different regions is shown in Fig. 19. PM_{2.5} ranked first in China, Europe, and the USA according to attributable DALY losses, accounting for over 50% of the IAP-BD. Benzene, NO₂, and formaldehyde all ranked in the top of the lists in these countries, each of which contributed nearly or even more than 1000 DALY losses per million.

Limitations and Future Study

This IAP-BD study in China has some limitations. Considering the IAP concentrations, the precision of the exposure parameters and concentrations depends on the original field studies from which it is difficult to assess the accuracy of these original data from small-size samples. From 2000 to 2017, the concentrations of some IAPs may change a lot, but this issue has not yet been accounted for in this study. Similarly, as the first estimation in China, we have not considered the province-level IAP concentrations given the lack of field measurement data. Further studies can organize the field measurement of IAP concentrations in different provinces across China during each year to acquire more reliable concentration data. Considering the health effects of IAPs other than PM_{2.5}, many available associations between IAP exposure and health outcomes are primarily based on case-control studies or cross-sectional studies due to the lack of cohort study in this field, and are insignificant after meta-analysis. Therefore, the evidence is insufficient to support causal relationships between IAP exposure and these diseases. Moreover, currently available C-R relationships in the epidemiological literature have not taken the co-exposure of multiple IAPs (especially from similar pollution sources) into consideration. Further studies can focus on cohort studies of large Chinese populations exposed to multiple IAPs to obtain the reliable and accurate C-R relationships between IAP concentrations and various health outcomes.

Discussion

The burden of disease methods allow for comparability of largely differing health outcomes for prioritization of risk mitigation. Risk assessment is a critical input toward quantifying the reduction potential of health losses. The risk assessment paradigm introduced risk characterization, and finally, the burden of disease approach allows for comparative quantification of attributable fractions. Health impact assessment by definition attempts to look at non-health sector policies and their impact on health, which must be implemented via complex exposure and exposure-change analyses.

In practice the current burden of disease estimates are quite clearly dominated by the years of life lost (YLL) component while the morbidity (YLD) remains less important in quantitative terms. Partly the YLL dominance originate from the handling of life expectancy: the current approaches use life-table projections for 2050 of the healthiest populations globally, leading to life expectancies that clearly exceed most actual national values. Thus, the calculated YLL component also accounts for the expected improvements in life expectancies over the coming decades. On the other hand, the morbidity component is the one that affects productivity, academic performance, lost working and school days, and general wellbeing of the populations. It may be important to consider these factors separately for better visibility.

Risk estimates contain many uncertainties including population representativeness, measurement errors, modelling errors, statistical uncertainties in exposures, and exposure-response relationships. The risk assessment community is continuously improving the assessment of uncertainties and the epidemiological parameters routinely come with confidence intervals. Alternatively, air quality modelers and exposure scientists do not regularly provide confidence intervals for their estimates. It remains on the responsibility of the risk assessors then to combine these sources of uncertainties using statistical and probabilistic techniques.

The GBD studies are looking at the richest set of risk factors, including 87 components or groups. Still, they can only attribute half or less of the national burden on these factors. It remains an open but important question: From where does the remaining half of the disease burden come?

Millions of chemicals are produced worldwide by industries, combustion processes and other anthropogenic and natural sources. While toxicological data suggests much larger relevance, currently the EBD/BOD methods account for a very small fraction of all chemicals and their environmental degradation products. It may be that there are many missing pollutants that would warrant to be added into the assessments. While writing this text in early 2022, the continuing global COVID-19 pandemic demonstrates also the importance of infectious agents that are not covered here. However, their contribution to burden of disease as well as the importance of time-use in indoor spaces and role of ventilation is high.

Summary

The environmental burden of disease provides a useful quantitative indicator of the population level health impacts of environmental factors, including chemical pollutants and noise. It allows quantitative comparisons of public health impacts associated with a wide range of environmental risk factors and targeting research and especially risk management to the major issues.

Environmental burden of disease methods have been successfully applied to a number of indoor air settings in Europe, North America, and China, although a number of challenges remain. Especially exposure assessment is substantially more complicated for indoor spaces than for ambient air, but also the number of pollutants found in indoor spaces is large and suitable health response models are not yet available for many of them.

The environmental burden of disease cannot directly be interpreted as a reducible burden. In many cases, exposures to natural sources of pollution or the existence of overlapping risk factors lead to the fact that exposures cannot be completely eliminated. Examples of such factors are, e.g., atmospheric particles and radon, both originating also from natural sources.

Further analysis may also be applicable for the cost effectiveness of various risk management actions. In some cases, reduction in exposures may require complex and potentially expensive legislative changes, e.g., removing lead from fuels, water pipes, canned foods, paints, and so on, over the past decades. Currently, similar challenges are being experienced, e.g., controlling exposure to fine particles, which also present widely and have very heterogeneous sources. Combining environmental burden of disease estimates with cost-effectiveness methodologies allows societies to target their environmental control efforts as efficiently as possible.

Acknowledgments This text is based, among other cited sources, on work and materials produced in the EBoDE project (by intramural funding by the participating institutes); HEALTHVENT project (by EU Health Programme Grant Nr. 2009 12 08.). Indoor exposure dependency on aerosol sizes was developed in TRANSPHORM (by EU FP7) and PMSIZEX (by Academy of Finland). Parallel work on health risk assessment was supported by the COST Action IS1408. Collaborators in these projects are warmly thanked for their intellectual contributions. The French study was supported by the French Agency for Food, Environmental and Occupational Health and Safety (Anses; Grant n°CRD-2011-11) and the French Indoor Air Quality Observatory.

Abstract

This chapter sets out a rationale and some detailed recommendations for selecting the most efficient metrics and methods for applied research on how any factor that determines Indoor Environmental Quality (IEQ) – such as Indoor Air Quality (IAQ) – affects building occupants, with the specific purpose of obtaining a scientific basis for the economic and engineering decisions that must be made when constructing and operating buildings. These are decisions that affect a building's first cost, operating cost, energy-efficiency, environmental impact, and sustainability. The expense of meeting the goals in each of these areas must be justified in terms of how IEQ will affect the occupants of the building in terms of their health, comfort, and performance. There may be costs and benefits in each of these areas, and the IEQ effects on them must be quantified if they are to be used in cost-benefit analyses to justify the above expenses. The metrics and measures and the research strategy discussed in this chapter can be used for this applied purpose, to assess the effects of any environmental factor in the indoor environment, including those determining thermal conditions, air quality, acoustic conditions, and lighting.

Keywords

Cognitive performance · IEQ · IAQ · Research strategy · Metrics · Methods

Introduction

A great deal of published IEQ research cannot be used to justify costs and was not intended to be so used because it was motivated by a search for basic knowledge, such as how individuals differ, or the nature of the causative pathways by which IEQ affects occupants. These areas of IEQ research are outside the scope of the present chapter, because buildings and their heating, cooling, and ventilation systems are usually designed and operated for occupants as a group, with no knowledge of the requirements of the individual or of the mechanisms by which IEQ affects different individuals differently. In those few buildings where some control of local IEQ is delegated to the individual occupant's workstation, occupants must still endure the general conditions when they are elsewhere in the building and the control that is provided at each workplace averages out and has only a peripheral effect on energy use.

It is important to realize that all of the costs of constructing and operating a building, and even the cost of eventually demolishing and disposing of it, must be covered by the value added by the activities of its occupants. Not by the benefits the building provides for their health and comfort, as safeguarding these outcome variables often involves additional costs, but by the added value of what they do in the building. This comes down to their cognitive performance, as very little physical work is performed in modern buildings. In school and university buildings, the

added value will occur in the future when the students perform work in other buildings and perform it better as a consequence of the learning that took place at school and university, and learning requires effective cognitive performance. In buildings that house dwellings, the added value is that the rest and recuperation that a dwelling provides can improve productivity at work, for example, if bedroom IAQ affects sleep quality and through this, next-day performance, improving bedroom IAQ adds value. In buildings that house workplaces, such as offices, factories, workshops, and commercial premises, the added value is the improved productivity that good workplace IEQ can promote by ensuring effective cognitive performance. To assess how IEQ affects added value, research must therefore use methods and metrics that quantify how IEQ affects cognitive performance. It is worth noting here that the bottom line is determined by group average workplace productivity and that individual differences determine its variance but not its mean value. It is thus the size of group average effects that must be experimentally determined for use in cost-benefit analyses.

This chapter discusses in general terms the research strategy that should be used to assess IEQ effects on occupants. It is not a review of the literature, because an exhaustive review of such a general field would be far too long for a handbook chapter. However, a small number of published research reports are cited as examples to support some of the conclusions and recommendations.

The Metrics That Might Predict Productivity

The overall goal of applied IEQ research is to identify, reduce, and preferably eliminate all negative effects on metrics that characterize health, comfort, and cognitive performance, but they are not all equally able to predict and quantify IEQ effects on added value in terms of productivity improvements.

Health

Buildings provide shelter from the outdoor environment that safeguards the health of the occupants – shelter from excessive heat or cold and from wind and rain, and shade to eliminate the health risks of direct solar radiation. Preventing any residual negative effects on health is therefore the first priority of all IEQ research. If IEQ factors increase the risk of accidents or illnesses that cause absence from study or work, they clearly reduce productivity and the added value that good IEQ promotes. Real-world cross-sectional surveys can be conducted to identify such risks, and field-intervention experiments can even be used to demonstrate them, although it would be unethical to prolong the exposure of control groups to unimproved conditions solely for that purpose. Where no such risks have been demonstrated, negative IEQ effects on health can usually be avoided by ensuring that neither comfort nor performance is negatively affected, because these two categories of outcome variable are almost always more sensitive to IEQ than are health metrics.

Comfort

Buildings are constructed and operated to facilitate and promote the human activities they contain and achieving comfort is a secondary goal, basically because comfort can be achieved elsewhere. It should not be assumed without proof that the cognitive performance of occupants who do not complain of discomfort is optimal, because subjective comfort can often be preserved at the expense of performance – by working more slowly or by taking longer breaks from work, for example. This is especially true for thermal comfort under conditions warmer than group average neutrality, because the level of concentration required for efficient performance of cognitive tasks may result in postural changes (sitting up straight, leaning forward, etc.) and the involuntary tensing of opposing muscle groups that is associated with a higher level of activation, causing an increase in metabolic rate that contributes additionally to heat stress. There are several demonstrations in the literature that subjective thermal comfort does not necessarily lead to optimal performance, for example, Pepler and Warner (1968) as reinterpreted by Wyon (1970), Lan et al. (2020, 2021). Further demonstrations of this truism are clearly required to validate or correct the increasingly widespread tendency to equate thermal and other kinds of comfort with optimal performance.

Self-Estimated Productivity

Self-estimated productivity, in some publications also termed “IEQ productivity belief,” co-varies with other subjective estimates such as thermal, acoustic, and visual comfort, due to the “environmental halo effect” discussed in a later section of this chapter. While comfort ratings are personal and cannot be either disputed or validated, self-estimated productivity can and should be validated against measured productivity. In the few instances where this has been done, it has been found to provide very unreliable predictions, differing by up to 30% from objectively measured productivity (Kroner et al. 1992; Wargocki et al. 2000; Haneda et al. 2009; Lan et al. 2021) because what subjects are able to report is how hard they are working, and working hard is not the same as working efficiently. Under conditions that make it possible to work efficiently, it is possible to work well without the feeling that one is working hard. Self-estimated productivity can therefore be a very misleading outcome variable. There is no substitute for using measured task performance as the dependent variable in experiments whose purpose is to promote productivity by optimizing IEQ, because while improving subjective comfort and reducing subjective symptom intensity are valid and useful goals in themselves, these changes do not guarantee improved performance or productivity.

Component Skills

Real work always consists of performing a complex sequence of subtasks, which may each be differently affected by the working environment, obscuring any overall

effect. Simulated work can be used to examine the effects of the environment on the performance of each separate subtask, such as text typing, proofreading, mathematical calculation, logical thinking, and creative thinking, each of which requires the exercise of a different “component skill.” These tasks can be presented on paper, if this is appropriately realistic, or on a computer screen, in which case both remote presentation over the internet and automated analysis of performance is possible (Toftum et al. 2005). As all of these subtasks are involved in the performance of real office work, environmental effects on any one of them may become the metric on which the limiting criterion for a particular parameter of the working environment is set. While it would be valuable to determine which subtasks are critical in a given workplace, this has not yet been attempted and would not necessarily apply to all workplaces.

Field Validation

However realistic the IEQ simulation, experiments in which paid volunteers perform simulated work differ from real workplaces in terms of motivation, recruitment, and the consequences of poor performance, so their ability to predict productivity in the real world must be validated. It might be thought that they are more sensitive to changes in IEQ metrics, but in the case of both educational and office workplaces it has been found that they are less sensitive, probably because volunteer subjects are able to maintain a higher level of motivation and effort throughout the necessarily short duration of experimental exposures than is normal in the routine performance of daily work. End-of-year examination results as a function of classroom ventilation rates have been shown to be successfully predicted from laboratory exposures in which IAQ effects on tasks typical of school-work were quantified (e.g., Haverinen-Shaughnessy and Shaughnessy 2015), and talk-time at call centers has been successfully predicted from laboratory experiments in which IAQ effects on tasks typical of office work were quantified (e.g., Tham et al. 2003; Wargocki et al. 2004). Both of these outcome metrics are close to being “bottom-line” metrics of productivity – the learning that takes place in schools is assessed in terms of examination results, and call-center operators interact with their computer software to answer the enquiries of callers in what amounts to a paradigm of office work. More learning would be required to improve examination results, and more call-center operators would have to be employed if poor IEQ increased talk-time. Kroner et al. (1992 op. cit.) successfully used the time to resolution of insurance claims as a metric of the productivity of claims assessors over several weeks or months, and not only validated the extent to which individual control of thermal conditions at the workplace would improve productivity, as shown by Wyon (1996b), but also that self-estimated productivity failed completely to predict the loss of actual productivity following a move to new premises. Field-intervention experiments in which these and similar outcome variables are used to validate or refute self-estimated productivity as a predictor of actual productivity are long overdue

Research Strategy for Cost-Benefit Analysis of IEQ

To prove that IEQ affects occupants in an experiment it is necessary to demonstrate that an observed effect of IEQ could not have occurred by chance. To do this and to reliably estimate the size of the effect requires an experiment in which human subjects are exposed to two or more IEQ conditions. The design of the experiment must rule out alternative explanations. Experimental design is one of the most important methods to be considered in this chapter, more important than the choice of the metrics used to quantify the observed effects. The metrics determine the level of measurement (Nominal, Ordinal or Interval) and thus the choice of statistical methods, but the experimental design determines what assumptions must be made in the statistical analysis, as discussed below. The more assumptions that are involved in a statistical analysis, the lower the “face validity” of the conclusions. Face validity – how easily non-scientists can be convinced that the findings are valid and applicable – is what makes research of practical use for decision-makers who must justify the cost of constructing and operating a building.

The International Centre for Indoor Environment & Energy (ICIEE), referred to as “the Centre” in the following, was established at the end of the last millennium as part of the Department of Civil Engineering at the Technical University of Denmark. Its purpose was to develop the knowledge and insights necessary to resolve the conflict between improving the quality of indoor environments, to safeguard health and improve comfort and productivity, and the need to conserve energy in buildings. Research conducted at the Centre was to have the scientific goal of acquiring new knowledge and the practical goal of developing solutions that are acceptable to building occupants and shown to be economically viable for building owners and operators and for society at large. The human criteria by which solutions are judged are at three levels: health, comfort, and productivity. This chapter sets out the methodological choices that came to characterize research on human criteria for IEQ at the Centre, and the rationale behind these choices. The 25 basic choices set out in the paper, here expressed so that 17 of them are straight either/or choices, and 8 as multiple choices, for example where neither or both would each be a valid approach, define almost two billion different ways of conducting indoor environmental research (1,719,926,784 ways). Making a choice of method that differs from the one indicated by the rationale described in this chapter would radically alter the nature of an experiment and would thus affect its chances of serving a particular purpose. It is essential to identify where different methodological choices have been made when comparing findings obtained by different research strategies. Very few such different choices have so far been found to be appropriate in the search for limiting criteria for environmental factors such as temperature, air quality, outside air supply rate, lighting, or noise.

The 25 basic methodological choices that must be made.

1. *Field or laboratory studies?*

Both are essential, separately and combined in the form of realistic simulation experiments. Problems encountered and perhaps investigated initially in the

field can often be studied experimentally only in simplified form in the laboratory, while solutions that have been developed or discovered in the laboratory must be validated in the field. Even realistic simulation experiments require field validation, with real subjects performing real work, as opposed to paid subjects performing simulated work, as motivation and attitude to work may still differ. Only field experiments in which subjects need not be paid to participate can usually be of sufficient length for longer-term negative symptoms to develop.

2. *Field surveys or field intervention experiments?*

Surveys cannot distinguish between the effects of two factors that change in a related way, that is, when their effects are confounded. This is often the case in the field. Field intervention experiments in which one factor such as the outdoor air supply rate is changed while all other factors remain unchanged combine the realism of field studies with the power of the experimental approach. However, field surveys that are designed to determine the frequency of certain symptoms or complaints, the types of building in which they occur and the environmental conditions with which they are associated are often used to guide the focus of the experimental work. Field intervention experiments are the preferred approach to validating results obtained in laboratory studies, or hypotheses of causation derived from survey data. With smart buildings connected to the internet, new types of field intervention experiments are becoming possible: this was recently demonstrated in a remotely conducted experiment in over a hundred buildings, in each of which temperature set-points were being adjusted by occupants using their cellphones (Wyon and Ridenour 2018). Adjustment of a set-point up or down was taken to indicate that the temperature was considered to be too low or too high, respectively, by some member of the household and as these adjustments and measurements of the indoor temperature were available over the internet to the operator of the buildings' heating system, it was possible to determine which of two control regimes led to the least thermal discomfort and the smallest thermal excursions, without visiting any of the buildings. The experimental design included week-long repetitions and was balanced for order of presentation over a period of 4 weeks. This approach had the added advantages that the costs were negligible, as no additional equipment was installed, no interviews were conducted, and no questionnaires were distributed. As the experimenters did not need to visit any of the buildings or contact any of the subjects, this meant that the subjects were blind to the interventions and so could not bias the results due to their own expectations.

3. *Moderate or extreme levels of environmental stress?*

Environmental researchers and toxicologists have historically preferred to expose subjects to fairly extreme levels of a given environmental factor, assuming that human response will then be greater and thus easier to demonstrate, and that it is possible to interpolate the severity of effects between those occurring at extreme and neutral levels of the causative factor. This tradition began because of the high levels of stress encountered by military personnel and by workers in heavy industry. Research on the civilian population almost always exposes subjects to very moderate levels of environmental stress, for the following

reasons: (1) the results are intended to be applicable to the civilian population, light industry, office work, and dwellings; (2) the mechanisms by which moderate stress has an effect are different, involving psychological as well as physiological processes; and (3) it is thus not necessarily valid to assume that the magnitude of moderate stress effects will be predicted by interpolation from the effects of extreme stress.

4. *Subjects: male or female, old or young?*

Environmental researchers have traditionally studied the responses of young adult male subjects. Research should usually involve equal numbers of male and female subjects, but where Sick Building Syndrome (SBS) symptoms are expected to appear on the chain of causation, it may be an advantage to expose only female subjects, because female employees are found in field surveys to report more of such symptoms and are thus expected to be the more environmentally sensitive category. Young adults 20–35 are preferred because so many are available as volunteers for experiments, while older volunteers tend to be less representative of the underlying population who are engaged in paid work.

5. *Normally healthy subjects or especially sensitive sub-groups?*

Research should usually be conducted on randomly selected volunteer subjects, excluding only those suffering from colds or other forms of ill health, or using medication that is likely to have relevant side-effects. Subgroups expected to be especially sensitive may be studied when their requirements are likely to be critical in a workplace, for example, female subjects in the case of SBS and contact-lens wearers in the case of low humidity.

6. *Personality and IQ assessments?*

Many psychological laboratories engaged in the investigation of environmental stress begin by assessing the personality traits and intelligence of their subjects and may even select subjects according to the results of such tests. Research on the indoor environment has the practical goal of ensuring that they are acceptable to all building occupants and so the discovery of some unexpected bias due to personality or intelligence would be of merely academic interest.

7. *Naïve or fully informed subjects?*

Ethical considerations mandate full and informed consent. However, if possible, subjects should be kept “blind” to the interventions in field experiments, that is, they should not be informed of when each condition is established even if they must be told what each condition entails, and they should be randomly assigned to conditions in the laboratory without knowing which is which. In this way, not even the expectations of subjects who have given full and informed consent can bias the results.

8. *Repeated-measures or independent-measures experimental designs?*

Physiological measures are unaffected by prior exposure (unless acclimatization takes place). This is not true for subjective judgments and even less so for performance. Learning, increased familiarity, and over-familiarity (boredom leading to reduced motivation) can have as powerful effects as those of the environmental factors whose effects are being studied, and it is not always

possible, even theoretically, to devise parallel tasks of equal difficulty. Independent-measures designs, in which subjects are randomly assigned to conditions and each subject is exposed to only one condition, avoid all of these problems. However, it has been found empirically that repeated-measures designs with balanced order of presentation are a more efficient approach even when subjective and performance criteria are used.

9. *Health parameters – objective or subjective?*

Objective measures that cannot be affected by expectation are a valuable way of proving that mechanisms are real and not imagined. However, subjective ratings of symptom intensity are usually found to be the most sensitive to environmental influences and the most immediately relevant to human goals. They may often be the only available measure, for example, in the case of pain, soreness, difficulty in thinking clearly or headache.

10. *Subjective rating – category scales or visual-analogue (VA) scales?*

For a change to be reported on a category scale, the subject must believe that a change has taken place. The response obtained is thus a function of the subject's mental model of the underlying mechanism, which may be mistaken. Reports obtained by having subjects mark VA-scales can be unconsciously affected by environmental factors, independently of mental models, and can thus document changes in subjective response even when the subjects themselves do not think that a change has taken place.

11. *Graduated or ungraduated VA-scales?*

In repeated-measures designs in the field or laboratory, subjects must provide successive responses during or after each exposure to each of a set of experimental conditions. If the scales are graduated, it is too easy for them to remember where they marked the scale before. Their response then communicates only how they themselves think changes in the indoor environment affect them – and they may well be wrong.

12. *Acceptability – yes/no or reported on a continuous scale?*

Environmental research often obtains subjects' environmental perceptions on verbally defined scales, for example, of warmth, odor, or loudness. What is "acceptable" is later decided quite arbitrarily by the experimenter. There is no substitute for asking subjects directly whether conditions would be acceptable for daily occupation. It is more efficient to obtain judgments on a continuous scale that is divided between acceptable/unacceptable, to force subjects to make a clear choice, while asking them additionally to rate the degree of acceptability or unacceptability. The DTU Split Scale of Acceptability was developed for this purpose. The two "End-Labels" characterize one end of an ungraduated line as denoting "Completely Acceptable" and the other end as "Completely Unacceptable." The line has a gap in the middle whose two sides are labeled "Just acceptable" and "Just not acceptable." Subjects are asked to place a mark on the scale to indicate the acceptability of the conditions to which they are exposed for everyday occupation. Instead of the 1 Bit of information conveyed by a "Yes/No" rating of acceptability, each response contains much more than 1 bit of information, and responses obtained from a limited number of subjects can more

accurately predict population acceptability. Using Probit Analysis (Finney 1971), a sigmoidal relationship can be derived to estimate the proportion dissatisfied (PD) as a function of the average scale marking, pooling all scale markings across all experimental conditions. The average scale marking in each condition that is used to estimate the PD in that condition is then based on all the available data instead of on a tally of binary responses. This is particularly valuable when the number of subjects exposed to a given condition is low.

13. *Inactive or hard-working subjects?*

Subjects in physiological experiments are traditionally required to do nothing except endure the environmental stress. Following this tradition, subjects in subjective thermal comfort experiments were historically required to do nothing except express at intervals their degree of discomfort, reading or staring into space meanwhile. When asked “Is the temperature comfortable?”, their response should really have been “Comfortable for what? Reading? Doing nothing? Dozing off?” It is now known that performing even sedentary work can raise metabolic rate sufficiently to affect thermal comfort. Recent results suggest that air quality and background noise, by affecting alertness, can have a similar effect. To ensure realism, even subjects in experiments whose dependent variables are subjective should be required to perform simulated work even if it is thought unlikely that the environmental exposure will measurably affect performance.

14. *Highly motivated or unmotivated subjects?*

Environmental stress can have the effect of reducing motivation. This mechanism would not affect the performance of unmotivated subjects. On the other hand, unusually high motivation may be assumed to reduce environmental effects to unrealistically low levels. Volunteer subjects are often motivated by a desire to prove what they can do, both to oblige the experimenters and to justify to themselves the time they have spent attending the experiment. Only long exposures and repetitive work can bring motivation down to the levels that are characteristic of real workplaces.

15. *Diagnostic tests or performance tasks?*

Diagnostic tests attempt to assess a particular facility, usually a theoretical construct such as memory or spatial perception. Environmental researchers have often assumed that such tasks are more sensitive to environmental effects than performance tasks that involve using several facilities. This turns out to be untrue. Diagnostic tests should be used sparingly, for three main reasons: (1) they have repeatedly been found to be less sensitive than performance tasks to environmental effects; (2) they are unfamiliar so learning effects render them unsuitable for repeated-measures designs; and (3) results obtained with them have less face-validity than results obtained on tasks that are closely similar to actual work, because it would require an unrealistic amount of additional research to determine how important each facility is for the performance of each real-world task.

16. *Well-practiced or unfamiliar tasks?*

Unfamiliar tasks are more difficult for subjects to perform. Environmental researchers have historically assumed that the greater the level of difficulty of a

task, the more sensitive it will be to environmental effects. This turns out to be untrue. Well-practiced tasks such as typing, proofreading, and addition should be used in indoor environmental research, for three main reasons: (1) they have repeatedly been found to be more sensitive to environmental effects; (2) learning effects are minimized, which makes them suitable for repeated-measures designs; and (3) their similarity to normal work means that the results are immediately applicable to workplaces. Practice and familiarity determine the level of difficulty of a task under optimal IEQ conditions. Suboptimal IEQ conditions increase the level of difficulty, decreasing average performance. It is axiomatic that if the level of difficulty is sufficiently low, all subjects will be able to perform it efficiently, while if it is impossibly high, no subject will be able to do so. Performance, however assessed, asymptotically approaches zero as level of difficulty increases, and 100% as it decreases. There is in other words a sigmoidal relationship between performance and level of difficulty, with a point of inflection somewhere between the extremes. It is at this point that the slope of the relationship reaches its maximum value, that is, that a given change in the level of difficulty has its greatest effect on performance. The sensitivity of an experiment to changes in IEQ is maximized by ensuring that the level of task difficulty is at this point, providing always that it is a level of difficulty that is encountered in the daily activities of building occupants and is thus a realistic simulation of their daily work.

17. *Real work or component skills?*

Real work always consists of performing a complex sequence of subtasks, which may each be differently affected by the working environment, obscuring any overall effect. Simulated work should therefore be used to examine the effects of the environment on the performance of each separate subtask, such as text typing, proof-reading, mathematical calculation, logical thinking, and creative thinking, each of which requires the exercise of a different “component skill.” As all of the subtasks are involved in the performance of real office work, environmental effects on any one of them may become the basis on which the limiting criterion for a particular factor of the working environment is set.

18. *Speed or errors?*

In the performance of repetitive tasks, experimental subjects have been found to trade off speed against errors, that is, they reduce the rate at which they perform a task if they have the impression that errors would otherwise increase, even if no feedback on errors is provided. Recording only the rate of correct responses does not permit an examination of this trade-off, which may itself be affected by environmental stress. In real workplaces, the consequences of error determine the rate at which work can be performed. At one end of the scale, errors may be lethal or catastrophically expensive, while at the other extreme the consequences may be trivial. In simulated work, there are no real consequences of making an error, yet it is empirically observed that when environmental stress increases task difficulty, subjects still tend to adjust their rate of working to maintain a constant percentage error, although they do not always succeed in doing so. For these reasons, the performance of repetitive work should be evaluated by recording speed and percentage errors separately.

19. *Convergent thinking or divergent, open-ended thinking?*

Most repetitive tasks require convergent thinking – there is only one correct response, and the subject must employ rule-based logical thinking to find it. This is true of text-typing, proofreading, grammatical logic, and all mathematical tasks. Speed and errors are adequate criteria for such tasks. Computers perform or at least supervise an increasing proportion of such tasks but are unable to undertake or even supervise divergent and open-ended tasks. Creative thinking is no longer a preferred activity of the privileged few – it is the daily responsibility of the many. In open-ended tasks there are an unlimited number of correct answers, which are distinguished only by their utility and their originality. Speed is secondary and errors are tolerated, but originality is highly prized and rewarded. Simulated work should include an open-ended test of creative thinking, in which responses are first screened for utility, then numerically scored for originality. The score is obtained by using information theory to convert the probability of occurrence of each response into reduction of uncertainty, measured in bits. The probability that a randomly selected subject would have given a particular response is empirically estimated by determining the proportion of all the subjects in the experiment who did so. This approach, originally conceived to place individuals on a continuous scale of creativity that was found to be “orthogonal” to IQ (i.e., not predicted by an individual’s IQ score), is used as a paradigm of divergent thinking, to reveal environmental effects (Wyon 1996a). It is not claimed to be real creative work, but it is assumed to be subject to the same mechanisms of environmental influence.

20. *Number of subjects: $N = 15, 30, 60?$*

Published physiological studies have sometimes been carried out on a single subject (usually the author), and often on as few as five subjects. Fifteen would be a large number of subjects for such research, and even experiments on mental performance have used this few. It is usually unwise to expose fewer than 20 subjects to each condition in an independent-measures design intended to reveal environmental effects on performance. Research involving environmental effects on simulated office work in a closely controlled environment has successfully used 30 subjects in repeated-measures designs. In field experiments where there are many uncontrolled but still influential factors, only the availability of large amounts of existing performance data can justify running even a repeated-measures experiment with so few subjects. In all other cases, field experiments should aim to expose at least 60 subjects to each condition.

21. *Exposure times in laboratory experiments: 2, 4, 8 h?*

One- and 2-h exposures are the norm in performance experiments, corresponding to the length of time university students with a course requirement to participate in research as experimental subjects are able to attend. Employees currently work for about 8 h per day, but seldom for more than 4 h at a time. Environmental effects on simulated work are usually studied in exposures lasting from 3.5 to 5.5 h, depending on the latency of the mechanisms believed to be on the causal chain. Exposures of this length, particularly when

they are scheduled late in the day, allow a realistic degree of fatigue to develop. In field experiments, of course, exposure sessions continue throughout the working day, and in view of the inevitable break in exposure at each weekend, it is usually expedient to arrange interventions so that each condition is established for one whole working week. Repetitions are required to reduce chance confounding with external conditions such as weather.

22. *One or more independent variables?*

Although physiological responses usually show very little interaction between such factors as heat and noise, or light and air quality, subjective judgments of acceptability may do so, and performance may be affected in very complex and unexpected ways by combinations of stressors. Research should include a systematic examination of the nature of interactions between two and more environmental stress factors at these higher levels of environmental response.

23. *Reconnaissance or crucial test of a hypothesis?*

Experiments should always be designed to provide a crucial test of one or more hypotheses rather than as “fishing expeditions” into unknown territory.

24. *Physical and chemical measurements?*

Research on human criteria need include only those physical and chemical measurements that are necessary to document that experimental interventions have succeeded and that exposure conditions are sufficiently similar to conditions in the field for the findings to be applicable in practice. The emphasis is always on determining human response to the environmental changes that are experimentally induced, and the temptation to measure everything in sight should be resisted, as it can inflate costs well beyond what is justified.

25. *Physiological measurements?*

Research whose purpose is to optimize IEQ need to include only a very limited number of physiological measurements, as the environmental conditions of interest involve such low levels of physiological stress that such physiological responses would not provide a basis for setting limiting criteria. Limiting criteria are usually based on the more environmentally sensitive subjective and behavioral response measures.

Experimental Strategy

In general, the three main strands of applied experimental research that have been conducted with the above approach are:

1. Scientific experiments whose purpose is to discover and describe the mechanisms by which environmental factors affect building occupants.
2. Based on this understanding, engineering development of solutions to the conflict between energy conservation and improved indoor environmental conditions.
3. Field validation of laboratory findings and field determination of the acceptability and applicability of the proposed solutions.

Strategy When Selecting Sample Size

There are two main issues: (1) the number of subjects that must be studied to be able to prove that the effects observed could not have occurred by chance; and (2) the number of subjects that must be studied in order to be able to generalize the results to the entire population. These two issues are discussed below.

Significance of an Experiment

Inferential statistics are used to determine the probability that the observed result could have occurred by chance even if there were no effect of the environmental factor under study, that is, if the Null Hypothesis were true. If this probability is less than 0.05, it is conventional to regard the result as statistically significant, but the criterion for accepting that it is a real effect will always depend on the consequences of a decision based on the finding, which may be economic or human, trivial or severe. It may be appropriate to discount an apparent effect that would in any case occur in 5% of experiments by chance, and to select a lower probability, such as ($P < 0.01$) or even ($P < 0.001$), accepting the result as genuine only if these higher levels of statistical significance are reached. The frequency distribution of the observed dependent variable is always the basis for the statistical calculation, whether it conforms to a parametric distribution such as the Gaussian distribution, or not. A frequency distribution is the relative frequency with which different magnitudes of a variable, from the smallest to the largest possible, will be observed, all else being equal. If the Null Hypothesis is true, the two or more experimental conditions can be regarded as random samples and the measurements obtained under all conditions can be pooled when deriving the frequency distribution. This is therefore what is assumed in the calculation of probability of occurrence.

The main source of variability is to be found in the innumerable differences that exist between individual subjects in terms of their age, gender, size, weight, intelligence, personality, training, experience, and attitude, to name but a few. Two characteristics of the frequency distribution determine the probability that will be calculated by parametric or nonparametric statistical methods: (1) the size of the effect that appears to be due to a change in an environmental factor; and (2) the variability between the measurements obtained. The probability of obtaining a result by chance will be reduced if the apparent effect is large and/or the variability between measurements or between subjects is small. If these characteristics were known, it would be possible to determine in advance how many subjects should be studied for an effect of a given size to become statistically significant at the selected level. They are indeed known to the extent that the measure has been used before in similar experiments, but as research is the process of extending existing knowledge and one or more aspects of each experiment will usually differ from what has ever been tried before, it is logically impossible to predict either with 100% accuracy.

Best practice is then to make an educated guess as to the likely size of the environmental effect and to assume that the variability will be the same as in previous

experiments. Outcome variables used to assess health, comfort, and performance have been found to differ significantly between environmental conditions in which 5–10% of subjects are dissatisfied in the best or reference condition and 40–80% are dissatisfied in the worst condition if 30 subjects are used as their own controls in a repeated-measures design and balanced for order of presentation, while considerably more subject-exposures would be required in independent measures designs in which subjects are assigned at random to conditions (50–80 randomly selected subjects would have to be exposed to each condition to achieve the same statistical power).

Sample size can be determined empirically: enough subjects have been tested if the result can be shown to be statistically significant. Significance depends on the characteristics of the outcome variable and on how it is affected by the indoor environment, but it has nothing to do with having large subject numbers or with whether the subjects are representative of the general population.

Validity of an Experiment

The result of an experiment is valid if it predicts what happens in the real world. For this to happen, the probability that the observed result could have occurred by chance must be low, as discussed in the preceding subsection, but the subjects and the conditions to which they were exposed must also be representative of the real world. In order to be able to control certain environmental factors within narrow limits, experiments carried out in a laboratory may expose subjects to very unrealistic conditions, for example, in windowless climate chambers with stainless steel surfaces, so that the results cannot be assumed to be transferable to the real world without validation. Environmental research should preferably be carried out in a “field laboratory” that outwardly resembles a real office in terms of its dimensions, acoustics, lighting, surface finishes, windows, view out, furnishing, and decoration. This increases the “face validity” of the experiment, that is, it seems likely to most unbiased commentators that similar results would occur if the subjects were exposed to the same environmental conditions in the real world.

Validation may still be deemed necessary when experiments are carried out using paid subjects exposed for a limited time and performing simulated work. Attitude and motivation may be different in the real world, as may fatigue and the consequences of a mistake, so the effect of the environment may differ. Only validation studies in the field can eliminate this possibility. It has been demonstrated in several field experiments in call-centers, one in Denmark and the others in the Tropics, that the effects of air quality on the performance of office work that were first discovered by exposing 30 young Danish women for 5 h in a field laboratory really do occur in practice when call-center employees perform real work 8 h a day for 9 weeks. It would obviously be absurd to insist that such findings should be validated in every workplace, country, and climate of the world, and the onus is now on the skeptic to show that there is reason to believe that a different result would be observed if the gender, age, workplace, type of work, or national characteristics of the subjects were different. It is generally accepted that

clinical trials need not be repeated in different but generally similar populations, as physiology and disease are so universally the same. The physiological and psychological determinants of behavior in response to the indoor environment may well be as universal as those that determine pharmacological effects on patients suffering from the same disease.

It is therefore more important to perform validation experiments in the field than to increase the sample size in the laboratory, bearing in mind that differences between experimental situations may be as influential as differences between people.

Interpretation in Terms of an Environmental Halo Effect

When we consider a person good (or bad) in one category, we are likely to make a similar evaluation in other categories. It is as if we cannot easily separate categories. It may also be connected with dissonance avoidance, as making them good at one thing and bad at another would make an overall evaluation difficult. Thorndike (1920) found that when army officers were asked to rate their charges in terms of intelligence, physique, leadership, and character, there was a high cross-correlation. This was later confirmed by Asch (1946).

This has led to the halo effect being defined as the extension of an overall impression of a person (or of one particularly outstanding trait) to influence the total judgment of that person. The effect is to evaluate an individual high on many traits because of a belief that the individual is high on one trait. The halo effect occurs when you form an overall *positive* impression of someone because of one good characteristic. That positive judgment carries over into areas where that person might or might not have any competence. The halo effect is often cited as a major reason why interviews are so unreliable for evaluating potential employees, because the result is influenced by a person's strengths, weaknesses, physical appearance, behavior, or any other single factor. The halo effect is most often apparent in situations where one person is responsible for evaluating or assessing another in some way. Examples of such situations include assessment of applicants for jobs, scholarships, or awards; designating job or committee assignments based on perceived capabilities or past performance; and in evaluating academic, job, or athletic performance. The halo effect can undermine an individual's effort to be objective in making judgments because people respond to others in a variety of ways, making true objectivity nearly impossible. However, the halo effect causes one characteristic or quality of an individual to override all others. To counteract the halo effect, decision makers can break the evaluation process into specific steps, evaluating only one characteristic at a time, but human judgments can never be free of complex influences.

By extension, an "environmental halo effect" can be said to occur when one particular aspect of the environment that is judged very positively, such as air quality, has a positive influence on how other aspects, such as temperature, noise,

cleanliness, and lighting, are rated. Wargocki et al. (2002) seem to have been the first to invoke an environmental halo effect to explain why subjects in an experiment in which one factor was improved systematically rated other factors more positively even though they had not been improved, but it is not difficult to find further examples of this effect.

The Ethics of Experimental Research on Human Subjects

Not all research on human subjects must be approved by an Ethics Review Board (ERB). In this section the main reasons for seeking ERB approval are set out. ERBs were originally set up to protect the interests of patients undergoing medical treatment, balancing any health risk, pain, or discomfort involved against the possible benefits for them personally. In an imperfect world it cannot be assumed that researchers always act in the interests of their subjects. Instead, it must be assumed that the proposed experiment may bring some benefit to other interests, which might be commercial, political, military, or personal career advancement. ERBs take an impartial view of this. There is nothing wrong with advancing other interests, provided that the interests of the subjects are safeguarded.

Health Risk, Pain, and Discomfort

When experiments that increase the risk of illness or injury are undertaken it is obvious to all concerned that ERB approval must be obtained, for even if subjects are prepared to run the risk, their interests must be protected by weighing the risks for the subjects against any possible benefit for them personally. That there is benefit for other members of society is not a sufficient reason for allowing researchers to impose risks on the subjects in the sample. ERBs are prepared to allow subjects to take an informed risk provided that some genuine benefit for them personally may result and will allow volunteers to undergo considerable discomfort even if this is not the case. ERBs pay great attention to the detailed information on the risks and possible benefits of the experiment that is made available to subjects, and they insist that subjects are clearly informed that they may terminate their participation at any time. An important function of an ERB is to be able to make an expert assessment of the potential risks imposed in an experiment. The fact that researchers wish to conduct an experiment is no guarantee that they are sufficiently competent in the relevant area of expertise to be able to make a correct assessment of the risks. ERB members are experts in risk assessment, and their time is valuable. It is for this reason that it would be absurd if all planned research on human subjects should be obliged to obtain ERB approval, as ERBs would no longer have sufficient time for risk assessment in cases where subjects are exposed to unusual conditions.

Invasion of Privacy

ERB approval is always required when researchers wish to access personal medical files, or to obtain directly from subjects their medical or social history, including for example their medication, tax, social, or criminal records. Similarly, covert surveillance however conducted (by video camera with or without recording or even by systematic direct observation) is in most countries against the law in public places, and even in homes and workplaces, and ERB approval for it is very difficult to obtain even if subjects are first made aware of it and consent specifically to it. ERB approval must always be sought for both kinds of invasion of privacy.

Social Pressure to Participate

Subjects may feel an obligation to volunteer to participate in an experiment. This is certainly the case for patients who are or have been in medical care. One of the main reasons for requiring ERB approval for all experiments conducted by physicians is that their patients do feel this obligation, not only in gratitude for the care they have received but also out of the somewhat base suspicion that the standard of care they will receive in the future might be compromised if they do not volunteer. Nobody is exempt from some form of this pressure and medical journals therefore stipulate that they will not publish research unless ERB approval for it was granted. Scientific and engineering journals do not make this stipulation. The reason is that while altruism and respect for science as the search for truth may give rise to some residual social pressure to participate in scientific experiments, experience shows that few subjects nowadays volunteer altruistically. In engineering, which is the art of making things work even if the underlying processes are not fully understood, altruism would be misplaced so subjects make their decision based firmly on their own interests. The same is true for marketing surveys and opinion polls. Clinical practice and most pharmaceutical trials, in a way that is analogous to engineering, must be regarded as the art of helping patients to return to good health even if the underlying processes are not fully understood, so to apply the term science to all research conducted by physicians is misleading. However, as shown above, there are sufficient reasons for requiring ERB approval for all research conducted by physicians.

Experiments That Do Not Require ERB Approval

If there clearly are no risks, no pain or discomfort, no invasion of privacy, and no social pressure to participate, ERB approval is not required. This is the case for a very large proportion of research involving human subjects. There is never zero risk in any human activity, and in this connection the correct rule of thumb is that if the experiment is so designed that subjects will be exposed to conditions within the range that is normally experienced by members of the public, or if the subjects are members of a particular category, such as factory workers in a particular branch of

industry, within the range normally experienced by that category, the risks are acceptable and ERB approval is not required on the grounds of risk. The same yardstick may be used for pain and discomfort. It would clearly be a waste of everybody's time, not least of ERB time, if marketing surveys and opinion polls were obliged to obtain ERB approval. Similarly, if the engineer responsible for commissioning a heating and ventilation system by optimizing the temperature set point and the outside air intake dampers had to obtain ERB approval to do so and to ask occupants whether the resulting conditions were acceptable, most building systems would not be optimized and ERBs would be able to consider little else. Most IEQ research is much closer to the optimization of building systems than it is to medical research, and it is for this reason that ERB approval is seldom required.

Documenting the Argument

The above argument does not amount to a claim that IEQ research is exempt from obtaining ERB approval. On the contrary, every time a new study involving human subjects is planned, at the point where the detailed experimental protocol has been defined, active consideration must be given to the need for obtaining ERB approval. Point by point, the above reasons for requiring ERB approval must be evaluated. Only if they clearly can be dismissed should preparations continue without an application for ERB approval. The arguments behind a decision not to seek ERB approval should in every such case be formulated in writing and should become an explicit part of the protocol itself, just as ERB approval, if sought and obtained, would have become a part of the protocol. It may often be appropriate to include this section of the protocol in the covering letter when a manuscript reporting the study is submitted for peer-reviewed publication.

Strategy for Dealing with Missing Data

Missing data is a constantly recurring problem in the analysis of all experiments. In the physical sciences and in engineering it simply reduces the sample size, which can be remedied by running more experiments, but in research on human subjects this may not be possible, that is, due to the difficulty of recruiting more subjects at short notice. At the same time, missing data is much more likely to occur in research on human subjects than in the physical sciences, due to the many possible reasons for unplanned and unforeseeable absence of subjects from some of the exposures. Subjects may become ill, may unintentionally oversleep or fail to arrive in time for many other reasons, or may simply change their priorities and decide to do something else instead. Increasing the hourly amount paid to subjects can affect only the last of these reasons for absence, which in practice tends to be the least frequent. As the problems presented by missing data in independent-measures designs and repeated-measures designs are very different, and the remedies that can be recommended differ, they are treated separately in the following. Common to both

is that any report of the analysis must always state what data was missing from the intended design, for example, how many subjects were missing under each condition, and must also provide a detailed account of what was done about the problem in modifying the design of the experiment or of the analysis.

Independent-Measures Designs

Subjects who miss an exposure in an independent-measures design should ideally be replaced with other subjects. As subjects are randomized between conditions, the only bias introduced is that subjects recruited later may differ from those recruited originally. It may therefore be a good idea to run the same number of extra subjects in each condition, so that they can continue to be randomly assigned to all conditions instead of only to those in which missing data occurred. Exceeding the intended sample size is never a problem, while exposing too few subjects to one or more condition may unacceptably reduce the power of the available comparisons. Provided that the maximum number of subjects missing does not exceed the original group size for each exposure, the number of additional exposures required need not be greater than the number of conditions being compared.

If it is not possible to supplement subject numbers in this way, comparisons between conditions should always be made using all of the available data. Although here too subject numbers will differ between conditions, this does not present any problems in the statistical analysis. Similarly, diagrams showing how the group mean or median varied between conditions should be based on all the available data, not just on those subjects who were originally recruited.

Repeated-Measures Designs

In a repeated-measures design, subjects who miss even a single exposure cause major problems of analysis, because it will seldom be possible to replace individual subjects without either: (a) introducing bias to an otherwise balanced order of presentation of conditions; or (b) repeating the whole design to avoid this problem. The latter is usually not possible because of the cost, time, resources, and recruitment it would incur.

In any comparison across all conditions, an analysis omitting all subjects who were not exposed to all conditions should always be made so that the reader can better estimate the consequences of the various assumptions that are necessary in substituting for missing data in any supplementary analysis. As it is not usually legitimate to make pair-wise comparisons between conditions unless a test of the Null Hypothesis (NH) of no difference between any of the conditions approaches significance, this is a very important rule to obey even if the reduced number of subjects available results in a reduced level of significance. If it is reasonable to reject the NH, any pair-wise comparison between conditions should then be made using all of the data available, that is, data from all of the subjects who were exposed to both

those conditions. The result is that pair-wise comparisons between different pairs of conditions will be conducted on slightly different samples of subjects. This does not matter for the statistical test of the NH of no difference between the two conditions, as the subjects were in each case only a sample of the same underlying population from which they were recruited. However, in deriving mean or median values for each condition for the purpose of creating a diagram that enables the reader to visually compare each condition with all others, it is not advisable to use all available data, because some of the differences that will be apparent will be due to differences between subjects that were eliminated in the within-subjects statistical comparison. It is therefore better to derive the group means and medians used for this purpose only from subjects who were exposed to all conditions.

Reconstructing missing data so as to be able to use the genuine data that was obtained from all subjects is only worth undertaking if the overall NH of no difference between any of the conditions cannot be rejected without this arbitrary procedure. Researchers should bear in mind that readers will always cynically assume that they have adopted the strategy that best favors their preferred result and will be unimpressed by the rational arguments that can be advanced for it. Unless reconstruction of missing data results in formal significance that could not otherwise be achieved, it may thus be a waste of time.

Missing data can be reconstructed by assuming either: (a) that within-subject differences between conditions arose by chance; or (b) that between-subject differences arose by chance. Both these assumptions are more plausible than the many required to justify mathematical models of human response. Under assumption (a), missing data is replaced by the mean or median value (as appropriate) of data obtained from the same subject under the remaining conditions. Although this may seem like the most rational procedure, as (a) is the NH that underlies the within-subject comparison, it has the effect of altering the group mean or median values for any condition in which there was missing data, which may lead readers to assume that this was the reason that the strategy was adopted. Although no bias has been introduced to the within-subject comparison, reconstructed missing data should still not be used to derive the group means shown in diagrams, as explained above. Under assumption (b), missing data in each condition is replaced by the mean or median of all the subjects who were in fact exposed to it, or at least of those subjects in the same category, for example, of the same age or gender. It should be noted that although this does not change the group mean value for each condition, it is capable of introducing some bias into a within-subject comparison between conditions. In a genuine search for the truth, the relative validity of (a) or (b) must be based on a necessarily subjective assessment of the observed variability between and within subjects.

Experimental Protocols

Experiments that appear to address the same information requirement may differ in terms of apparently trivial details that nevertheless turn out to affect their findings. If an intended replication fails to validate a prior experiment, because some apparently

trivial change has been made, the advance of scientific knowledge is delayed. This may have very expensive consequences, not just in terms of the cost of further repeating the experiment, but also in terms of the consequential losses that may be caused by the need to base practical decisions on imperfect knowledge, pending the acquisition of firm knowledge. This section of the present chapter defines a formal document that describes a proposed experiment in such detail that any researchers who are qualified and experienced in the field of research and acting independently, would be able to perform the experiment in an identical manner without further briefing. This document, known as the “Protocol” for the experiment, sets out the hypotheses to be tested, summarizes prior knowledge, provides a rationale for the approach, describes the experimental design, the methodology, the data that will be acquired, and the statistical analysis and presentation of the findings, specifying in detail every aspect of the proposed experiment that might affect those findings.

The experimental protocol serves three main purposes: (1) it ensures that an experiment can be replicated exactly; (2) it documents what has been agreed and ensures that all those involved in the experiment know exactly how it will be carried out; and (3) its preparation ensures that the experimental process has been completely thought through from data acquisition to analysis to presentation of results in good time to make the necessary changes to the experimental design, that is, if more data would be needed for a given conclusion to be valid, or for certain tables or figures to be prepared.

Protocol

In order to serve the above purposes, all 30 of the following sections should be completed before the experiment can be considered as being ready to start:

1. Project title

Choose a brief title that describes the general nature of the experimental effort, and preferably also an acronym based on it, then prepare a subtitle that delimits the scope of the experiment.

Example: “Indoor Air Quality effects on self-estimated and objectively-measured Cognitive Performance (IAQCP)”

2. Project nature and purpose

Provide a single paragraph description of what is proposed and why.

Example: “Self-estimated performance as rated by office workers is often used as an outcome variable in experiments whose purpose is to optimize the working environment but may reflect effort rather than achievement. The proposed field-intervention experiment will obtain both of these measures over a period of several weeks in working call-centers, using routinely-recorded talk-time records as an objective indicator of cognitive performance. The intervention will be to covertly change the rate at which outdoor air is supplied to the call-center in a repeated-measures design balanced for order of presentation of conditions.”

3. Project leader

Designate the person responsible for running the project and provide contact details.

4. Team members

Designate team members, their contact details, their respective responsibilities, and the extent of their contribution to the project.

5. Funding agencies

List the funding agencies, their respective contributions to the total cost, and the dates by which progress, financial, and final reports must be provided to each of them.

6. Budget and facilities

State the total budget and the amount released each year, then list the experimental facilities that will be used, with their nominal leasing value per day.

7. Liaison with stakeholders

List the persons to whom progress reports must be submitted, any “milestones” (defined points in the process) by which they must receive a progress report and their due dates. List the confidentiality agreements that have been signed with any commercial funding sources. On a separate list, identify the target groups for the project findings, and specify which of them should receive one or more of the following forms of report: a heads-up notice that the project is on-going; preliminary confidential notification of the findings; reprints of any published articles; the final report.

8. Current knowledge

Summarize previous research findings that are relevant for the projected research, including papers reporting any use of the proposed methodology. List all references under Point 30 below for future use in the preparation, analysis, and reporting of the research. Distinguish between field and laboratory studies, and between experimental and observational (cross-sectional) surveys. Cut and paste to the protocol the most relevant sections of the reports cited, for example, how-to descriptions of the methodology and the reported mean and SD of the measurements that were obtained by using it (for use in a power analysis to determine sample size and experimental design). Include subjective knowledge based on experience or reasoned expectation but distinguish this kind of knowledge very clearly from knowledge based on scientific observation and inferential statistics (with stated *P*-values that quantify the probability that the observed results could have occurred by chance).

9. Knowledge requirement

State clearly the new knowledge that the project is being undertaken to provide, in the form of questions that it should be possible to answer once the project has been completed, for example (for the project instance above) “Does self-estimated performance reliably indicate actual performance of office work? Does improving IAQ significantly improve either (or both) of these outcome variables? If so, what is the shape of the dose-response curve?”

10. *Formal hypotheses*

Formally state the hypotheses to be tested in the proposed analysis of the data.

11. *Rationale*

Describe the rationale for the experiment and justify the expense.

12. *Scope and approach*

Delimit the scope of the experiment and justify the approach to be adopted.

13. *Experimental design*

Stipulate and justify the design of the experiment, for example, how it will eliminate confounding and any unintended bias due to the influence of uncontrolled factors.

14. *Measurements to be made*

List the measurements to be made and justify the omission of others.

15. *Methodology and equipment*

Stipulate the methods and equipment that will be used, including the manufacturer, model, range, accuracy, and calibration status of each instrument (for inclusion in the final report).

16. *Database to be acquired*

Define the database to be acquired and set up the data management software for storing and retrieving data. List who has access to it and whether it will be made public.

17. *Statistical methodology*

List and justify the statistical methods that will be used for analysis. List the non-parametric methods that will be used if the data is found not to be Normally distributed. Specify where 1-tail and 2-tail *P*-values will be appropriate.

18. *Tables and Figures*

Prepare blank versions of the Tables and Figures that will be used to present the results. It is very important to do this in advance because it often serves as a reminder to include measurements and observations without which such a presentation would be impossible, before it is too late to include them.

19. *Possible conclusions*

List what conclusions it might be possible to draw from the experimental results, including the Null Hypothesis of no significant effects.

20. *Possible publication*

List the journals to which it is intended to submit a report of the experiment.

21. *Other dissemination of findings*

List other ways by which the results will be disseminated, for example, papers to specified future conference, internal reports, lectures, press releases.

22. *Venue*

Stipulate the buildings and rooms in each building where the experiment will be conducted.

23. *Permissions required*

List the permissions required and where they will be obtained, for example, from employers, building operators, building owners, Ethics Review Board (if applicable), personal data protection authority. In Europe, ensure GDPR compliance (General Data Protection Regulation).

24. Cost estimates

List all the estimated costs, including salaries, leasing of premises and equipment, calibration of instruments, consumables, payment to subject, travel, accommodation, etc.

25. Recruitment required

State where, when, and how subjects and research assistants will be recruited, including the exclusion criteria to be applied.

26. Time schedule

Prepare a provisional time schedule for all preparations, set-up, data acquisition, analysis, and reporting.

27. Duty roster

Stipulate who will be responsible for what and when.

28. Contingency plans

Prepare contingency plans for dealing with delays, illness, absenteeism, and missing data.

29. Exit plan

Describe what will happen when the experiment ends – what will be dismantled and by whom, what equipment will be left in place, etc.

30. References

List all the references cited above for possible use in the final report.

Conclusion

In IEQ research whose purpose is to justify the cost of the construction and operation of the building concerned, the research strategy adopted must be very carefully considered. The design of the necessary experiments will usually differ from what is appropriate in basic research whose sole purpose is to advance scientific understanding. This chapter discusses in detail how to select appropriate metrics and methods for applied IEQ research and recommends the most effective approach.

Pathways · Cognitive performance · Homeostasis · Physiological · Neurological · Psychological · Exposure

Introduction

There is a complex set of relationships involving various stimuli and their pathways that affects cognitive performance (Fig. 1). Within any indoor environment, exposure presents the context in which human responses occur. Cognitive outcomes are the main interest as it is the main determinant of performance. Cognition is fundamental to the entire process of work. Cognition refers to “the mental action or process of acquiring knowledge and understanding through thought, experience, and the senses” (Stevenson 2010). It encompasses many aspects of intellectual functions and processes such as attention, the formation of knowledge, memory and working memory, judgment and evaluation, reasoning and “computation,” problem-solving and decision-making, comprehension, and production of language (Wolfe et al. 2006; Barsalou 2014). Cognitive processes act on assimilated knowledge to process and generate outcomes. In the office environment and knowledge-based work, cognitive processes are fundamental to productivity, and in schools, to learning.

Upon exposure, sensory stimulation invokes the initial reactions that spawn physiological and neurological mechanisms. Physiologically, the body seeks to restore the state of steady internal, physical, and chemical conditions maintained by various regulation systems for optimal functioning, through continual homeostasis (Cannon 1929; Davies 2016). Depending on the route and effect of stimuli, mechanisms are triggered which impact neurological adjustments that affect cognitive function. These effects may be direct and instantaneous if they directly engage and disrupt cognitive processes or may occur over time as a consequence of homeostasis.

Upon exposure, sensory stimulation can also invoke psychological responses. These perceptions lead to instantaneous interpretations of the environment which

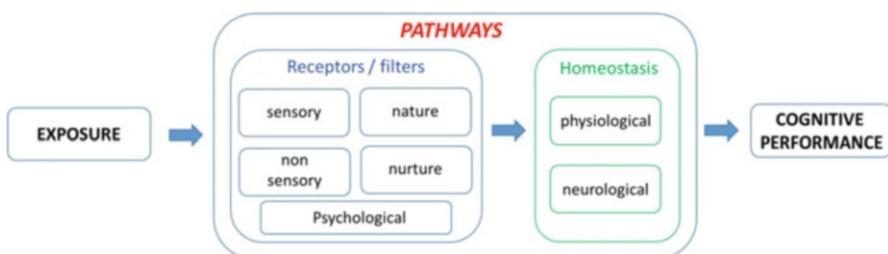

Fig. 1 Postulated pathways linking exposure to cognitive performance

influence the affective state (mood and emotions), and in turn attitude and inclinations toward work, and hence performance.

The effects and responses to stimuli are also moderated by individual diversity and personality (Røysamb et al. 2018). The “make-up” of each person is constituted by nature and molded by nurture via acclimation, culture, and societal practices. Exposure to the same set of indoor environmental conditions often results in differing responses and effects on performance for different individuals.

These interweave to provide a holistic set of pathways between exposure and performance outcomes. Active behavioral response is often resorted, at the individual level, to achieve immediate mitigation against undesirable sensory or physiological, and even neurological, effects. Such adaptive behavior is not included in this chapter. Seldom do indoor environmental conditions fall so far outside the thermal comfort zone that motor (muscular) control is affected; this will also not be addressed in this chapter.

Sensory Responses as Initiators of Pathways

Exposure may broadly be categorized as *environmental* (generally referred to as indoor environmental quality (IEQ)) or *nonenvironmental*. IEQ dimension is further categorized as indoor air quality (IAQ) or non-IAQ (thermal, noise, vibration, light, visual, and so on). Although thermal and IAQ are almost inextricably linked in most analyses, a distinguishable consideration is that IAQ results in contaminants entering the body (whether through inhalation, ingestion, or dermally), whereas thermal parameters act similarly to the non-IAQ parameters in that they impact the sensory or perceptive dimensions evoking responses that are not associated with contaminants uptake.

Heat, moisture, light, sound, and odorants constitute sensory inputs to the occupant picked up by a plethora of sensory receptors in the eye, ear, skin, nose, mouth, and mucous membranes. Most sensory receptors have a threshold of conscious detection, below which it remains subliminal. Whether subliminal or overt, these stimuli lead to *physiological*, *neurological*, and *psychological* responses that are direct or causative pathways that impact performance.

The responses are manifestations of the body’s systemic adjustment and stress which range from instantaneous through transients and eventually steady state where a new equilibrium is established via homeostasis. The detection of sensory input initiates these pathways leading to effects on performance.

Physiological and Neurological Pathways

Overt (conscious) sensations initiate physiological (homeostasis) responses, and some may invoke psychological reactions; neurological responses may also be affected. Subliminal exposures, though not invoking a conscious psychological perceptive response (which include instantaneous reactions), nonetheless lead to a

homeostasis response after a period of transience when the respective organs react to the pollutants conveyed by the circulatory system (Hutter et al. 2013). The body's sympathetic nervous system (SNS) governs all the organs as the body assembles a holistic and coordinated response to maintain homeostasis. Examples include constriction/dilation of the pupil of the eye in response to light intensity and blood flow regulation to thermal environments. In so doing, other organs are involved.

Reactive responses exhibit *transience* through which adaptation occurs, often reducing the impacts as adjustment occurs to mitigate or de-sensitize the effects of the stimuli, or *accumulation* of effects leading to a build-up of stress that progressively deteriorates cognitive performance. Reactive responses are associated with homeostasis as the body adjusts to minimize the effects of adverse sensory inputs as well as alleviation of stresses resulting from the accumulation of contaminants. The effects are usually bidirectional: When stimuli impose adverse stress, homeostasis may provide limited compensatory adaptation beyond which the deterioration of cognitive function and increase of biochemical stress accumulate, and subsequently, performance increasingly worsens. When the stimuli return toward optimal conditions, the homeostatic stress is relieved, returning cognitive function to the original levels.

Examples pertinent to pathways of performance include the following:

- Heart rate and heart rate variability, blood pressure as the heart optimizes blood regulation (Zhang et al. 2017; Azuma et al. 2018).
- Brain functions (tied intimately with cognitive function) modulate as manifested by the fluctuation of brainwaves of different frequency (as detected by electroencephalography (EEG) (Lang et al. 2022; Abbasi et al. 2020) and cerebral blood flow (Nishihara et al. 2014).
- Lung function reaction to odor and contaminant stimuli detected through end-tidal CO₂ concentration and volume, breathing rate (Mishra et al. 2021).

The intensity of the responses increases mostly disproportionately with the stimuli. The nonlinear effect is exemplified by the Predicted Mean Vote (PMV) thermal response (Fanger 1970), sound loudness (dBA) scale, glare, and olfactory perception (Fanger 1988) scales. Within *comfort* or *acceptable* levels, the responses do not impose significant physiological demands on the body. Less diversion of resources for homeostasis is required, enabling the capacity to maintain performance. As conditions move further away from the comfort or acceptable levels, several mechanisms result in deterioration of performance.

One important receptor which does not have a threshold of consciousness is the intrinsically photosensitive retinal ganglion cells (ipRGCs) which suppress melanopsin expression (Provencio et al. 1998; Hattar et al. 2002). Recently, melanopic light intensity for the workplace and living environment is widely discussed (Vetter et al. 2021).

Whether conscious or otherwise, these stimuli detection initiate bodily responses that subsequently affect cognitive performance, perception, and health. The exposure duration evokes transient responses which are the immediate (first) perception

and sensory reactions, followed by an adaptation where homeostasis effects adjust the physiological and neurological states toward an equilibrium state.

When homeostasis is insufficient to mitigate the adverse effects of pollutant accumulation or sensory discomfort, sick building symptoms (SBS) (called also non-clinical acute health symptoms or building-related symptoms) begin to manifest and have been demonstrated to adversely deteriorate cognitive performance (Tham and Willem 2005). Even the perception of inadequate air quality adversely affects cognitive performance (Wargocki and Wyon 2017; Lan et al. 2020).

Instantaneous effects result from overt (conscious) sensory inputs that directly affect cognitive function. The effect may be favorable or adverse. Adverse effects occur when:

- Compromising the effectiveness of the sensory signals is essential for conveying information for cognitive processes that precede the performance. Glare deteriorates visual acuity, hampering visual content. Loud sounds reduce the speech transmission index (efficiency of communication) by reducing the signal-to-noise ratio rendering it increasingly difficult to differentiate the intended auditory signals from competing disturbances. The tear film quality was reduced and the inter-blink interval was changed at very low RH (Wyon et al. 2006).
- Directly disrupting the primary cognitive processes (Jones et al. 2000; Macken et al. 2003; Sorqvist 2010). Noise, especially irrelevant sounds that contain semantics or rhythm, distracts and leads to the depletion of finite attentional resources that one can devote to focus and decipher the intended message. It also results in interference causing a momentary shift in attention from the focal task due to an unexpected change in the sound environment, which could contain either specific (e.g., their name being called) or generic cues (e.g., phone ringing) to the listeners.
- Sudden overpowering stimuli evoke acute responses and disrupt cognitive resource deployment. Sudden strong odor, a large increase in sound pressure level, or illuminance level are triggers of immediate cognitive disruption, though this is rare, and not usually considered in performance literature.

There are also favorable effects which are attributable to:

- Relief from fatigue that evokes attentional and stress recovery from focused work. Biophilia, or its digital and physical versions, have been demonstrated to affect attention and restoration (Kaplan 1995) and stress recovery (Ulrich et al. 1991).

Two most frequently alluded psychological models of reactive response to stimuli that impact cognitive performance are the arousal (*inverted U*) theory (Yerkes and Dodson 1908) and the *Extended U (Maximal Adaptability) model* (Hancock and Warm 2003).

The *arousal (inverted U)* theory (Yerkes and Dodson 1908) assumes that stimuli directly determine the task performer's cognitive efficiency regardless of other factors. This reduces to a dose-response relationship. Performance of a particular

task improves as arousal (activation, stress, and motivation) increases until reaching an optimal level, especially for cognitively challenging tasks. Beyond this optimum, performance starts to decline when the arousal level continues to rise, and likewise with a reduction below the optimal level of arousal. As an example, for thermal effects, this implies there is an optimal temperature or its subjective perception (thermal sensation, often characterized by the thermal sensation vote) for cognitive performance (e.g., Enander and Hygge 1990; Witterseh et al. 2004).

The alternative *Extended U (Maximal Adaptability) model* (Hancock and Warm 2003) posits that human performance remains relatively stable across a broad range of acceptable stimuli but rapidly deteriorates at the boundaries of stimuli acceptability. Within this range, the attentional resources, alternatively referred to as cognitive capacity, are being drawn upon to compensate for the adverse effects of increasing stimuli stress. When this is depleted, cognitive performance drops sharply. It is not difficult to assume that cognitive adjustments are easily accomplished within the stimuli's comfort zone to maintain near-optimum performance.

Not all stimuli are adverse, and the effects are dependent on the cognitive functions being engaged. Not all work is best suited for the same environment, and the nature of work is best supported by a corresponding combination of the environment to achieve the optimal outcomes. Creative work is better facilitated in slightly warmer environments as contrasted against mundane repetitive work which thrives better in slightly cooler environments.

There is a dichotomy of results of the effect of stimuli on performance: those showing statistically significant effect versus those that do not. Such a dose-response effect is either nullified by the individual diversity or the extended-U model whereby adaptation, or motivation, draws upon the cognitive capacity to sustain performance. For simpler tasks, the sustenance of performance is easily achieved, whereas the stress becomes increasingly difficult as task difficulty/complexity increases. The depletion of attentional resources is accompanied by secretions from the sympathetic nervous system (SNS) and manifested as measurable biomarkers (e.g., α -amylase) (Tham and Willem 2005) and could eventually lead to neurological symptoms of fatigue, headache, and difficulty concentrating and thinking clearly.

Psychological Pathways

Non-IEQ parameters encompass a wide spectrum of factors that influence perception, satisfaction, and affective state with a consequential impact on cognitive performance. Innate (health predispositions and sensitization, personality) and acquired (preferences, expectations, and stereotypes) factors influence the psychological evaluation; mismatch between the actual environment and these personal factors results in environmental stress.

Environmental stressors act indirectly on work performance by reducing state variables: motivation, alertness, and focus that support high-functioning work performance. Exposure to environmental stress appears to erode individuals' ability to compensate for environmental stress, reducing motivation and focus. These results

indicate that environmental stressors reduce not only the cognitive capacity for work but also the rate of work (i.e., motivation) (Lamb and Kwok 2016). Other parameters such as type of space, building design, and working conditions have an impact on the overall satisfaction of indoor occupants. Workspace design, conditions of the ambient environment, lighting, visual and acoustical privacy, status indicators, social relationships, and the availability of personal control are of critical importance to worker satisfaction and productivity (Wineman 2016).

Affective state or mood is susceptible to IEQ parameters. Light can affect mood in several ways: by directly modulating the availability of neurotransmitters such as serotonin, which is involved in mood regulation, and by entraining and stabilizing circadian rhythms, thereby addressing circadian de-synchronization and sleep disorders, which are rather common in people suffering from mental disorders (Blume et al. 2019). A positive mood is demonstrated to lead to better short-term memory and problem-solving.

Environmental and individual diversity coincides with an intrinsic desire for control over the workplace environment.

Concluding Remarks

Sensory receptors constitute the first gateway to pathways of impact. These are moderated by age, health, bodily build (Body mass index, size, and shape), and acclimation (that accounts for adaptation after a sufficient period of adjustment between climates). Genetic inheritance confers predisposition in physiological and neurological responses, asthma being a good example (Dold et al. 1992).

Personality strongly influences the individual's response and resilience to stimuli. It is also partly nature and partly nurture (Røysamb et al. 2018). Personality drives motivation and resilience in tackling and completing tasks, harnessing different degrees of persistence and effort. This often leads to different performance outcomes even when the stimuli are the same.

These pathways impact the response of a person.

Physiologically, homeostasis evokes responses from various organs as the body seeks to restore balance against adverse, or undesirable, states caused by the stimuli. The processes of such balancing may lead to the accumulation of stresses especially when the natural capacity to adapt is insufficient to restore the balance. This accumulation of stresses manifests as SBS symptoms (reduced well-being) in the short term; prolonged and sustained stress eventually impacts health.

In parallel, psychological reactions determined by mindset, values, and attitude express in terms of affective or mood manifestations and influence perception, satisfaction, and acceptability of the environment.

Behavioral adjustment is also relied upon through allostasis; these are actions external to the body including adjustment of clothing level, seeking visual relief through biophilia, and so forth.

As effort is deployed toward tasks, cognitive capacity is depleted and may cause mental fatigue, stress, change in concentration, and alertness; these have been

demonstrated by brain waves of various frequencies through, e.g., EEG measurements, near-infrared spectroscopy (NIRS), and functional magnetic resonance imaging (fMRI).

Physiological, psychological, and neurological responses are interrelated. Together, they impact the cognitive performances across the spectrum of indicators (such as attention, memory, language processing, reasoning, computation, and decision-making).

Abstract

This chapter summarizes information published to date on the effects of human bioeffluents and carbon dioxide (CO_2) on cognitive performance. Few studies have been carried out in this domain. They used simulated office tasks such as mathematical calculation and proof-reading and highly demanding cognitive tasks such as

X. Zhang (✉)

decision-making tests and simulated flights to examine the effects on cognitive performance. Concerning the effects of bioeffluents, the literature shows that the performance of simulated office work was reduced at CO₂ levels above 3000 ppm; at CO₂ levels between 1600 ppm and 3000 ppm, the effects have been observed; below 1600 ppm, no effects were observed. For highly demanding tasks, the effects were seen at the CO₂ level of 950 ppm and over. Concerning the effects of pure CO₂, it was shown that highly demanding tasks were affected at the levels at and over 1000 ppm; however, the results were inconsistent in the published studies, some showing no effects above 1000 ppm; for the tasks simulating office work, incidental effects were seen at CO₂ level of 1200 ppm and 3000 ppm and no effects until 20,000 ppm, and even higher concentrations. These results require validation in future experiments, and mechanisms underlying the observed effects need to be delineated, especially since studies with human cells, *ex vivo*, indicate physiological impacts at the levels of 1000 ppm and higher, above the background level of CO₂. Potential confounders also need careful examination, and they include, among others, an accurate exposure control, quality of cognitive performance measures, population diversities, and the length of exposure.

Keywords

Human bioeffluents · Carbon dioxide · Cognitive performance · Physiological impacts

Introduction

Over the last three decades, the focus in the field of indoor air quality has been on the emissions from building and furnishing materials and equipment. Not much work was dedicated to studying the effects of emissions from humans (human bioeffluents). Because reduced emissions from building and furnishing materials result in human bioeffluents becoming the dominant indoor pollutants, their effects require attention and further studies. Also, they are dominant in densely occupied spaces such as school classrooms and conference rooms. Consequently, the focus has been turned on bioeffluents and carbon dioxide (CO₂), a primary human bioeffluent. Recent studies have documented that they may impair cognitive performance at levels typically occurring indoors (Fisk et al. 2019; Du et al. 2020).

This chapter summarizes the published evidence on the impact of human bioeffluents and CO₂ on cognitive performance and explores the possible mechanism underlying the observed effects.

Effect of Human Bioeffluents (with Carbon Dioxide) on Cognitive Performance

Very few experiments attempted isolating the effects of bioeffluents from the effects caused by exposures to other pollutants. In these studies, different concentrations of bioeffluents were established by varying ventilation rates.

Consequently, the concentrations of pollutants emitted by other sources also change unless reduced to a minimum and could, therefore, contribute to the observed effects (Du et al. 2020).

Only six studies provide information on cognitive performance during exposures to human bioeffluents alone. Four out of the six studies examined the effects using tasks representing real-world performance. Bakó-Biró (2004) exposed 23 subjects to two different levels of human bioeffluents for 2.8 hours. They observed no change in the performance of simulated office work, including the tasks such as text typing, addition, and multiplication when metabolically generated CO₂ levels, representing the exposure level to bioeffluents, increased from 650 ppm to 1100 ppm. Maula et al. (2017) created two bioeffluent exposures so that CO₂ levels were 540 ppm and 2260 ppm; the experiments were performed in a low-polluting office and different exposure levels by altering the ventilation rate. After 4-hour exposure, 36 subjects reported only a weak effect on their work memory performance at higher bioeffluent exposure level represented by the higher CO₂ concentration, while various other task types were unaffected. Zhang et al. (2017a, b) exposed 25 subjects in a climate chamber for 255 minutes to three levels of human bioeffluents with the corresponding CO₂ concentrations of 500 ppm, 1000 ppm, and 3000 ppm. They examined the effects of exposure to human bioeffluents on cognitive performance using multiple tasks similar to those used by Bakó-Biró and tests measuring different cognitive abilities and found a significant decrease in simulated office tasks and cue-utilization tests only when the CO₂ level was 3000 ppm. In a follow-up study, Zhang et al. (2017c) compared the responses of ten subjects at a bioeffluents level with CO₂ concentration at 1600 ppm with that at 500 ppm and did not observe any significant differences in performance of office-like tasks.

The remaining two studies examined the effects on highly demanding cognitive skills using the Strategic Management Simulation (SMS) test. Maddalena et al. (2015) showed that, when 16 subjects were exposed for 4 hours to bioeffluents when CO₂ was at the level of 1800 ppm, there was a significant reduction in their decision-making performance compared with 900 ppm, although there were no differences between the conditions in terms of subjectively reported perception of air quality or acute health symptoms. Allen et al. (2016) used SMS to examine the relationship between human bioeffluents exposure (by altering ventilation rate) and decision-making performance among 24 subjects. Their results show that during exposures to a moderate bioeffluents level with a CO₂ concentration of 950 ppm, subjects scored higher in eight of nine domains of the decision-making test than their performance at reference exposure with a CO₂ level of 500 ppm.

In summary, the short-term exposures to human bioeffluents (≤ 4.5 hours) at the levels corresponding to real life-exposures (CO₂ ≤ 3000 ppm) were shown to negatively affect the tasks simulating office work when CO₂ levels representing the levels of bioeffluents were above 1600 ppm, while highly demanding cognitive functions at the CO₂ level of 950 ppm. Further research on the discrepancy between different findings is necessary.

Effect of (Pure) Carbon Dioxide on Cognitive Performance

This section examines studies that investigated the effects of exposure to pure CO₂, independently of other bioeffluents.

CO₂ is classified as a central nervous system depressant by National Institute for Occupational Safety and Health (NIOSH). Chronic exposure to elevated levels of CO₂ (>8000 ppm) can lead to symptoms like headache, sleepiness, irritability, tremors, and enlarged retinal veins (NIOSH 1976). The Occupational Safety and Health Administration (OSHA) specifies a permissible exposure limit (PEL) as 5000 ppm, averaged over an 8 hours per day, 5 days working week (OSHA 2019); the ceiling level is 30,000 ppm for 15 minutes exposure.

The negative effects of exposure to elevated CO₂ can also be expressed by the increased partial pressure of CO₂ in arterial blood (PaCO₂). The effect is called hypercapnia, an excess of CO₂ in the human body, and is agreed to occur when PaCO₂ > 45 mmHg (Aida et al. 1998; Kawata et al. 2007).

Effects at Carbon Dioxide Concentrations Typically Occurring Indoors (CO₂ < 5000 ppm)

Studies in the past two decades since 2000 have focused on exposures to CO₂ levels under the OSHA's PEL of 5000 ppm; such exposures are relevant for nonindustrial environments. Some of these studies have reported that exposures to pure CO₂ reduced performance with complex decision-making (Strategic Management Simulation – SMS), at 1000 ppm, 1400 ppm, and 2500 ppm (Allen et al. 2016; Satish et al. 2012), and reduced successful completion of subjectively rated maneuvers in a flight simulator at 1500 ppm and 2500 ppm (Allen et al. 2019). However, the performance in SMS tests administered to trainee astronauts (Scully et al. 2019) and submariners (Rodeheffer et al. 2018) did not decline during exposures to pure CO₂ at 2500 ppm, 5000 ppm, and 15,000 ppm. However, Scully et al. (2019) observed a decline in performance, using SMS, at CO₂ of 1200 ppm compared to 600 ppm, but no effects at higher exposures to CO₂.

The tests conducted using office-like tasks and neurocognitive test batteries on the contrary have not found performance being affected at exposures to pure CO₂ between 500 ppm and 5000 ppm (Zhang et al. 2016, 2017a, b), at 3000 ppm (Liu et al. 2017) and 4000 ppm (Xia et al. 2020), and comparing 1500 ppm and 5000 ppm or 3500 ppm and 5000 ppm (Zhang et al. 2020). However, Kajtar and Herczeg (2012) observed reduced performance of proofreading at 3000 ppm, Snow et al. (2019) found an absence of learning effect with CO₂ exposure of 2700 ppm, and Zhang et al. (2020) reported a significant decline in performance of the Multi-attribute Task Battery (MATB) tasks when the CO₂ concentration increased from 1500 ppm to 3500 ppm; no significant differences were actually observed between 1500 ppm and 5000 ppm, or 3500 ppm and 5000 ppm. Scully et al. (2019) noted a declining trend in aggregate accuracy, speed, and efficiency scores at CO₂ exposure of 1200 ppm compared to the baseline of 600 ppm (similar

to the effects observed for SMS performance reported above), but no effects at higher levels of CO₂. Lee et al. (2022) proposed an integrated task performance measure, combining task performance and EEG signals, using which they found an impact on cognitive tasks related to working memory and simple reaction, for tasks undertaken at 500 ppm versus 1000 ppm, but no impact was found for 500 ppm versus 2500 ppm.

Using human neutrophils, an ex vivo study showed the elevated generation of microparticles with a high inflammatory cytokine content when incubated in a buffer equilibrated with 1000–4000 ppm additional CO₂, above background level (Thom et al. 2017). The enhanced production of these microparticles lasted for several hours after short-term exposure to elevated CO₂. An increase of the end-tidal CO₂ levels (ETCO₂) to hypercapnic levels of 47 mmHg while breathing through a mouthpiece did not affect cognitive performance or alertness (based on EEG) (Bloch-Salisbury et al. 2003). Zhang et al. (2021) noted greater effort expended, based on ECG and EEG signals, at CO₂ exposures of 3000 ppm and 5000 ppm, compared to 1500 ppm. These results indicate a possible mechanism of how elevated CO₂ levels may impact the functionality of human organs that needs careful further investigations.

Effects at Carbon Dioxide Concentrations Higher than PEL (CO₂ > 5000 ppm)

Though not found in typical buildings, levels of CO₂ higher than the PEL from OSHA (>5000 ppm) can be encountered in specialized circumstances like submarines, granaries, breweries, etc. Rodeheffer et al. (2018), even when using SMS with submariners, did not detect any impact on cognitive performance at exposure to 15,000 ppm of CO₂. In a sustained exposure to CO₂ at 20,000 ppm, over 4 hours, which included bouts of exercise, specific physiological parameters like blood pH and respiratory rate increased but remained within normal ranges, and task performance was not impacted, vis-à-vis exposure at 700 ppm (Maniscalco et al. 2021).

Divers, breathing air with 10,000 ppm and 20,000 ppm CO₂ over 60 minutes (Haran and Lovelace 2015) and 15,000 ppm and 30,000 ppm CO₂ over 30 minutes (Selkirk et al. 2010), did not show significant impact on cognitive and postural stability assessments. Some of the divers reported increased depth and rate of breathing, headaches, and labored breathing (Haran and Lovelace 2015), and long-term memory showed a slight adverse impact (Selkirk et al. 2010). Even at 30,000 ppm exposure, the divers' ETCO₂ had not reached hypercapnic levels.

For concentrations well above OSHA PEL, Sayers et al. (1987) found a threshold of 55,000 ppm CO₂ inhalation or 51 mm Hg for ETCO₂ for exposures of 20 minutes, beyond which the performance in reasoning tasks was reduced, but accuracy and short-term memory remained unaffected.

Breathing 75,000 ppm CO₂ showed an arousal effect, helping focus attention during simpler tasks, but increased respiratory rate during a complex task (Diaper

et al. 2012). In combination with physical strain, the inhalation of 40,000 ppm CO₂ showed an impact on stimulus encoding and response choice (Vercruyssen 2014), but the inhalation of CO₂ at 30,000 and 40,000 ppm (Vercruyssen et al. 2007) and 40,000 and 50,000 ppm (Sheehy et al. 1982) did not have any effect on the performance of psychomotor and cognitive tests.

Long-Term Exposures (>1 Day)

Most of the research reported above examined short-term exposures to pure CO₂ from minutes (inhalation experiments) to maximum of an office day – 8 hours (Allen et al. 2016). There have been a few studies examining exposures beyond 24 hours. Twenty-six days at CO₂ of 7000 ppm had a small effect and at 12,000 ppm had a significant effect on tracking performance (Manzey and Lorenz 1998), but the effect sizes of neither were such to consider that they had an operational significance. Head-down tilt bed rest (HDBR) is used as a space flight analog. A 26.5-hour HDBR in ambient air increased response speed and adversely affected accuracy while overall cognitive efficiency remained comparable; when HDBR was combined with exposure to 5000 ppm CO₂, response speed reduced and accuracy improved (Basner et al. 2017). Self-reports of mental fatigue and physical fatigue increased as more time was spent in the CO₂ exposure condition. Exposed to 5000 ppm CO₂, participants were less likely to report a headache, sleepier, and less bored. Examining cognitive tasks performance of nine astronauts, with exposures of up to 7 days, no clear association was found between CO₂ levels and performance though it was concluded that CO₂ levels of 2600–3300 ppm in the space stations could likely lead to a 1% risk of reported headaches (James et al. 2011). The anecdotal report had suggested that during space flights, crew ability with complex tasks reduces – compared to when on the ground – and analysis pointed to a level of 2000 ppm is the limit above which decision-making was affected (James 2013). A limitation of studies related to space flights concerning the effects of pure CO₂ is that the exposures confound the impact of just CO₂ with other pollutants, including bioeffluents.

Exploring the Possibility of Underlying Physiological Mechanisms

Figure 1 illustrates the plausible physiological pathways explaining the effects of exposures to CO₂ with and without other bioeffluents.

If required, the human body can store up to 120 liters of gaseous CO₂ (Adolph et al. 1929; Seed et al. 1970). It is difficult to ascertain a single value of CO₂ as a safe exposure limit due to wide inter-individual variations (Permentier et al. 2017). Hypercapnia can affect multiple bodily systems, including the brain and central

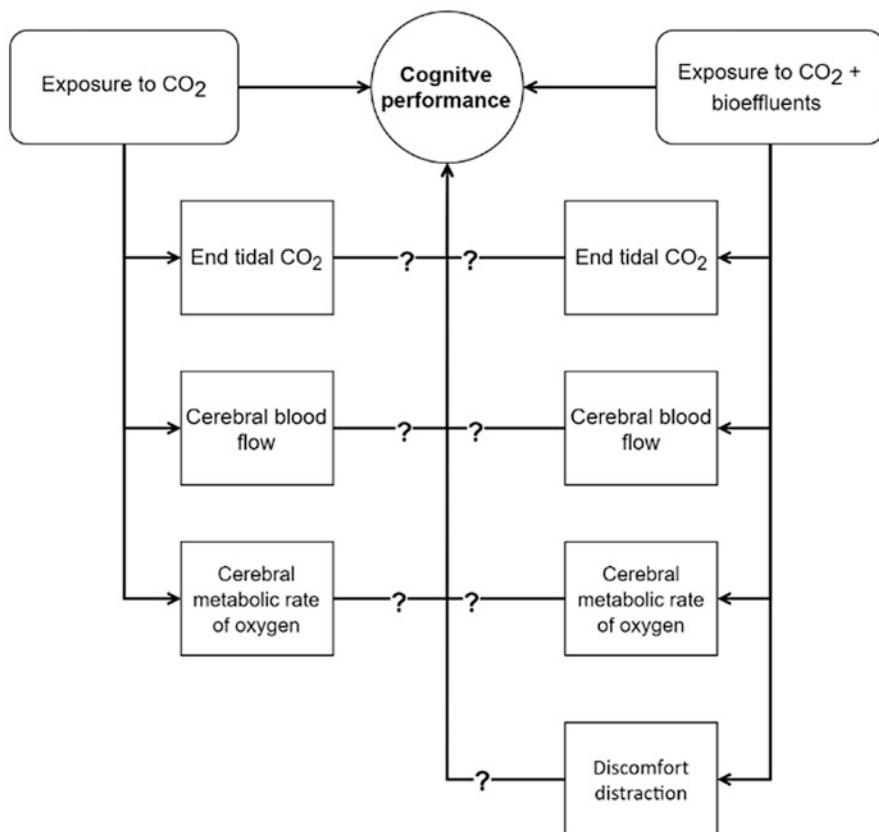

Fig. 1 An illustration of hypothesized modes of how exposures to CO₂ and bioeffluents could physiologically impact cognitive performance

nervous system (CNS) and the cardiorespiratory system. ETCO₂ relates closely to PaCO₂ and, thus, body CO₂ levels (McSwain 2010; Young et al. 1991).

While the impact on the cardiorespiratory system does not directly impact performance as the impact on CNS, an increase in heart rate and blood pressure and labored breathing could very well impact task performance. The likely mechanisms are explained below.

Physiological responses to increased levels of bioeffluents (at lowered ventilation) include increased cerebral blood flow (CBF) (Sliwka et al. 1998). PaCO₂ is the most influential regulator of CBF (Madden 1993). Increased CBF can cause headaches, thus impacting performance (Madden 1993; Nishihara et al. 2014). A minimal increase in PaCO₂ tension (4–6 mmHg) is probably required to initiate cerebral vasodilation (Battisti-Charbonney et al. 2011; Patterson et al. 1955; Wasserman et al.

1962), but this is an effect of breathing ~25,000 ppm CO₂ (Patterson et al. 1955). These levels are unlikely to occur indoors.

Change in cerebral metabolic rate of oxygen (CMRO₂) was found to be proportional to change in ETCO₂ (Xu et al. 2011). Without a significant change in ETCO₂, it is likely that CMRO₂ does not change either. Exposure to CO₂ with bioeffluents, and not just high levels of CO₂, can increase ETCO₂ (Schaefer et al. 1963; Vehviläinen et al. 2016; Zhang et al. 2017a, b; Garner et al. 2011), hence can impact CMRO₂. In a poorly ventilated meeting room with a mean CO₂ level of 2756 ppm, the PaCO₂ levels of occupants reached ~48 mmHg (Vehviläinen et al. 2016). Similar levels of PaCO₂ have been recorded at much higher exposures to just pure CO₂ (without bioeffluents); these levels were >15,000 ppm CO₂ (Reich and Rusinek 1989; Schaefer et al. 1963).

Another reason behind the cognitive effects of bioeffluents could be the symptoms that result from poor ventilation like odor dissatisfaction, tiredness, tightness in the chest, nose/sinus symptoms, etc. (Apte et al. 2000; Kim et al. 2018; Lu et al. 2015; Myhrvold et al. 1996). The human brain has limited capacity, and the cognitive load theory of performance (Sweller 2011) suggests that if it is distracted due to discomfort, performance would also be negatively impacted.

Research so far has not included vulnerable populations like children, the elderly, and people with respiratory issues (chronic obstructive pulmonary disease (COPD), asthma, and alike). It is known that age reduces sensitivity to hypoxia and hypercapnia, but that does not allow extrapolation regarding cognitive effects (Janssens et al. 1999; Permentier et al. 2017). Studies would also need to consider longer-term chronic and chronic-intermittent exposures. Since low ventilation levels lead to an increase in other pollutants along with bioeffluents, future studies would need to explicitly exclude the impacts of other pollutants when examining cognitive performance.

Conclusions

The evidence in the literature suggests that both human bioeffluents and CO₂ itself, at the level typically occurring indoors (CO₂ ≤ 5000 ppm), could impair cognitive performance. However, the effects could occur at different levels also depending on the type of cognitive tasks performed (Fig. 2).

It should also be underlined that there remain significant inconsistencies in the findings regarding the impact on performance, especially with the effects of pure CO₂. At the same time, there is an incomplete understanding of how exposure to bioeffluents affects cognitive performance. An aspect that needs careful consideration in future studies is accurate exposure control. Isolating the exposure to bioeffluents from other indoor pollutants is a much-needed step. Other potential confounders include duration of exposure, use of a standardized set of cognitive measures, and backgrounds of participants. One aspect that has not been investigated is the role of CO₂ in modifying the effects of other pollutants, i.e., an adjuvant effect of CO₂.

	CO_2	Human bioeffluents (with CO_2)	
Cognitive impacts	 Office-like tasks  Highly demanding tasks	No adverse effects until 20,000 ppm, possibly higher. Incidental effects at 1,200 ppm and 3,000 ppm. Adverse effects at and over 1,000 ppm, but inconsistent. Adverse effects over 1,600 ppm.	
Physiological impacts	 End-tidal CO_2  Human neutrophils- <i>ex vivo</i>	Hypercapnic levels reached between 15,000 to 25,000 ppm and over. Significant increase in inflammatory cytokines generation at 1,000 ppm and higher, above background levels.	Hypercapnic levels at 2,700 ppm. No data.

Fig. 2 A summary of observed effects, on different physiological and cognitive aspects, due to exposure to CO_2 and CO_2 with other bioeffluents

Abstract

We reviewed 32 studies published since 1980 that have examined the effects of indoor air quality (IAQ) on work performance in non-industrial and non-educational spaces. We found that (i) reduced ventilation rates (VR)—indicative of poor air quality—can affect some aspects of cognitive performance, hence the performance of office work; (ii) toluene effects on work performance

were only found at high concentrations that are not common in office buildings; (iii) the effects of CO₂ – as a pollutant and not as a proxy for ventilation – were not consistent, as some studies found effects, others did not; (iv) similar inconsistencies as for CO₂ were found for the effects TVOCs. Plausible reasons explaining the discrepancies are differences in tested populations such as participants' age and occupation, sleep quality, experiment design, exposure time, task complexity, and uncertainty in pollution exposure. In addition to the research necessary to clarify the observed discrepancies, future investigations should focus on developing a shared understanding of the meaning of work performance and what are the methods and metrics to measure it, and estimating the magnitude and shape of the relationship between different variables that represent IAQ such as ventilation rate or CO₂ and performance.

Keywords

Indoor air quality · Ventilation · CO₂ concentration · VOC · Work performance · Productivity · Cognitive performance

Introduction

Humans spend more time living in enclosed spaces, such as buildings, than at any other time in their evolution (Kleppeis et al. 2001). Indoor air quality (IAQ) is different from outdoor air quality. It has received increasing attention from governments, political institutions, and the scientific community. In this subchapter, we aim to review publications that have examined the effects of IAQ on work performance in non-industrial and non-educational spaces and were published from 1980.

We proposed 1980 as the starting date because two documents were published around this year that highlighted the importance of IAQ and probably increased the scientific community's interest in the subject. The first document, titled *Health Aspects Related to Indoor Air Quality* (WHO 1979), created awareness about the possible health consequences of decreased ventilation rates (VR) in buildings due to the adoption of several energy-saving proposals to counteract the oil crisis of the 1970s. The second document, *Indoor Pollutants Field* (National Research Council 1981), requested by the US Environmental Protection Agency (EPA), noted that insufficient importance had been given to indoor air exposure despite IAQ potentially being more critical to human health and well-being than outdoor air.

Studies Examining the Effects of IAQ on Work Performance

We found 32 studies in 28 peer-reviewed journal articles published between 1983 and 2021; Table 1 provides the summary. The difference between the number of studies and articles is because Tham and Willem (2005), Kajtár and Herczeg

Table 1 Summary of studies examining the effect of indoor air quality on office work performance

Study	Journal	Location	Exposure place	No. of conditions ^{a/} Duration of exposure per condition	No. of participants ^{b/} Occupation	Performance assessment	Summary of results ^{c/}	Classification ^{d/}
Cedeño Laurent et al. (2021) ^k	Environmental Research Letters	China, India, Mexico, Thailand, USA, and UK	NA	12 months (Longitudinal observational study)/ 15 min/ week	302/ Office workers	Stroop color-word test and two-digit, visual addition–subtraction test	Five cognitive performance metrics of office workers were significantly associated with real-time indoor concentrations of PM2.5 and CO ₂	C

^a Number of comparable IAQ conditions (e.g., indoor environmental parameters remained barely unchanged except for one of the proxies of the IAQ – CO₂, VOCs, VR)

^b Number of subjects per IAQ condition (The studies of Belum et al. (1985, 1990) and Rodeheffer et al. (2018) were a between-subjects experiment)

^c All experiments used a within-subjects intervention design except for Rodeheffer et al. (2018) and Belum et al. (1990), that used a between-subjects intervention design, and Cedeño Laurent et al. (2021) that was a longitudinal observational study

^d (A): Studies where IAQ was altered by modifying the concentration of specific pollutants (e.g., adding CO₂ or VOCs). (B): Studies where pollution levels were altered by modifying ventilation rates. (C) Studies where pollution levels were altered by adding or removing a pollution source and/or sink

^e Neurobehavioral Evaluation System (NESF): (1) Primary Behavioral Tests: Auditory Digit Span, Visual Digit Span, Finger Tapping, Continuous Performance Test, Symbol Digit Substitution, Serial Digit Learning Pattern, Pattern Memory, Switching attention, Mood scales. (2) Secondary Behavioral Tests: Associative Learning, Pattern Comparison, Simple Reaction Time, Grammatical Reasoning, Horizontal Addition

^f Walter Reed performance assessment battery (PAB): two-letter search, two-column addition, logical reasoning, serial addition/subtraction, Stroop 1, running memory, six-letter search, and code substitution. Simulated office work: Text typing, addition, knowledge test, and recall test.

^g Ventilation rates in combination with air filters

^h Cognition tasks: Motor Praxis (MPT), Visual Object Learning Task (VOLT), Fractal 2-Back (F2B), Abstract Matching (AM), Line Orientation (LOT), Digital Symbol Substitution (DSST), Balloon Analog Risk (BART), Psychomotor Vigilance Test (PVT), Matrix Reasoning (MR), Emotion Recognition Task (ERT)

ⁱ Strategic Management Simulation (SMS) measures: Basic Activity Level, Task Orientation, Breadth of Approach, Basic Strategy, Applied Activity, Level Focused Activity, Level Information Orientation, Information Utilization, and Initiative

^j CNS Vital signs: executive function, reaction time, working memory, complex attention, simple attention, sustained attention, and cognitive flexibility

^k Results are based on modeling rather than experimenting. Generalized additive mixed models were used to quantify the individual effects of PM2.5 and CO₂ on each of the five cognitive test metrics of interest:

Two environmental target levels were evaluated per environmental exposure of interest:

PM2.5	CO ₂
Low	High
Concentrations of below 50% (<6 $\mu\text{g m}^{-3}$) of the US National Ambient Air Quality Standard (NAAQS)	Concentrations of above 100% (>12 $\mu\text{g m}^{-3}$) of the US National Ambient Air Quality Standard (NAAQS)
	Low <600 ppm High >950 ppm

(2014), Maddalena et al. (2015), and Allen et al. (2016) reported two studies per publication each. In our literature search, we only looked for peer-reviewed journal articles that examined the effects of IAQ on office work performance. As independent variables representing IAQ (exposures), we used ventilation rates, CO₂ concentration, fine particles, and volatile organic compounds (VOC) but not odor exposure. The dependent variables (effects) were diagnostic tests, simulated office work tasks, and the existing work performance outcome metrics. Absence rates and self-estimated performance were not considered.

The reviewed studies were conducted in 12 countries with 1212 young adults and adults whose weighted mean age was 31 years. In the identified studies, 45% of the participants were college or university students (which we consider as young adults), 13% were call center agents, 19% had different professions such as nurses, pilots, university staff, submariners, and astronauts, while for the remaining 23%, the occupation was not reported. The median number of subjects per study was 27 persons, while the largest included 302 participants (Cedeño Laurent et al. 2021) and the smallest ten subjects (Kajtár and Herczeg 2014; Zhang et al. 2016a). The exposure time to each indoor quality condition examined ranged between 1 and 8 h (mean exposure time = 247 ± 113 min), except for the studies conducted in call centers and the study of Cedeño Laurent et al. (2021), which lasted longer than one day.

We classified – and summarized below – the studies into three groups according to which effects were examined and how the indoor air pollution load was altered. The classification was done as follows:

- A. Studies where IAQ was changed by modifying the concentration of specific pollutants (e.g., adding CO₂ or VOCs) while maintaining all other parameters unchanged: The exposure to the particular pollutant is changed.
- B. Studies where pollution levels were altered by modifying ventilation rates: At higher VRs, a decrease in the exposure level is expected due to the dilution of the contaminants.
- C. Studies where pollution levels were altered by adding or removing a pollution source and/or sink: An increase/decrease in the exposure level is expected, but the pollutants added or removed and the changes in their concentrations are not specified.

Figure 1 shows a timeline chart with the 28 articles ordered by the year of publication. It can be seen that while during the eighties, the focus was on examining the effects of toluene and other VOCs on work performance, attention shifted to ventilation rates at the beginning of this century and to CO₂ in the last decade. This latest shift is probably a consequence of the awareness among researchers of the increasing levels of CO₂ in outdoor air and how the subsequent increase in indoor concentrations could affect work performance in the future.

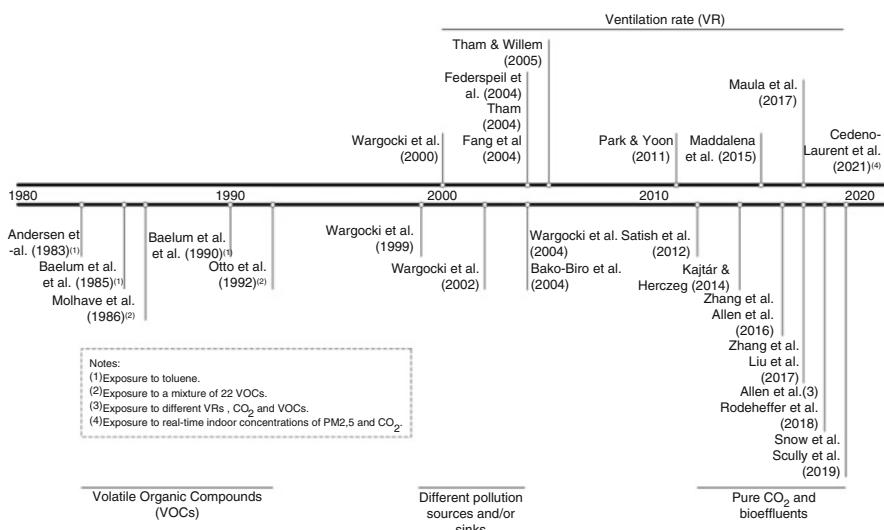

Fig. 1 Timeline chart showing the articles included in this review ordered by year of publication

Studies Where Pollution Levels Were Altered by Modifying the Concentration of Specific Pollutants

The Effects of CO₂ on Work Performance, Simulated Work Performance, and/or Cognitive Abilities

Before 2012, CO₂ was considered to have significant effects on human performance only at very high concentrations (>10,000 ppm) (e.g., Sayers et al. (1987)). Therefore, studies that, before this year, documented associations between indoor CO₂ and performance at the typical concentrations that occur in non-industrial buildings attributed them not to the presence of CO₂ but a change in the indoor air pollutant load indicated by a change in the levels of CO₂, i.e., CO₂ was considered a marker of other contaminants and not a pollutant itself. However, this way of thinking was challenged by the results of the experiment of Satish et al. (2012), which showed that when CO₂ concentration was increased from 600 to 1000 ppm by injection rather than emitted by humans, moderate and statistically significant decrements occurred in the performance of a computerized test called Strategic Management Simulation (SMS) – a decision-making performance test – while large reductions occurred at 2500 ppm.

The results of Kajtár and Herczeg (2014) and Allen et al. (2016), published a few years later, supported this statement. Kajtár and Herczeg (2014) conducted two studies. Although no significant differences were observed in the first experiment, the participants performed significantly worse at the high CO₂ levels (3000 and 4000 ppm) in the second one. For their part, Allen et al. (2016), who used the same testing battery as Satish et al. (2012), observed that the scores of seven of the nine SMS

decision-making measures decreased when the CO₂ concentration was raised from 945 ppm to 1400 ppm. However, Zhang et al.'s (2016a, 2017) and Liu et al.'s (2017) studies showed no significant effects of elevated artificially injected CO₂ exposures on cognitive performance. Zhang et al. (2017) hypothesized that a plausible explanation for the discrepancies found was the difference in the cognitive tasks applied and their difficulty – the tests included in the SMS battery were more complex than the "*simple cognitive tests and tasks resembling office work*" they applied. This may be further explained by the Maximal Adaptability Theory, which posits that subjects were able to draw upon their cognitive capacity to compensate against adverse effects of higher CO₂ exposures to maintain their performance under less cognitively demanding tasks.

Unlike previous studies that used SMS, Rodeheffer et al. (2018) did not observe significant differences for any of the nine SMS measures of decision-making between the CO₂ exposure conditions (600, 2500, and 15,000 ppm) and Scully et al. (2019) – who also used the Cognition test battery – observed them only at 1200 ppm, but not at 2500, or 5000 ppm; in Scully et al. (2019) the effects at 1200 ppm were seen both for the performance of SMS and other cognitive tasks. Rodeheffer et al. noted that the effect sizes in their experiments were very low, suggesting that any potential change in cognitive function attributed to CO₂ exposure is of little importance in practice. They also argued that differences in the results could be attributable to the acclimation of their participants – submarine sailors who were used to work in environments with high CO₂ concentrations. For their part, Scully et al. (2019) pointed out three possible explanations for the disagreements with previous studies. The first one refers to differences in population type – while in the studies of Satish et al. and Allen et al., the participants were university students, Scully et al. and Rodeheffer et al. used astronauts and submariners, who by their profession could have high performance and due to their rigorous training, could be better prepared to withstand the cognitive impairment/demand and could have developed compensatory responses. However, this does not explain the performance decline when the astronauts were exposed to 1200 ppm of CO₂. The second reason stated by Scully et al. was the age of the participants – they were older in the Scully et al. (mean age = 38.8 year) and Rodeheffer et al. (mean age = 30 year) studies, and according to Scully et al., there is abundant evidence that the way young and/or novice individuals make decisions differ from those who are older and/or more experienced. As proof of this, Scully et al. found that there is a more remarkable similarity in the most affected measures between the studies of Satish et al. and Allen et al. and their study and Rodeheffer et al. Finally, the third reason is related to the amount of sleep obtained by the subjects before the exposure to CO₂. According to the study by MacNaughton et al. (2017), who also used SMS, an increase in sleep hours by 25% was associated with improvements in cognitive functions by almost 3%. The difference in sleep time between the participants of Scully et al. and Satish et al. could not be carried out because the latter did not report this information.

Allen et al. (2018) – same research group as Allen et al. (2016) – conducted an experiment to examine the effects of elevated CO₂ on commercial airline pilots in a flight simulator, finding that performance was better at 700 ppm and 1500 ppm than at 2500 ppm.

Finally, Snow et al. (2019) experimented in a small naturally ventilated office, where participants were exposed to three conditions: baseline, normal CO₂ (830 ppm), and high CO₂ (2700 ppm). The results showed that performance did not decrease during the high CO₂ condition; however, the authors interpreted the absence of an expected learning effect in two tests to suggest that CO₂ might still have adversely affected performance. Self-reported sleepiness was significantly higher in the normal and high CO₂ conditions relative to baseline but was not correlated with the CO₂.

In summary, the discussion on whether CO₂ is in itself a pollutant that affects cognitive performance is not settled for now because there are substantial discrepancies between the results of the experiments. Five studies found effects ((Satish et al. 2012; Kajtár and Herczeg 2014; Allen et al. 2016, 2018; Snow et al. 2019), but another five did not (Kajtár and Herczeg 2014; Zhang et al. 2016a, 2017; Liu et al. 2017; Rodeheffer et al. 2018), and one found them at 1200 ppm, but not at 2500 and 5000 ppm (Scully et al. 2019). Moreover, a physiological mechanism has not been yet proved, and Mishra et al. (2021) showed that CO₂ found in buildings does not affect human respiration performance.

The Effects of Volatile Organic Compounds (VOCs) on Cognitive Abilities

Three studies examined the effects of toluene on cognitive performance (Andersen et al. 1983; Bælum et al. 1985, 1990); all of them were conducted by the same research group in Denmark. Participants were exposed to conditions that ranged from clean air to 377 mg/m³ (100 ppm) of toluene. Bælum et al. (1985) were the only ones who found significant effects on two perceptual and one visuo-motor tests; however, the impact occurred when the toluene concentration was 377 mg/m³ (100 ppm), which will only happen in workplaces where toluene is used industrially, so the results do not constitute evidence that this VOC will reduce work performance in non-industrial buildings, at least not at the levels indoors.

Mølhav et al. (1986) and Otto et al. (1992) investigated the effects of a low-level concentration combination of 22 VOCs – typical of those present in new buildings – on performance; both experiments exposed participants to concentrations of 0, 5, and 25 mg/m³ measured as a toluene equivalent concentration. These values were chosen to reflect pure (clean) air, typical new-home concentrations, and the highest concentration found in new Danish homes. While the first study results showed that the scores on both digit span forwards and backwards decreased significantly, in the second one only a marginal deterioration was observed in the forward visual digit span at 25 mg/m³. Because this finding was isolated and not expected, it was considered a random occurrence. According to Otto et al., the differences found between the results of both studies were because of two reasons: design problems in the experiment by Mølhav et al. that they attempted to amend (e.g., unlike Mølhav et al., all sessions were conducted at the same time and control and exposure sessions were separated by at least one week to reduce fatigue, carry-over effects and effects time of day), and differences in sample characteristics (e.g., Mølhav et al. used an equal number of men and women, the age range was wider, and the participants were selected because were chemically sensitive and had a documented history of indoor weather problems).

Studies Where Pollution Levels Were Altered by Modifying Ventilation Rates

Office-Like Controlled Environments

Wargocki et al. (2000) examined the effects on cognitive performance by changing ventilation rates (VRs) set to be 3, 10, and 30 L/s per person. A 20-year-old carpet equivalent to floor room size was placed behind a partition so the participants could not see it. The results show that the participants typed 4% more characters per minute when the VR was increased from 3 to 30 L/s per person. Fang et al. (2004) conducted a study that used the same space, carpet, sample size, office work tasks, and exposure time as Wargocki et al. (2000) but new subjects. Despite these similarities, increasing VR from 3.5 to 10 L/s per person did not cause significant effects on cognitive performance. The authors argued that their experiment was not specifically designed to look at the effect of VRs on performance – as Wargocki et al.’s did – which could explain the differences in the results.

With an experimental design similar to the previous ones – but without adding additional sources of indoor air pollution other than those generated by the participants (bioeffluents) – Park and Yoon (2011) and Maula et al. (2017) examined the effects of different VRs on cognitive performance: 5, 10 and 20, and 2.3 and 28.2 L/s per person, were used respectively. In Park and Yoon’s (2011) experiment, participants performed better on the tasks of text typing (5.2%), addition (4.7% above), and memorization (8%) at higher VRs, confirming Wargocki et al.’s (2000) findings and extending their results to other cognitive abilities. After analyzing indoor air during exposure, researchers found high concentrations of volatile organic compounds (VOCs) due to a recent renovation of the exposure chamber. For their part, Maula et al. (2017) found no differences in the text typing task as in previous experiments. In contrast, participants performed statistically significantly better at the information retrieval and operation span tasks. Because differences were only found in one task and as a trend in another, while performance was unaffected in five tasks, the authors categorized the effect of VR on cognitive work performance as “weak”.

Maddalena et al. (2015) carried out two experiments with a slightly different experimental procedure; the cognitive performance was measured with SMS. In the first one, ventilation rates of 2.6 and 8.5 L/s per person were provided while maintaining a ventilation rate of ≥ 5.6 L/s per m^2 ; while in the second, 5.5 and 0.8 L/s per m^2 were provided while maintaining a ventilation rate of ~ 8.4 L/s per person. The results of both studies showed that at low VRs, there was a moderate but statistically significant reduction in cognitive function of all performance metrics – except for Information Management – from the SMS battery test.

Call-Centers

Five studies have examined the effects of VR alone (Federspiel et al. 2004), or in combination with temperature (Tham 2004; Tham and Willem 2005), or air filters (Wargocki et al. 2004) on the work performance of call center agents. Tham (2004)

examined two levels of outdoor air supply rates (5 and 10 L/s per person) at two temperature settings (22.5 °C and 24.5 °C). The author found that talk time was reduced significantly when the outdoor air supply rate was increased from 5 L/s per person to 10 L/s per person at 24.5 °C.

Fedderspiel et al. (2004) studied the effects of ventilation as the only variable on performance; for this purpose, the difference between indoor and outdoor CO₂ concentrations (ΔCO_2) was increased from 13 to 610 ppm. However, the authors did not observe significant changes in wrap-up time, and even though the talk time was faster when the VR was higher, the relationship was not strong.

Wargocki et al. (2004) conducted a study in a call center where the participants were exposed to four different conditions by alternating a new air filter with one that had been in place for 6 months and by adjusting the outdoor air supply rate to 2.5 and 25 L/s per person. The results show that increasing the outdoor air supply rate reduced talk-time by 6% with a new filter in place but increased talk time by 8% with the used filter. Replacing the used filter with a clean filter reduced the talk-time by approximately 10% at the high ventilation rate but had no significant effect at the low rate. Ozone chemistry on the dirt accumulated in used filters is known to produce by-products with an adverse effect on the olfactory sense and likely affected performance (Bekö et al. 2007; Fadeyi et al. 2009).

Tham and Willem (2005) used a 2X2 intervention experiment design where supply rates and temperatures in two call centers were modified. In call center A, the VRs were 3 and 6 L/s per person, while in call center B, 9 and 18 L/s per person. The temperatures were the same at the two sites (22.5 °C and 24.5 °C). The authors found that at 24.5 °C, doubling the VR significantly reduced the talk time by 7% to 9%, while at 22.5 °C, the talk time increased in both call centers, but differences were not significant. As causal mechanisms, Tham and Willem (2005) suggested that a decrease in the VR could have increased symptoms related to neurological behavior and reduced self-perceived productivity, which in turn could have manifested itself through the observed increase in mean talk time.

In summary, except for the studies of Fang et al. (2004) and Fedderspiel et al. (2004), all other studies conducted in controlled office-like settings and call centers positively impacted cognitive performance by increasing ventilation rates. Improvements were found in (i) decision-making tasks – all the SMS battery tests except for the Information Management test, (ii) office work tasks, (iii) cognitive abilities tests (memory), and (iv) existing performance outcomes (talk time). Higher VRs could improve the IAQ by removing and/or diluting pollutants. The outdoor air was assumed to be clean but chemical characteristics were not always reported. This assumption does not hold in many parts of the world. As discussed by Maula et al. (2017), it is essential to underline that significant effects were found only in a subset of the tests and tasks applied and sometimes in only one of the metrics used to measure cognitive performance (i.e., speed or accuracy). Furthermore, it would be convenient to estimate the magnitude of the effect (the effect size) predicted by the research hypothesis to know if the difference found is large enough to be of practical importance (Lakens 2013).

Relationships Between Ventilation and Cognitive Performance

Using nine studies published between 1997 and 2004 in journals, conferences, and reports, Seppänen et al. (2006) developed a relationship between work performance and increased ventilation. Five studies were conducted in call centers (Wargocki et al. 2000; Heschong Mahone Group 2003; Federspiel et al. 2004; Tham 2004; Tham and Willem 2004), one in an office building (Heschong Mahone Group 2003), two in an office-like controlled environment (Wargocki et al. 1999; Bakó-Biró 2004), and one in a classroom with students aged 16 to 19-years (Myhrvold and Olsen 1997). According to the authors, the reviewed studies showed an improvement in the average performance – between 1 and 3% – when the ventilation with outdoor air increased by 10 L/s per person. In the proposed relationship, the authors estimated that performance improves in the ventilation range of 6.5 to 17 L/s per person with a 90% confidence interval (CI) and up to 15 L/s per person with a 95% CI. Ventilation rates above 45 L/s per person were not seen to improve the performance. Despite its wide use, some limitations should be considered before using Seppänen et al.'s relationship. The limitations of a relationship between temperature and work performance developed by the same authors following a similar approach, and which may thus be applied to this relationship, are discussed in detail by Porras-Salazar et al. (2021).

Studies Where Pollution Levels Were Altered by Adding or Removing a Pollution Source and/or Sink

Wargocki et al. (1999) carried out a study in Denmark in which the pollution levels were altered by introducing and removing a 20-year-old used carpet. The results show that when the pollution source was present, the participants typed 6.5% less text. Using a similar experimental methodology as Wargocki et al. (1999), Wargocki et al. (2002) carried out an experiment in Sweden where the speed and accuracy of text typing were 1.5% and 7% lower when the old carpet was present. When comparing both experiments – Danish and Swedish – the authors found that the agreement between them was moderate ($Kappa = 0.477$, $P = 0.0005$).

Bakó-Biró et al. (2004) performed a similar experiment but under the presence or absence of 3-month-old personal computers (PCs) with the cathode-ray tube (CRT) monitors. Throughout the exposure, the outdoor air supply was maintained at 10 L/s per person. Text typing and reading speed decreased by 0.5% and 4% respectively, and errors increased by 20% with the PCs present.

Allen et al. (2016) examined the effects of different IEQ conditions that were representative of “conventional” (higher concentrations of VOCs – between 500 and 666 $\mu\text{g}/\text{m}^3$) and “green” (low concentrations of VOCs – less than 50 $\mu\text{g}/\text{m}^3$) office buildings in the United States. Before the participants arrived, different sources were placed in the diffuser that provided air to the office cubicles to enhance the level of VOCs. Authors found that, on average, cognitive scores were 61% higher under “green” building conditions, their cognitive performance being measured using SMS.

The main limitation of the studies described above is that the use of an uncharacterized source of pollution makes it difficult to compare the results with other studies and/or generalize the findings.

Limitations and Future Work

Across the selected studies, various work performance assessment methods were used including simulated work tasks, cognitive tests, and existing work performance outcomes. However, some of them have shortcomings, such as that the tasks could be simple and could not capture the complexity of office work (Mishra et al. 2020), or the selection of task or test batteries was not always justified. An exception is the study of Scully et al. (2019), where the selection of the Cognition battery was based on the fact that it was explicitly designed to evaluate the cognitive performance of astronauts, and each of the included tasks is related to a cognitive domain and the areas of the brain that are primarily recruited to perform them. The increase in the use of physiological and biochemical evaluations in the indoor environmental quality (IEQ) field has opened the possibility of a better understanding of what the causal mechanisms involved in the relationship between IAQ and work performance could be; however, more research is required on the subject because so far few studies have used them (e.g., Zhang et al. 2016a, b).

There is a need to discuss how the results of the studies in which IAQ effects on performance were observed should be interpreted. The discussion should extend to how the results are reported so they can be used in meta-analyses. The debate should help answer some questions: Is a statistically significant effect on one or two tests reason enough to conclude a deterioration in overall work performance? Which type of tests are affected? Are the effects on some abilities more critical than others? Besides the statistical significance, should the magnitude of the effect be considered? Lack of shared agreement can lead to misinterpretations or opposing interpretations of similar findings. For example, Park and Yoon (2011) applied seven tests and found statistical significance in two of them. They concluded that increasing VRs would improve work performance. On the opposite, in the study of Maula et al. (2017), where a battery of seven tests was used to assess the performance, the authors concluded that the effect of VR on work performance was “weak” because statistically better results were obtained only in two out of the seven tests.

Regarding the magnitude of the effect, the null hypothesis significance test method (NHST) should be complemented with the estimation and notification of the effect size (ES) and its confidence interval (CI), as has been the case in other research fields among behavioral and social sciences (Nickerson 2000; Johnson 2016). ES is a quantity that directly measures the strength of the association or difference between variables and has the advantage that allows researchers to: (i) present the magnitude of the effects in a standardized manner, (ii) easily compare the results of different studies, and (iii) plan new studies (e.g., estimate sample sizes) (Lakens 2013). Across the included articles, only Rodeheffer et al. (2018) reported

the Eta-squared (η^2) – that as the r^2 describes the proportion of variance that is explained by group membership (Lakens 2013) – and its 95% CI. Another good practice that will allow the subsequent estimation of the ES – when not reported in the articles – and will ensure research can be reproduced and reanalyzed, is to provide raw data or data allowing the calculation of the effect size.

Ventilation rates are likely to affect work performance; however, an optimal VR has not yet been defined that, for example, allows adequate removal or dilution of pollutants without using excess energy, or can reduce the spread of airborne pathogens, or be efficient in controlling heating and cooling loads.

With the exception of the studies by Mølhave et al. (1986), Bælum et al. (1990), Allen et al. (2018), and Scully et al. (2019), the subjects who participated in the selected studies were generally healthy young adults between 20 and 35 years old, and there were no studies where the mean age of the subjects was greater than 40 years. This may be related to the difficulties of recruiting middle-aged subjects (36–64 years) to participate in the experiments; however, as life expectancy and retirement age increase, it is necessary to investigate the effects of IAQ in middle-aged workers and people with health problems.

Finally, the selected studies, regardless of whether they were carried out in a call center, a flight simulator, or in a climatic chamber, followed similar procedures in which the participants worked individually and in front of a screen where they had to complete a list of very specific tasks for a short time without real-life consequences if the work was not done correctly. Under these circumstances, essential performance dimensions like contextual, adaptive, and counterproductive performance could not be assessed. However, in most office workplaces today, employees are exposed to a complex and dynamic environment where, for example, prosocial and adaptive behaviors are highly desired by organizations because of the importance of skills such as leadership, communication, negotiation, teamwork, creativity, honesty, and self-management. Therefore, extrapolating overall work performance from these simple tasks is hard. Consequently, IAQ researchers have so far been able to examine the effects of IAQ on task performance primarily and laterally and sporadically capture contextual and prosocial performance indicators (e.g., attention to duty, creativity). It would be desirable to advance experimental designs and performance metrics further so that the effects of IAQ on overall job performance can be better described.

Conclusions

Table 2 presents our conclusions for each of the three categories we divided the 32 studies included in this literature review. The results show that (i) an increase in ventilation rates has a positive impact on cognitive performance – at least for some cognitive abilities – and therefore for the performance of office work; (ii) toluene effects on work performance were only found at high concentrations that are not common in office buildings. The results are inconsistent for the studies that examined the effects of pure CO₂ and TVOCs.

Table 2 Summary of conclusions

Categorisation	Subcategorisation	Number of studies	Main conclusion
How pollution load was altered	Type of space/ type of pollutant		
By modifying the concentration of specific pollutants	NA/ CO ₂	11	The results of the studies have substantial discrepancies. Five studies found effects ((Satish et al. 2012; Kajtár and Herczeg 2014; Allen et al. 2016, 2018) + Snow et al. (2019) who found no differences between conditions, but concluded that the absence of an expected learning effect suggested that CO ₂ may have affected performance), another five did not (Kajtár and Herczeg 2014; Zhang et al. 2016a, 2017; Liu et al. 2017; Rodeheffer et al. 2018), and one found them at 1200 ppm, but not at 2500 and 5000 ppm. (Scully et al. 2019). Four of the studies used a computer-based test of decision-making performance called the Strategic Management Simulation (SMS), half of them found effects, and the other half did not.
	NA/ TVOCs	3	Only three studies have been conducted, and the results are contradictory and difficult to compare due to the design of the experiments. Therefore, more research is needed to resolve the discrepancies found.
	NA/ Toluene	3	One of the three studies showed effects but at a toluene concentration rarely found in non-industrial spaces – 377 mg/m ³ (100 ppm). Consequently, it can be concluded that at the concentrations under which toluene is commonly found in office buildings, it does not affect workers' performance.
By modifying ventilation rates	Office-like controlled spaces/ NA	6	Increasing VRs improved participants' performance in all SMS battery tests except for Information Management, as well as on office tasks – typing and addition – and cognitive abilities tests — memorization. Higher VRs may have improved air quality by displacing and/or diluting pollutants.
	Call centres/ NA	5	Four of the five studies found effects; however, three of them belong to the same research group and were conducted in the same location.

(continued)

Table 2 (continued)

Categorisation	Subcategorisation	Number of studies	Main conclusion
How pollution load was altered	Type of space/ type of pollutant		
			Taking into account that an increase in VR had a positive effect on performance in office-like controlled spaces, it would be expected that it will also have it in office centers. New studies could strengthen this hypothesis and the findings so far.
By adding or removing a pollution source and/or sink.	NA/ NA	4	There are five studies and due to their characteristics are difficult to compare with other experiments.

Plausible reasons that may explain the discrepancies in the results include (i) differences in populations, i.e., age (Scully et al. 2019), occupation (Rodeheffer et al. 2018; Scully et al. 2019), and health status of the participants (Otto et al. 1992); (ii) differences in experimental designs, i.e., sample size, within or between subjects design (Rodeheffer et al. 2018); (iii) presence of uncharacterized contaminants (Maula et al. 2017); (iv) sleep status of the participants (Scully et al. 2019); (vi) exposure time (Kajtár and Herczeg 2014; Allen et al. 2018); (vii) task complexity (Zhang et al. 2016a); and (viii) uncertainty in pollution exposure. Additionally to the research needed to address the discrepancies observed in the studies examining the effects of CO₂ and TVOCs, future investigations should focus on: (i) developing a shared understanding of the meaning of work performance and the methods and metrics to measure it, (ii) estimating the magnitude and shape of the relationship between ventilation rates and performance, (iii) exploring the effects of IAQ on the performance for mid-age workers and people with compromised health conditions, and (iv) exploration of the causal mechanisms involved in the relationship between IAQ and work performance.

Abstract

This chapter describes the evidence of the effects of indoor air quality (IAQ) on learning of children and gives an overview of the size of the effects expected. The results from the published experiments on the effects of classroom air quality on the performance of schoolwork do confirm that these effects are systematic and show that improving classroom air quality will have a significant positive effect on some aspects of learning, both on cognitive skills and academic attainment, as well as academic achievements and absence rates. Present studies show that to ensure classroom IAQ conducive to learning, CO₂ levels (indicating the adequacy of ventilation) should be kept below 900 ppm at all times. It should be ensured that windows can be opened when needed, to improve classroom IAQ, and CO₂ sensors should be installed to indicate when windows must be open (or any other

measure to improve IAQ must be executed) if the CO₂ concentration is too high and when they should be closed to conserve energy.

Introduction

Poor air quality in classrooms has been shown to occur frequently (Angell and Daisy 1997). In addition to increasing the risks of adverse health effects and discomfort, it has been shown to reduce schoolwork performance.

Classroom air quality was mainly examined by either monitoring outdoor air supply rates or changing them and observing the subsequent effects; only in a few cases, particle levels, ozone, and semivolatile organic compounds (SVOCs) in classrooms were measured and associated with learning outcomes.

CO₂ concentrations were used to assess classroom ventilation rates because CO₂ is emitted at a known rate by every occupant; thus, CO₂ levels are a convenient indicator of the outdoor air supply rate and ventilation efficiency. In this chapter, CO₂ should therefore be considered such an indicator and not a pollutant even though pure CO₂ was shown in a few studies to affect adults' cognitive performance though the effects were not consistent (Fisk et al. 2019; Du et al. 2020). No research was done in which pure CO₂ has been shown to affect the performance of tasks resembling schoolwork.

Different methods for measuring the effects on the learning performance of pupils were used in the published reports. Children's ability to perform schoolwork was assessed by simple cognitive tests examining different skills needed for proper learning, such as the ability to concentrate and to memorize and recall information, typical school tasks examining arithmetical and language-based skills, the tests developed by educational departments, the number of pupils passing public exams, and the rate of absenteeism. Most of the studies examining the effects of indoor air quality and ventilation on the performance of schoolwork and learning used psychological and neurobehavioral tests.

The studies were mainly carried out in schools.

The Effects on the Performance of Schoolwork and Absence Rates

The Effects on Psychological and Neurobehavioral Tests

Cross-Sectional Studies

Myhrvold et al. (1996) found a weak association between CO₂ levels and simple reaction time that suggested a positive effect of increased ventilation on performance when CO₂ was reduced from 1500–4000 ppm to <1000 ppm. Ribic (2008) observed

improved performance on the d2 test, a standard test for measuring concentration and attention when the CO₂ concentration was reduced from around 3800 ppm to 870 ppm (absolute level). Sarbu and Pacuraru (2015) found that students' performance on two psychological tests requiring concentration, and cue-utilization (Kraepelin test and Prague test) improved linearly when CO₂ levels were reduced from about 2000 ppm to 500 ppm.

Intervention Studies

Coley et al. (2007) and Bakó-Biro et al. (2012) improved the air quality in classrooms by either allowing students to open the windows or retrofitting the classrooms with an external ventilation system specially designed for the experiments, installed in the window and making it possible to either deliver outdoor air or to recirculate the air already in the classroom. In the former study, the levels of CO₂ were reduced from about 2900 ppm to 690 ppm, and this had a positive and significant effect on tests measuring reaction time; the authors concluded that the power of attention was improved. In the latter study, the ventilation rate was increased from about 1 L/s per person to 8 L/s per person (CO₂ levels were reduced from about 1500–5000 ppm to <1000 ppm). This intervention significantly improved the performance of tests examining reaction time, concentration and attention, recognition, and memory. The effects were from about 3% to 15%. None of these studies identified the level of ventilation for optimal performance, but they showed that improving the air quality in classrooms would provide benefits, and no threshold effect was identified.

Matsson and Hygge (2005) installed electrostatic air cleaners operated or disabled in two pairs of classrooms. Five tests similar to schoolwork were applied. The air cleaners reduced the concentration of airborne particles found in classroom air and tended to reduce the amount of cat allergen, but the effect did not reach statistical significance. When the air cleaners were operated, children "stating themselves to be sensitive to airborne particulate contaminants" experienced a significantly more significant reduction in eye and airway irritation. These pupils scored about 25% higher on one of the five performance tests (finding synonyms). However, the authors themselves cite "multiple testing" (i.e., chance) as a possible reason for the apparent significance of this isolated effect.

Effects of Specific Pollutants

Hutter et al. (2013) showed that the cognitive performance of about 600 pupils in the first and second grade in nine elementary schools improved with reduced levels of tris(2-chlorethyl)-phosphate (TCEP) in PM10, PM2.5, and dust; they also found an association between a polycyclic aromatic hydrocarbon and cognitive performance. This is one of the few studies reporting the effects of specific pollutants on the cognitive performance of children in schools. Hutter et al. (2013) observed that lower CO₂ levels (indicating a higher ventilation rate) were associated with improved performance in parallel to these observations. Cognitive performance was measured using the Standard Progressive Matrices test, a nonverbal assessment tool used to measure the reasoning component of general intelligence. The pupils

performed it for about 45 min. TCEP is a phosphor-organic compound used widely in plasticizers, flame retardants, and floor sealing and is currently a substance of serious concern in terms of its long-term health effects.

The Effects on Typical School Tasks

Intervention Studies

Many studies used shorter tests examining the ability to read, comprehend, and calculate (e.g., Wargocki and Wyon 2013). In studies reported by Wargocki and Wyon (2013), pupils performed arithmetical calculations and language-based tasks under different air quality conditions achieved by changing the outdoor air supply rate between 3 and about 10 L/s per person. The existing mechanical ventilation system was used after increasing the fan capacity and re-balancing the system to direct more outdoor air to one of the two classrooms in which performance was being compared. The children's usual teachers administered parallel versions of language-based and numerical performance tasks representing different aspects of schoolwork, from reading to mathematics. The presentation of tasks was distributed relatively evenly during each experimental week, and the teachers were asked to apply the same task always on the same weekday. The speed at which the tasks were solved was improved with increased ventilation, but there were no effects on errors. Similar results were observed in studies reported by Bakobiro et al. (2012), Petersen et al. (2015), and Hviid et al. (2020), who used research protocols very similar to those of Wargocki and Wyon. In the study by Bakobiro et al. (2012), the air quality in classrooms was improved by retrofitting the classrooms with an external ventilation system specially designed for the experiments, as described above. They showed that the time needed to solve simple mathematics tests was reduced when the ventilation rate was increased from about 0.3–0.5 to 13–16 L/s per person. Petersen et al. (2015) performed a double-blind 2x2 crossover intervention in four classrooms with 10–12-year-old children. The outdoor air supply rate was modified by the decentralized ventilation units installed in each classroom that did not change the background noise level, which was about 35 dB(A). They showed that increasing outdoor air supply rate from 1.7 L/sp. to 6.6 L/sp. improved performance for tasks involving addition, number comparison, grammatical reasoning, and reading and comprehension. No effects on the % errors were seen. Hviid et al. (2020) also used a crossover design in elementary school classrooms and measured the performance of 10–12-year-old pupils. They examined the effect of artificial light and ventilation rate and found that when the outdoor air supply rate was changed from 3.9 L/s per person to 10.6 L/s per person, and at the same time the lighting was changed from 450 lux (color temperature 2900 K) to a dynamic cool light (4900 K) at 750 lux, processing speed and concentration improved, as well as mathematical processing.

Wargocki et al. (2008) installed electrostatic air cleaners in 6 classrooms in 3 schools. The experiments were carried out in winter and early spring. The classrooms in which the experiments were conducted were mechanically ventilated with 100% outdoor air. The interventions were implemented in a crossover design in parallel classrooms. The electrostatic air cleaners had their intended effect on airborne

particle concentrations, which were substantially reduced by operating the air cleaners in all size ranges. Airborne particle concentrations were lower in all size ranges the more outdoor air a given school provided to its classrooms (as would be expected if there were significant indoor sources of particles) and were reduced more markedly in the smaller size ranges. Operating electrostatic air cleaners also reduced settled dust on horizontal surfaces. However, there were no effects on the performance of a wide range of tasks selected to be characteristic of schoolwork, including the language-based and mathematics tasks used by Wargocki and Wyon (2007). Since in the other experiments Wargocki and Wyon (2007) showed that increasing outdoor air supply rate improved the performance of pupils, it was inferred that the effects on the performance of schoolwork should be attributed to gaseous pollutants and not to the particles, since the operation of electrostatic air cleaners recirculating classroom air will not have changed the gaseous pollutants in the air (unless some gaseous pollutants such as semivolatile organic compounds (SVOCs) could permanently adsorb on the deposition plates and did not desorb).

The Effects on National and Aptitude Tests and Examination Results

Cross-Sectional Studies

Haverinen-Shaughnessy et al. (2011) measured CO₂ levels in 100 fifth grade classrooms in 100 schools and showed that poor ventilation reduced the number of pupils managing to pass language and mathematics examinations. A linear relationship was found suggesting 3% more pupils passed the tests for every 1 L/s per person increase in ventilation up to 7 L/s per person. In another study in 140 fifth grade classrooms in 70 schools, Haverinen-Shaughnessy and Shaughnessy (2015) showed that mathematics scores improved by about 0.5% for every 1 L/s per person increase in ventilation rate in the range from 0.9 to 7 L/s per person. Mendell et al. (2016) performed 2-year-long measurements in 150 classrooms in 28 schools and showed that increasing ventilation rates had positive effects on mathematics and English scores, although only in the latter case did the effects reach statistical significance: a 10% increase in ventilation resulted in a 0.6 point increase in the score obtained in the English test. This was a very small effect, as the average scores for this test were about 350–380 points. Toftum et al. (2015) evaluated academic achievement using scores from a standardized Danish test scheme, adjusted for a socioeconomic reference score; the scheme includes mainly language-based and mathematics tests and tests examining fluency in other subjects (for the higher grades only). The lowest national test scores were generally found for pupils in classes with CO₂ concentrations above 2000 ppm, although the association was insignificant. Pupils in schools with some means of mechanical ventilation scored on average higher in the national tests than pupils in schools with natural ventilation, probably because the efficacy of ventilation was higher. In contrast to these studies, Gaihre et al. (2014) did not find any relation between air quality approximated by the levels of CO₂ and educational attainment measured as the % of class attaining the average level expected for the group. The absence of an effect could be due to the choice of performance measure or the season when the measurements were performed: The measurements were made in 60 naturally ventilated classrooms

in 30 schools during the non-heating season (May–June). The range of CO₂ measured was quite large (between 600 ppm and 2100 ppm), but it is unclear whether the CO₂ levels measured for 3–5 days were representative of typical exposure levels experienced in the classrooms over the whole school year. Kabirikopaei et al. (2021) performed measurements in 220 classrooms in schools and found associations between higher ventilation rates and higher reading scores but no mathematical scores; seasonal dependence was observed in the effects observed in fall. Fine particle counts, but not coarse, were associated with mathematics scores, while ozone with reading scores. They also observed that the presence of unit ventilators was associated with lower mathematics scores compared with multizone systems; the presence of unit ventilators was associated with higher coarse particle counts, lower ventilation rates, and higher background noise (Lau et al. 2020).

Experimental Studies

Murakami et al. (2006) examined whether changing air quality affects learning by college students taking courses preparing them for architectural examinations. A recorded lecture was played from a DVD so that each class received the same amount and type of education and the same information from the same teacher, creating a reproducible learning environment. Indoor air quality was modified by changing the outdoor air supply rate between 0.4 h⁻¹ and 3.5 h⁻¹. Air temperatures also changed between conditions, from about 24–25 °C at the higher ventilation rate to 27–28 °C at the lower rate, so the observed effects of improved air quality on learning were confounded with a temperature change; it was not possible to disconnect the two effects. The results of experiments showed the positive effect of improving air quality on learning. Ito et al. (2006) performed laboratory experiments that were similar to the studies by Murakami et al. (2006), the difference being the students sitting in a climate chamber where the same conditions were created as in the field intervention experiment by Murakami et al. All other experimental aspects were the same. They obtained very similar results to those in the intervention experiments of Murakami et al.

The Effects on Absence Rates

Some studies measured illness absence and associated it with poor air quality or poor classroom ventilation to examine the effects indirectly on learning outcomes, although there is no clear evidence that short-term absence affects the academic performance of students (Mendell and Heath 2005).

Cross-Sectional Studies

Piloto et al. (1997) showed in a cohort study that air pollutants from gas heaters had a negative effect on attendance at school, which was presumed to be due to a negative effect on children's health. Berner (1993) showed an association between poor maintenance of schools and the children's poor academic achievement. Ervasti et al. (2012) found increased short-term sick leave among teachers in schools with poor perceived air quality. Shendell et al. (2004) found that student absence decreased by 10–20% when the CO₂ concentration decreased by 1000 ppm in 434 American

classrooms. A study of Gaihre et al. (2014) in Scottish schools showed that an increase of 100 ppm of CO₂ corresponds only to a 0.2% increase in absence rates (roughly one order of magnitude lower than the data of Shendell et al. (2004)) corresponding roughly to 0.5 days a year in the 190-day school year. Simons et al. (2010) found high student absenteeism associated with poor ventilation in 2751 New York schools. A study performed in day-care centers equipped with a balanced mechanical ventilation system found that increasing the air change rate by 1 h⁻¹ would reduce the number of sick days by 12% even though the ventilation rates were relatively high, high enough for the CO₂ levels to remain below 1000 ppm, and on average around 640 ppm (Kolarik et al. 2015). A very comprehensive study in 162 Californian classrooms observed that illness absence decreased by as much as 1.6% for each additional 1 L/s per person of the ventilation rate (Mendell et al. 2016); this is again lower than the data of Shendell et al. (2004) but higher than the data of Gaihre et al. Deng and Lau (2018) monitored conditions in 85 elementary school classrooms (ca. 1900 pupils) and correlated them with student illness-related absenteeism. They observed that the presence of fine particles during the cooling season increased absence rates, while the increased absenteeism during the heating season was caused by reduced ventilation (indicated by the increased CO₂ levels).

Sleep and Learning

Indoor air quality in homes can disturb sleep quality and next-day performance, as shown in studies that examined the correlation between sleep quality and next-day concentration (Tynjälä et al. 1999; Meijer et al. 2000). Disturbed sleep is a widespread problem, but insufficient data are documenting whether indoor air quality in bedrooms plays an important role in these outcomes. Akimoto et al. (2021) summarized studies reporting the effects of bedroom IAQ on sleep quality and showed that when CO₂ concentration in bedrooms is below 800 ppm, no disturbance to sleep is expected. Effects on sleep quality are likely between 800 and 1000 ppm and were seen to occur above 1000 ppm. At CO₂ levels at and above 2600 ppm, sleep quality and next-day performance are affected. The latter results were obtained in experiments in dormitories where students slept with high and low outdoor air supply rates that were achieved by a simple fan mounted in the air-intake aperture (Strøm-Tejsen et al. 2016). They reported that the air in their room was fresher, they felt more refreshed, and their mental state was better when the fan was in operation. Their objectively measured sleep efficiency (time spent asleep) was higher, and their performance on a concentration test taken in the morning was better when the fan was on.

The Relationships Between Learning and IAQ

Wargocki et al. (2020) summarized published studies on the effects of indoor air quality in classrooms on children's performance in schools. Using the published data, they created relationships between CO₂ (as a marker of ventilation efficiency

and the outdoor air supply rate) and the measured performance of schoolwork, national and aptitude tests and exams, and absenteeism; the performance of schoolwork was characterized by performance on tests measuring cognitive abilities and skills and school tasks including mathematical and language-based tasks.

Figure 1 shows the relationship between schoolwork performance (speed or reaction time) and the concentration of classroom CO₂ or ventilation rate; ventilation rate was estimated using CO₂ concentration. There were negligible effects on schoolwork performance regarding the precision (accuracy) with which the tests were performed, and these results are not shown. The results show that children perform schoolwork 12% faster (and 2% more accurately, not shown) when the outdoor air supply rate is such that the resulting CO₂ concentration in a typical classroom is 900 ppm instead of 2100 ppm.

Figure 2 shows the relationship between the performance of national and aptitude tests and examination results and the concentration of classroom CO₂ or the ventilation rate as estimated from the resulting CO₂ concentration. The results show that school test and examination results are 5% better when the outdoor air supply rate is such that the resulting CO₂ concentration in a typical classroom is 900 ppm instead of 2400 ppm. This demonstrates that the effects of classroom air quality on schoolwork performance do predict its effects on examination results, although the magnitude of the effect is only half as large. They also show that classroom air quality effects on school test and examination results predict national test results, widely regarded as the most reliable indicator of overall learning.

Figure 3 shows the relationship between absence rates and the concentration of classroom CO₂. The results show that reducing CO₂ from 4100 ppm to 1000 ppm

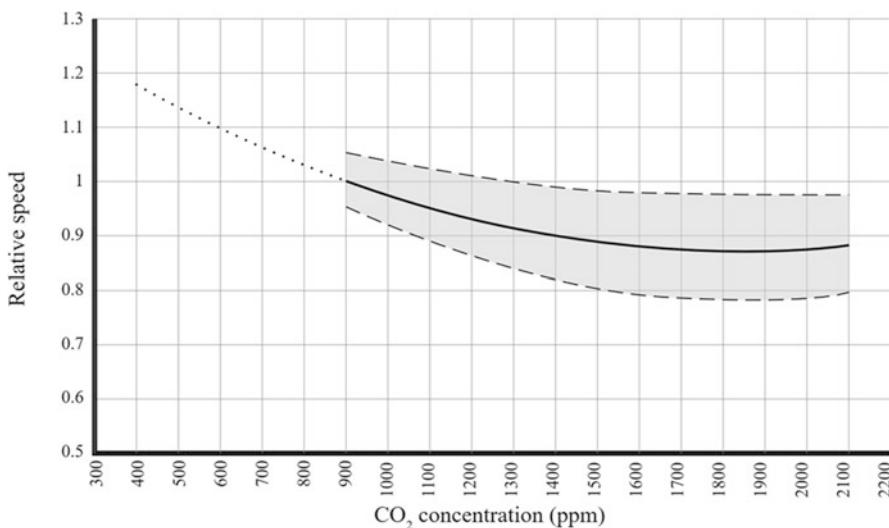

Fig. 1 Performance of schoolwork as a function of CO₂

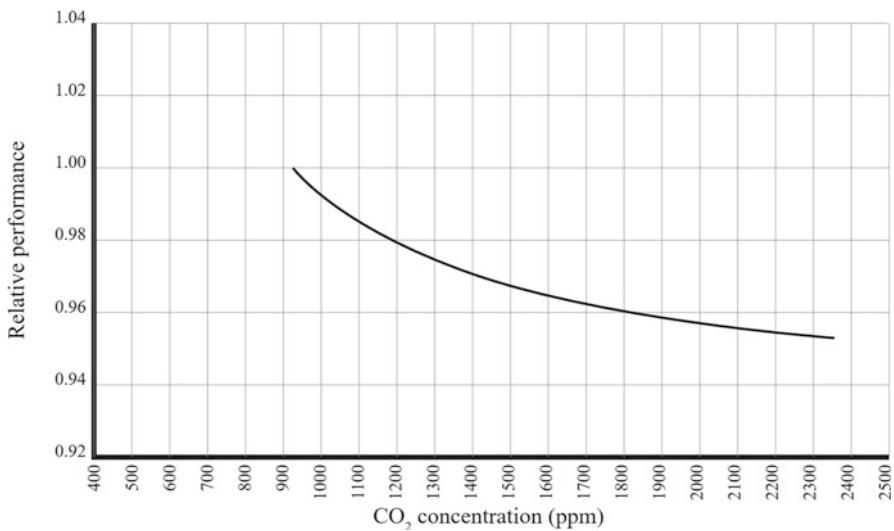

Fig. 2 The results of national and aptitude tests and examination results as a function of CO₂ indicating ventilation efficiency (left) and ventilation with outdoor air (right)

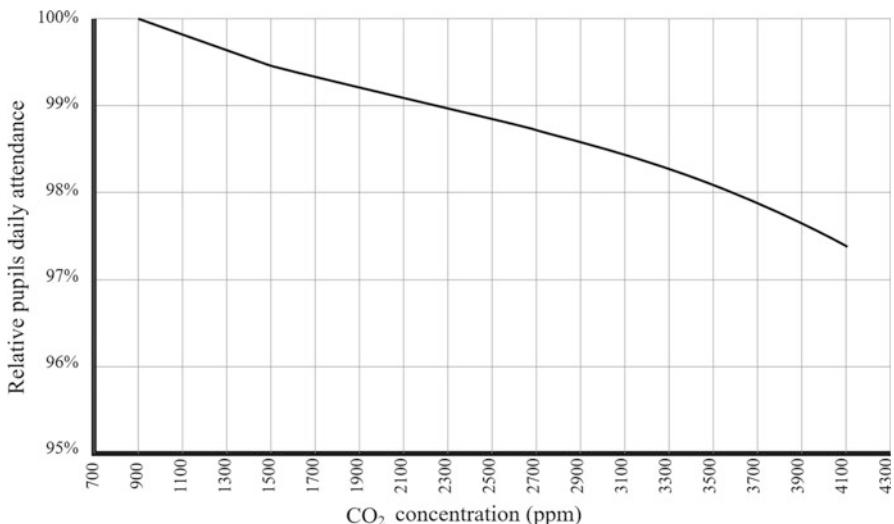

Fig. 3 Absence rates of pupils in a school as a function of CO₂

would increase daily attendance by 2.5%. They suggest that an increased outdoor air supply rate can reduce cross-infection between children or mitigate pre-existing conditions that cause absenteeism. An increased outdoor air supply rate removes and dilutes airborne pathogens as well as gas-phase air pollutants and the

concentration of airborne particles (Li et al. 2007), and to the extent that absenteeism is due to children staying home while sick, this must be presumed to be the mechanism for the observed effect on absenteeism. Therefore, to reduce the impact of future pandemics on learning in school, maintaining a high outdoor air supply rate must be viewed as a viable strategy. However, recirculation through filters that remove very fine particles from indoor air may remove some pathogens. Even recirculation through coarser filters will benefit pupils suffering from allergies during the season when pollen is present in classroom air.

Conclusions

The results from the published experiments on the effects of classroom air quality on the performance of schoolwork do confirm that these effects are systematic and show that improving classroom air quality will have a significant positive effect on some aspects of learning, both on cognitive skills and academic attainment, as well as academic achievements and absence rates. The level of this effect is not the same across different studies as might be expected since learning can also be affected by the IAQ conditions in homes.

Although long-term learning outcomes are expected to be affected by the absence of abilities to perform simple psychological tests and the ability to read, calculate, and comprehend, the connection between the progress in learning and these abilities is not very well documented. Therefore, some studies measured IAQ effects on long-term learning using standardized tests, which national education departments often develop. These tests monitor progress in learning, benchmark individual pupils and schools, and evaluate teaching methods and curricula effectiveness over time. The studies described did not use interventions to classroom conditions. However, they used a cross-sectional approach, i.e., they monitored classroom ventilation in many schools and related these measurements to the results obtained by the children in those classrooms in standardized tests adjusting the results for numerous confounders, including socioeconomic factors. These studies showed that long-term learning outcomes are affected by the poor air quality in classrooms in the same way as the ability to perform simple psychological tests and the ability to read, calculate, and comprehend. They thus validate the use of simple tests to predict progress in learning.

The results of studies examining the effects on absence rates in schools are quite systematic and suggest that increasing classroom ventilation may substantially decrease illness absence. This may affect the learning experience though there is no clear evidence linking the short-term absence of pupils and academic performance. It is also worth mentioning that many other factors not necessarily related to school environments can influence the absence rates.

Learning can also be affected by the effects of bedroom air quality on sleep quality, but the studies published to date are only a few and inconsistent.

Summarized results suggest that increasing the ventilation rate in classrooms estimated using measured CO₂ concentrations from 2 L/s-person to 10 L/s-person

(see also Wargocki et al. 2020) can bring significant benefits in terms of learning performance and pupil attendance; no data are available for higher ventilation rates. However, there are still many unanswered questions, for example, the extent to which classroom occupant density and a low outdoor air supply rate affect cross-infection, whether there are any negative indoor air quality effects on teachers that affect teaching quality, and whether thermal effects interact with the effects of air quality; the latter was not explicitly explored in the previous studies. The mechanisms for the negative effects of air quality on cognition and the physiological processes by which this occurs should be examined, and it has already been shown that lung capacity is temporarily reduced by exposure to poor indoor air quality (Shriram et al. 2019; Mishra et al. 2021). If the mechanisms were known, it might be possible to identify the airborne molecules responsible for these negative effects and somehow eliminate them from indoor air. This evidence would also help in developing an IAQ metric from studies attributing the effects to gaseous pollutants.

Present studies show that to ensure classroom IAQ conducive to learning, CO₂ levels should be kept below 900 ppm at all times, it should be ensured that windows can be opened when needed, to improve classroom IAQ, and CO₂ sensors should be installed to indicate when windows must be open (or any other measure to improve IAQ must be executed) if the CO₂ concentration is too high and when they should be closed to conserve energy, i.e., when CO₂ has reached the intended low level, e.g., below 900 ppm or even lower. To ensure good sleep quality, bedroom CO₂ should be kept below 800 ppm, but the data is scarce. These recommendations are tentative and should be revised when new research evidence is published. At the time of publication of the present Handbook of Indoor Air Quality (December 2021), it is unknown what ventilation rates and CO₂ levels should be provided in classrooms to reduce the risk of infection with airborne viruses.

Abstract

Sleep is essential for our mental and physical health. People typically sleep 8 h and consume 26.8% of total air inhaled per day when sleeping. Indoor air quality (IAQ) in bedrooms may influence sleep quality. Many IAQ problems, including high CO₂ and fine particulate matter (PM2.5) levels, have been observed in studies on bedrooms. Considering the CO₂ level as an indicator of indoor air pollution caused mainly by human bioeffluents, these findings indicate that the studied bedrooms were poorly ventilated. Although current studies are limited, they suggest that poor IAQ may result in poor sleep quality, indicating the

necessity to improve IAQ in bedrooms. However, most of the current studies measured sleep quality with sleep trackers or subjective questionnaires, resulting in a wide range of associations and no clear mechanisms. Future studies should use a more accurate assessment of sleep quality, such as polysomnography (PSG), and control air pollution exposure to examine the exact effects and mechanisms of IAQ on sleep quality. As people tend to close windows/doors during the sleeping period, which decreases the air exchange rate and accumulates pollutants in the bedroom, specific alternative solutions to improve the IAQ in bedrooms should be researched.

Sleep quality · Bedroom · Pollution · Fine particulate matter · Ventilation

Introduction

For young adults and adults (18–64 years), a sleep duration of 7–9 h per night is recommended (Hirshkowitz et al. 2015), which corresponds to one-third of a total lifetime. It is estimated that the air inhaled during sleep accounts for approximately 26.8% of the total air inhaled per day if the total sleep time is 8 h (Sekhar et al. 2020). Hence, the air quality in bedrooms is important in contributing to both acute and chronic exposure to indoor air pollutants. Because insufficient sleep impairs the immune system, disrupts blood sugar levels, increases cardiovascular disease, and decreases next-day work performance, such exposures are a particular concern if the sleep quality of occupants is affected. However, it is evident in some recent review articles that bedrooms are not as studied as other parts of houses in this regard (Liu et al. 2020). Among the hundreds of articles on semi-volatile organic compounds (SVOCs) and indoor air quality (IAQ), very few refer to concentrations of air pollutants in bedrooms. In this chapter, the current situation of IAQ in bedrooms and the possible consequences of both outdoor and indoor air quality on sleep quality are summarized. Additionally, mechanisms that mediate the effects of air pollution on sleep are indicated, and finally, some possible solutions for improving IAQ in bedroom are suggested.

The Importance of Good Sleep

Measurement of Sleep Quality

Normal human sleep is comprised of two states – rapid eye movement (REM) and non-REM (NREM) sleep – that alternate cyclically across a sleep episode. Sleep begins in NREM (usually stage N1) and progresses through deeper NREM stages (stages N2 and N3) before the first episode of REM sleep occurs approximately 80–100 min later (Carskadon and Dement 2011). Light sleep is the term for sleep that

falls into the categories of stage N1 and stage N2. The stage N3 sleep is characterized by slow wave activity (brain waves of frequency 0.5 Hz–2 Hz), thus is referred as slow wave sleep (SWS) or deep sleep. REM sleep is characterized by random rapid movement of the eyes, accompanied by low muscle tone throughout the body, and the propensity of the sleeper to dream vividly.

To provide the basic information requisite for classification of the above sleep stages, polysomnography (PSG) is usually used, which records signals on brain wave, eye movements, and chin muscle tension (Fig. 1). Table 1 shows the sleep

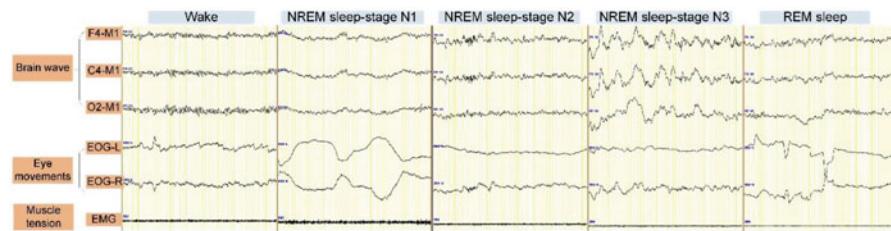

Fig. 1 Stages of wake, nonrapid eye movement (NREM) sleep, and rapid eye movement (REM) sleep. The tracings of brain wave were records from three electrodes at right frontal lobe (F4), right central lobe (C4), and right occipital lobe (O2) referenced to left mastoid (M1). Eye movements are recorded from the left (L) eye and right (R) eye. Muscle tension is recorded by two leads which are placed on the chin with one above the jawline and one below

Table 1 Parameters derived from objective measurements of sleep quality

Parameter	Explanation	Normative values of good sleep ^a
Lights out clock time	The clock time (in hh:mm) when the subject was instructed to allow himself or herself to fall asleep	/
Lights on clock time	The clock time (in hh:mm) when the subject was awakened	/
Total recording time, TRT	Elapsed time with lights out (in minutes)	/
Total sleep time, TST	Total time scored as sleep (in minutes)	>420 min
Sleep efficiency, SE	Percentage of time in bed actually spent sleeping, i.e., TST as a percentage of TRT (%)	90–96%
Sleep onset latency, SOL	Elapsed time from lights out to the first occurrence of Stage N1 sleep (the start of sleep) (in minutes)	<20 min
Wake time after sleep onset, WASO	Total time of wakefulness recorded from the start of sleep to lights on (in minutes)	<25 min
Duration of each sleep stage	Total number of minutes scored as N1, N2, N3, and REM sleep	/
Percentage of each sleep stage	Time scored as N1, N2, N3, and REM as a percentage of TST	N1: 2–5% N2: 45–55% N3: 13–23% REM: 20–25%

^aThe suggested normative values of good sleep are for young adults

quality statistics that are calculated based on PSG measurement. Lower sleep efficiency (SE), lower duration of N3 or REM stage, longer sleep onset latency (SOL), and/or higher wake time indicate poorer sleep quality. In recent years, more and more sleep trackers are commercially available. These trackers have the advantages of long-time recording and cause less disturbance to sleep, thus is commonly used in field study or large-scale survey. However, the reliability and validity of the trackers need further confirmation. Self-evaluated sleep quality on questionnaires is also usually adopted. There are two types of assessments, one examines sleep quality or habits in the previous month, e.g., the Pittsburgh Sleep Quality Index (PSQI), the other evaluates daily sleep quality, e.g., the Groningen Sleep Quality Scale (GSQS).

Sleep Functions

Sleep is essential for the body to recover from both physical and psychological fatigue throughout the day and to restore energy to maintain bodily functions. Without sleep, cognitive and emotional abilities are markedly disrupted. Sleep is an important requirement before learning, to prepare specific brain networks for the initial encoding of information, and after learning, for the subsequent consolidation and enhancement of procedural memories (Walker 2010). Moreover, sleep may offer the ability to test and build common informational schemas of knowledge, providing increasingly accurate statistical predictions about the world and allowing for the discovery of novel, even creative next-day solution insights (Walker 2010).

Sleep loss has been linked to heart disease, diabetes, obesity, and cancer. Sleep is also related to neurodegenerative disorders, such as Alzheimer's disease. The data presented by Fultz et al. (2019) suggest that the cerebrospinal fluid flow oscillations during SWS may contribute to the disposal of waste products, including toxic brain proteins that cause Alzheimer's disease (Fultz et al. 2019).

In summary, sleep problems can play a causal role in the development of mental and physical health morbidities. The benefits of good sleep affect a wide range of critical health outcomes and next-day work performance. The sleeping environment is expected to significantly affect the sleep quality, thus improving the sleeping environment including the IAQ in the bedroom is a necessary step toward achieving healthy sleep.

IAQ in the Bedroom

Indoor CO₂ concentration has been used as an indicator of air quality in buildings, indicating the quantity and effectiveness of ventilation with outdoor air. It has not been confirmed whether CO₂ is an air pollutant. Thus, in this section, reports on CO₂ levels and other indoor air pollutants in bedrooms are discussed separately.

CO₂ Levels in Bedroom

Studies usually observed higher CO₂ level during cooling and heating season owing to closed window and door for the need of energy conservation. The most comprehensive review of this topic was recently made by Sekhar et al. (2020). Figure 2 shows the CO₂ concentrations of some studies reviewed in Sekhar et al. (2020).

Liu et al. (2015) measured 454 children's bedrooms in Shanghai over one year and reported that the mean CO₂ level \pm standard deviation was 1123 ± 741 ppm (range: 367–4595 ppm) (Liu et al. 2015). Hou et al. (2018) measured CO₂ levels in 399 homes in Tianjin and Cangzhou (Hou et al. 2018). The median bedroom CO₂ levels during spring, summer, autumn, and winter were 1146, 575, 1313, and 1407 ppm, respectively. Lei et al. (2017) measured four bedrooms (two with four occupants each and two having six occupants each) in a naturally ventilated dormitory with radiant water heating during the heating season in Beijing and reported that the CO₂ levels ranged between 1057 and 5150 ppm (Lei et al. 2017).

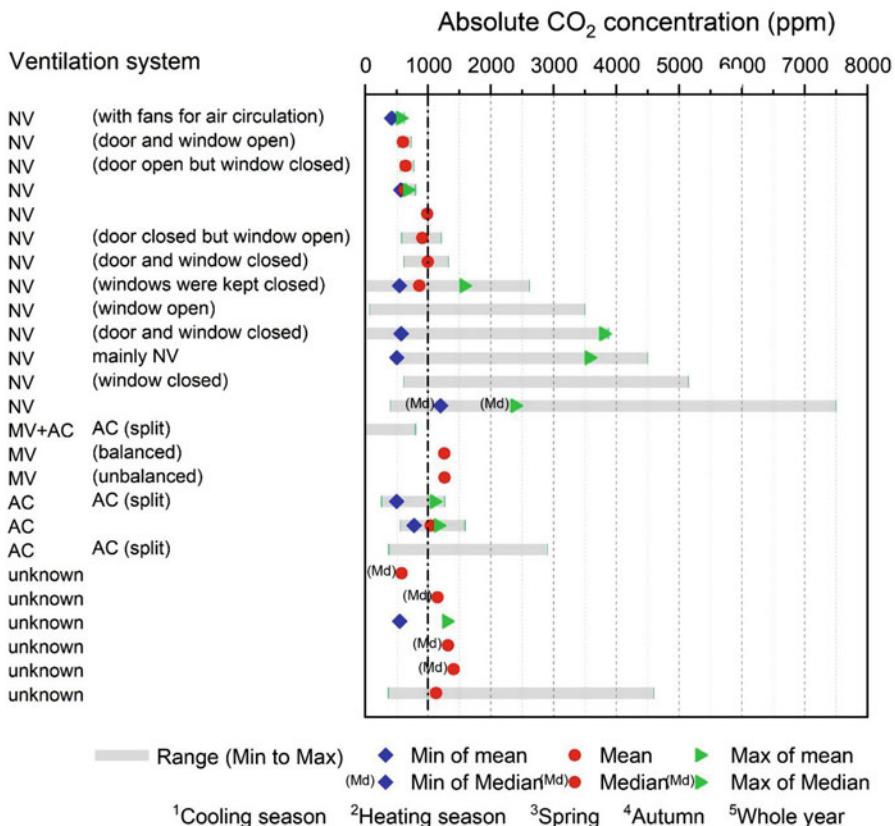

Fig. 2 Summary of CO₂ measured in bedrooms. For ventilation system, NV refers to natural ventilation, MV refers to mechanical ventilation, and AC refers to air conditioner

Wong and Huang (2004) carried out measurements in three residential buildings in Singapore and observed that the CO₂ levels in bedrooms using AC were consistently higher than those using natural ventilation (NV) (Wong and Huang 2004). The CO₂ levels built up and could reach approximately 1600 ppm in bedrooms using AC without ventilation, while they were approximately 550–600 ppm in bedrooms using NV. Sekhar and Goh (2011) reported CO₂ levels of around 420–560 ppm in bedrooms with NV in Singapore, which was around half that observed in bedrooms using AC (Sekhar and Goh 2011). Bedroom CO₂ levels can reach 2900 ppm with an occupancy of two adults and a child in approximately 8 h (Sekhar 2004).

High CO₂ concentrations have also been reported in many residential buildings in Europe. Batoga and Badura (2013) observed that when the windows and doors closed, the CO₂ levels of most tested sleeping rooms significantly exceeded the recommended hygienic standards (Batoga and Badura 2013). The CO₂ concentrations measured in bedrooms in Poland were 857 ± 217 ppm, with highest value of 1570 ppm (Kozielska et al. 2020). Bekö et al. (2010) performed measurements in 500 bedrooms during spring in Denmark, showing that Danish bedrooms were poorly ventilated: 23% of bedrooms exceeded 2000 ppm and 6% exceeded 3000 ppm in 20 min (Bekö et al. 2010). Fernandez-Aguera et al. (2019) measured the IAQ in naturally ventilated dwellings for one year in the south of Spain and found that in the bedrooms the CO₂ concentrations were above 3000 ppm, with peaks above 7500 ppm (Fernández-Agüera et al. 2019). Canha et al. (2017) performed three studies in Portugal to measure the IAQ in bedrooms. In one study, the lowest mean CO₂ level (550 ± 36 ppm, ranging between 484 and 672 ppm) was found in rooms with open windows and open doors, whereas the highest mean level was observed in rooms with closed windows and closed doors (911 ± 183 ppm, ranging between 565 and 1216 ppm) (Canha et al. 2017). In the second study, they observed that the mean CO₂ levels were significantly different between rooms of smokers and nonsmokers, 2029 ± 429 ppm and 1123 ± 479 ppm, respectively (Canha et al. 2019). In the third study, they measured CO₂ levels in bedrooms of ten couples and found that the mean CO₂ level during sleep was 1751 ± 819 ppm, ranging from 611 ± 107 ppm to 3466 ± 336 ppm (Canha et al. 2020).

The above studies indicate that, compared with mechanically ventilated rooms, in naturally ventilated rooms with closed windows and doors the CO₂ levels are higher, usually exceeding 1000 ppm; when the rooms were occupied by multiple person the CO₂ levels were increased and could be higher than 7500 ppm. Using of split air conditioners in the rooms also increased the indoor CO₂ level.

Other Pollutants in Bedroom

Fernandez-Aguera et al. (2019) reported the levels of total volatile organic compounds (TVOC) and PM_{2.5} in three dwellings with NV in the south of Spain (Fernández-Agüera et al. 2019). The annual average PM_{2.5} values were 16.09 ug m^{-3} , 7.1 ug m^{-3} , and 9.66 ug m^{-3} in the three dwellings. For 15–45% of the hours the PM_{2.5} levels exceeded the threshold of 10 ug m^{-3} . Indoor average

TVOC concentration is usually below the 1200 ppb threshold with uneven distribution. The indoor concentrations are higher in winter than in summer.

Canha et al. (2017) observed that the concentrations of several pollutants, including volatile organic compounds (VOCs), formaldehyde, and PM_{2.5}, exceeded the established Portuguese guidelines (Canha et al. 2017). They also observed that smokers were exposed to higher levels of PM, carbon monoxide (CO), and formaldehyde than nonsmokers while sleeping (Canha et al. 2019). Low compliance with guideline on VOCs (10%), bacteria (20%), and fungi (44%) were found (Canha et al. 2020). In 70% of cases, the PM_{2.5} concentrations ($15.3 \pm 9.1 \text{ mg m}^{-3}$) exceeded the WHO guideline of 10 mg m^{-3} . Notably, all bedrooms presented air change rates above the recommended minimum value of 0.7 h^{-1} , highlighting that good IAQ during sleep is not guaranteed.

Fan et al. (2018) measured the IAQ in five urban and five rural houses of elderly people in Beijing, China, during the heating season (Fan et al. 2018). They observed CO₂ levels higher than 1000 ppm in the bedroom during sleeping time. They also found that indoor fuel combustion resulted in extremely high PM_{2.5} (up to 550 ug m^{-3}) and CO level (up to 70 ppm) in rural houses.

Winkens et al. (2017) reported perfluoroalkyl acids (PFAAs) and their precursors from children's bedrooms in Finland: Higher PFAA concentrations were found in rooms with plastic floors than in those with wood or laminate (Winkens et al. 2017).

In summary, it was not until recent 10 years that researchers paid attention to the IAQ in bedrooms. Most studies found CO₂ levels that exceeded the limits stipulated in standards of each country. Considering the CO₂ level as an indicator of indoor air pollution caused mainly by human bioeffluents, these findings indicate that the studied bedrooms were poorly ventilated. Other pollutants including VOCs, formaldehyde, and PM_{2.5} have also been reported in bedrooms. However, these pollutants are caused by various sources, such as smoking and cooking in the room, furniture and bedding, the use of polluted materials, and poor ventilation.

Air Pollution Exposure and Sleep

While most studies have focused on ambient air pollutants and showed that air pollution resulted in poor sleep health, only a few have investigated the associations between bedroom IAQ and sleep. In this section, the effects of ambient exposure and IAQ on sleep are summarized, respectively.

Ambient Exposure and Sleep

Particulate Matter and Sleep

One major component of air pollution is particulate matter, which is composed of both solid and liquid particles found in the air and classified by aerodynamic diameter. Exposure to ambient particulate matter has been shown to reduce sleep quality.

Zanobetti et al. (2010) found that, in summer, increases in the respiratory disturbance index (RDI) and percentage of sleep time at less than 90% O₂ saturation, as well as decreases in sleep efficiency, were associated with increases in short-term variation in PM₁₀ (Zanobetti et al. 2010). This study is one of the very few that have examined the effects of particulate matter on sleep quality with objective PSG measurements.

Chen et al. (2019) performed a cohort study during 2015–2017 in rural areas of Henan Province, China, and observed that the odds ratios of poor sleep quality associated with per interquartile range (IQR) increase in PM_{2.5}, PM₁₀, and NO₂ were 1.15, 1.11, and 1.14, respectively (Chen et al. 2019). The authors concluded that long-term exposure to PM_{2.5}, PM₁₀, and NO₂ was associated with poor sleep quality in rural China.

Chuang et al. (2018) investigated the effects of personal exposure to metal fume fine particulate matter (PM_{2.5}) on lung function, urinary biomarkers, and sleep quality in shipyard welding workers (Chuang et al. 2018); the welding workers had longer waking times than did office workers, suggesting that exposure to heavy metals in metal fume PM2.5 may disrupt sleep quality in welding workers.

Two studies observed the negative effects of particulate matters on sleep in children (Abou-Khadra 2013; Nosetti et al. 2016). More significantly, the effects of particulate air pollution exposure on sleep disruption persist even during pregnancy; exposure during weeks 1–8 was associated with decreased sleep efficiency, during weeks 31–35 was associated with decreased sleep duration, and during weeks 39–40 was associated with increased sleep duration (Bose et al. 2019).

Multiple Air Pollutants and Sleep

Some studies have examined the effects of exposure to multiple air pollutants from ambient air on sleep.

Tang et al. (2020) conducted a study among the elderly in Ningbo, China, and found that short-term exposure to multiple air pollutants was associated with hospital visits for sleep disorders, with the strongest associations occurring 2–3 days prior to a clinic visit for traffic-related pollutants including the PM_{2.5}, PM₁₀, and NO₂, and for SO₂ and O₃ for 5 days prior to the clinic visit (Tang et al. 2020).

Yu et al. (2019) performed a five-year study among freshmen in Beijing, China; they observed that air pollution was associated with a reduction in sleep duration among freshman students living in Beijing: One standard deviation increase in air pollution concentration in PM_{2.5}, PM₁₀, and NO₂ was associated with a reduction in daily sleep of 0.68 h, 0.55 h, 0.70 h, and 0.51 h, respectively (Yu et al. 2019).

Lawrence et al. (2018) performed a large-scale study in children in seven northeastern cities in China (Lawrence et al. 2018). They found that sleep disorders were generally associated with all air pollutants, including PM₁, PM_{2.5}, PM₁₀, SO₂, NO₂, and O₃, with the highest odds found for PM₁ exposure. The strongest association was between exposure to PM₁ and disorders of excessive somnolence.

Kheirandish-Gozal et al. (2014) examined the association between habitual snoring of children and exposure to air pollutants, including PM₁₀, NO₂, SO₂, CO, and O₃ in five districts of Iran (Kheirandish-Gozal et al. 2014). Among the 4322

children aged 6–12 years, those living in regions with higher levels of pollutant exposure were more likely to show habitual snoring. This effect remained after controlling for other risk factors, such as family history of snoring, wheezing, respiratory problems, and parental smoking status.

IAQ and Sleep

Ventilation and Sleep

The studies on ventilation and sleep were recently summarized by Akimoto et al. (2021), Fig. 3. They used measured CO₂ as a marker of ventilation.

Strøm-Tejsen et al. (2016) conducted two field intervention studies in Denmark during the heating season: one pilot experiment in naturally ventilated dormitory rooms and one experiment in dormitory rooms with balanced MV (Strøm-Tejsen et al. 2016). In the pilot experiment, the mean bedroom CO₂ level was 2585 ppm (range: 1730–3900 ppm) with windows closed and 660 ppm (range: 525–840 ppm) with open windows. In the second experiment, the mean bedroom CO₂ level was 2395 ppm (range: 1620–3300 ppm) when the fan was disabled and 835 ppm (range: 795–935 ppm) when it was in operation. The lower CO₂ concentration resulted in improved sleep quality, both as rated by the subjects and measured by Actigraphy and improved next-day performance.

Mishra et al. (2018) changed the bedroom ventilation by opening or closing windows and doors (Mishra et al. 2018). The mean measured CO₂ levels were 717 ppm with the window and door open, 658 ppm with only the window open, 791 ppm with only the door open, and 1150 ppm with the window or door closed; it was noted that levels could exceed 3000 ppm when both the door and window were closed. Self-evaluated sleep depth and length, objectively measured sleep efficiency, and the number of awakenings measured using actigraphy correlated well with the measured CO₂ levels – the lower the CO₂, the better sleep quality.

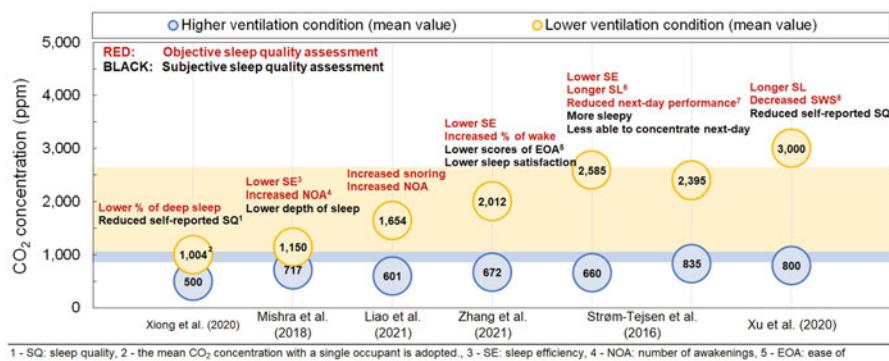

Fig. 3 Summary of studies investigating the effects of ventilation on sleep. (Modified from (Akimoto et al. 2021))

Xiong et al. (2020) conducted a field study during the Australian summer between January and early March 2019 in Sydney (Xiong et al. 2020). The bedroom CO₂ levels under different scenarios were as follows: fan 955 ± 721 ppm; AC 889 ± 521 ppm; and open window or door 542 ± 84 ppm. A 4.3% decrease in deep sleep was observed for every 100 ppm increase in the overnight average CO₂ concentration, with adjustments made for the other variables. However, few high CO₂ cases were observed in this study, and thus the results cannot represent those for typical bedrooms in hot summer areas.

Liao et al. (2021) examined the effects of open windows in the bedroom on sleep (Liao et al. 2021). The CO₂ levels were approximately 600 ppm with open windows and 1600 ppm with closed windows. The results showed that the poorer ventilation increased snoring and the number of awakenings.

Xu et al. (2021) investigated the impact of indoor CO₂ levels on sleep quality in climate chambers furnished and decorated as bedrooms for three CO₂ concentration conditions (800 ppm, 1900 ppm, and 3000 ppm) (Xu et al. 2021). Sleep quality was measured with PSG. The results showed that sleep onset latency increased and SWS decreased with the increase of CO₂ concentration.

Zhang et al. (2021) conducted a field study in bedrooms during spring and autumn (Zhang et al. 2021). Two groups with bedroom CO₂ concentrations of less than and more than 1000 ppm were compared, with an average of 672 ppm and 2012 ppm, respectively. The results showed that the wake stage percentage was lower and the sleep efficiency, ease of awakening, and sleep satisfaction were higher with higher ventilation (indicated by lower CO₂ levels).

Lan et al. (2013) and Zhou et al. (2014) proposed a personalized ventilation system that supplied clean air directly to the breathing zone of a sleeping person while cooling/warming the face (Lan et al. 2013; Zhou et al. 2014). The results showed that providing outdoor air directly to a sleeping person's breathing zone resulted in better sleep quality, as indicated by improved subjective evaluation, skin temperature, heart rate, and heart rate variability.

In general, poor bedroom ventilation, as indicated by increased levels of CO₂, has negative effects on several aspects of sleep and can also result in poor cognitive performance the next day.

Other Indoor Pollutants and Sleep

The studies investigating the effects of other indoor pollutants on sleep quality are scarce.

Wei et al. (2017) conducted a population-based cross-sectional study to examine the association between sleep quality and cooking oil fumes (COFs) in Chinese households (Wei et al. 2017). Individual sleep quality assessments were completed for 2197 participants with an average age of 37.52 years, using PSQI. Additionally, urine samples were collected and analyzed for 1-hydroxypyrene (1-HOP), a urinary biomarker of polycyclic aromatic hydrocarbons in COFs. The results showed that subjective poor kitchen ventilation, preheating oil to smoking, and cooking for over 30 min were positively associated with overall poor sleep quality (global PSQI score > 5). High urinary 1-HOP levels were also positively associated with overall poor sleep quality.

An intervention study was conducted to investigate the effects of biomass pollution on sleep of Peruvian children under the age of 14 years (Accinelli et al. 2014). Household exposure to biomass pollution was reduced by replacing highly polluting stoves with less-polluting Inkawasi stoves. Using parent reports of child sleep habits, improvements in sleep and respiratory-related symptoms (such as snoring and nighttime awakening) were found with decreased biomass pollution. Furthermore, lower levels of pollutant exposure were associated with increased willingness to sleep and ease of falling asleep and waking up for both exclusive and partial use of the improved stoves.

The limited number of studies published to date have consistently shown that poor IAQ in bedrooms has negative effects on sleep quality. A recent study investigated the effects of ventilation and ventilation noise on sleep quality, as measured objectively using PSG (Lan et al. 2021). This study confirmed that poor ventilation in bedroom resulted in poorer sleep quality, as indicated by a lower sleep efficiency and longer wake time after sleep onset. However, ventilation noise was perceived to be less acceptable, disrupt sleep, and cancel the positive effects of ventilation. It is expected that occupants will not operate the ventilation system as required if the ventilation noise is high. These results suggest that ventilation system for bedroom should be appropriately designed with low noise.

Possible Mechanisms

Mechanisms explaining the effect of air pollution on sleep are not fully understood and have only been studied minimally. Liu et al. (2020) reviewed the present evidence and summarized two potential mechanisms (Liu et al. 2020), as shown in Fig. 4; the pollutants affect regulation of sleep by central nervous system and changes in the physiology of the respiratory system. The causal models and

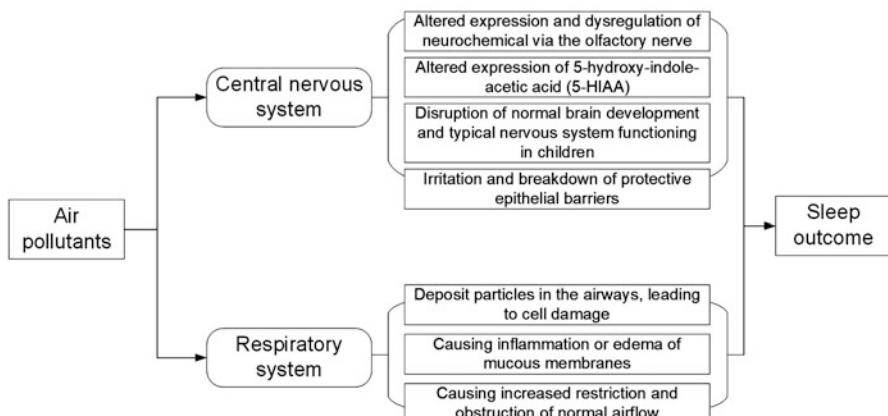

Fig. 4 Potential mechanisms by which sleep is affected by air pollutants

mechanisms linking air pollutants and sleep are currently limited; more fundamental research and epidemiological studies are needed to elucidate potential biological mechanisms underlying the association between air pollutants and sleep outcomes.

Interactions with Temperature

A comfortable thermal environment is crucial for good sleep quality. Studies have observed that when the air temperature deviates from a neutral temperature of 26 °C (higher or lower) by 3 °C, the subjects' sleep quality decreased; the sleep onset latency increased by 33 min and the duration of SWS decreased by 50 min, which corresponds to about one-third of the total SWS in healthy people (Lan et al. 2014, 2017).

Temperature may confound the effects of air pollutants on sleep. Weinreich et al. (2015) examined the relationships between PM₁₀, temperature, ozone levels, and relative humidity and sleep-disordered breathing (SDB) in middle-aged to elderly population (Weinreich et al. 2015). Positive associations between AHI and both temperature and ozone levels were observed and found to be strongest in summer. Conversely, using PSG and air monitoring stations to estimate exposure, Cassol et al. (2012) observed more SDB events in winter than in other seasons, and reported that AHI was inversely correlated with ambient temperature and directly correlated with atmospheric pressure, RH, and carbon monoxide levels (Cassol et al. 2012). These contradictory findings regarding the relationship between sleep outcomes and temperature emphasize that more studies are needed to understand both the relationship and the mechanism involved.

Aromatherapy and Sleep

As an adjunctive therapy to improve sleep problems, aromatherapy has been gaining popularity since the 1990s. Aromatherapy entails the absorption of oils extracted from the flowers, stems, leaves, roots, and fruits of various plants into the body through the skin or respiratory system to improve mental and bodily health.

Aromatherapy was found to be effective in reducing stress and improving depression and sleep quality in healthy adults. Lin et al. (2019) conducted a systematic review and meta-analysis and reported that aromatherapy effectively improves sleep quality (Lin et al. 2019).

Aromatherapy is suggested to be applied to special groups with a high incidence of sleep disorders, such as college students, shift workers, and elderly people. Nematolahi et al. (2018) reported that the use of rosemary significantly enhanced memory, reduced anxiety and depression, and improved sleep quality in college students (Nematolahi et al. 2018). Aromatherapy massage was shown to improve sleep quality in nurses with monthly rotating night shifts (Chang et al. 2017).

However, most studies on the influence of aromatherapy on sleep quality use subjective evaluation methods. It is recommended to include measurements of physiological indicators to increase the generalizability of the study results.

Possible Solutions to Improve IAQ in Bedrooms

With few exceptions, existing ventilation standards do not prescribe specific ventilation requirements for bedrooms; ventilation in bedrooms is merely the result of the ventilation requirements for the entire dwelling (Sekhar et al. 2020). Very few studies have specifically investigated ventilation technology in bedrooms.

Free-standing filters, also called room air filters or purifiers, may help to reduce pollutants in bedrooms. A study evaluated the long-term effectiveness of high-efficiency particulate air filters in Baltimore, MD, and found PM10 reductions of up to 39% compared to a control group (Eggleson et al. 2005). More sophisticated air cleaning/ventilating units can further improve IAQ, but expensive building modifications may be required (Xu et al. 2010).

During the sleeping period, people are immobile and occupy a relatively small space, which is a favorable condition for the use of local ventilation. A bedside personalized ventilation (PV) system that supplies fresh and cool/warm air to the head and face of a sleeping person was proposed by Lan et al. (2013). This PV system was applied to human subjects of different ages (including children, adults, and the elderly), for whole nights, in both winter and summer seasons and was shown to potentially improve sleep quality (Lan et al. 2013; Zhou et al. 2014).

Conclusion

Many IAQ problems, including high CO₂ and PM_{2.5} levels, have been observed in studies on bedrooms. During sleep, people may breathe passively and are exposed to air pollutants for several hours. Although current studies are limited, these evidences suggest that poor IAQ may result in poor sleep quality, indicating the necessity to improve IAQ in bedrooms. However, most of the above studies measured sleep quality with sleep trackers or subjective questionnaires, resulting in a wide range of associations and no clear mechanisms. Future studies should use a more accurate assessment of sleep quality, such as PSG, and control air pollution exposure to examine the exact effects and mechanisms of IAQ on sleep quality. As people tend to close windows/doors during the sleeping period, which decreases the air exchange rate and accumulates pollutants in the bedroom, specific alternative solutions to improve the IAQ in bedrooms should be researched.

Abstract

Indoor air quality (IAQ) affects the quality of life by increasing the risks for health problems and reduced work performance. Consequently, different societal costs are incurred. By reducing pollutants elevating exposures indoors, and improving IAQ, these costs can be reduced or avoided. This chapter attempts to summarize the evidence and the methods for estimating the costs and economic

consequences of poor IAQ affecting work performance. The value of lost work is discussed considering discomfort and health, absence from work (absenteeism), or working with limitations due to illness (presenteeism). The impact of air quality and other environmental factors on work performed at home is also presented as a hypothesis, but this evidence is limited.

The Costs and Benefits Related to IAQ

Air quality in buildings affects financially mainly not only occupants, building owners, and employers, but also other stakeholders such as insurance companies, thereby affecting societal costs. The societal costs at the community and national levels can increase insurance claims, workers' compensation claims, litigation, and increased payments for sick leave with potential consequences for the gross domestic product (GDP).

For *occupants*, the costs associated with exposures to indoor air pollution may include, among others, reduced salary or wages due to lost days at work and minor restricted activity days, medical costs associated with visits for medical assistance, including visits to general practitioners, specialists as well as emergency room visits and hospital admissions, and the costs of health insurance policies. Moreover, adverse health effects can result in the loss of productive years owing to premature disability. Increased sick leave or suboptimal performance can also result in less diligent work, less care of customers, etc., which may also have consequences in the form of increased costs. In addition to absenteeism, so-called presenteeism needs also to be considered, i.e., coming to work when ill because of previous exposures to poor IAQ and despite poor IAQ, which is expected to generate considerably higher costs than taking sick leave or holidays. However, these estimations are not accurate (Lohaus and Habermann 2019).

The increased costs for individuals may be expected in up to 10% of buildings where building-related illnesses (BRI) have been observed. Additionally, some costs may be expected in up to 20% of buildings where sick building syndrome (SBS) has been observed. These data suggest that the increased costs due to poor IAQ can be expected in up to 30% of the buildings. However, it must be recognized that BRI and SBS have multifactorial etiology, poor IAQ being one of the factors. In addition, although the definition of SBS assumes the relief of symptoms when leaving the school or office, this relief may not occur because the contaminants in homes causing SBS symptoms may be the same as in the workplaces.

The costs for *building owners* include those related to sharing of rented or leased space in the building, utility costs including energy costs associated with controlling the building environment, maintenance, cleaning and operating costs, capital assets including costs of capital equipment, furniture, and other interior furnishings, and

construction costs (first costs) including those of planning, designing, and constructing nonindustrial buildings. Especially, the operating, cleaning, and maintenance costs can be strongly affected by poor IAQ.

Wargocki and Djukanovic (2005) performed a simulation comparing the life-cycle costs of investments improving IAQ in a hypothetical office building with the expected revenues from increased work performance. The benefits from improved IAQ were estimated to be up to 60 times higher than the necessary investments, which were shown to be generally recovered in no more than 2 years, the rate of return being up to 7 times higher than the minimum acceptable interest rate. Furthermore, the estimations suggested that the total costs of installing and running the building can be offset by productivity gains of just 10% (Wargocki et al. 2006).

The costs for *employers* include salaries and wages, some of which can be paid by the insurance companies in case of prolonged morbidity or mortality. They also cover the costs of staff turnover. When customers, visitors, or guests choose to stay away from retail stores, restaurants, hotels, and other public facilities because of the fear of exposure to poor air quality, the employer's revenue is lower also because the company's image is somewhat compromised.

A 1% increase in productivity would correspond to reduced sick leave of 2 days per year, fewer breaks from work, improved effective time at work of 5 minutes per day, or a 1% increase in the effectiveness of physical and mental work (Wargocki et al. 2006). Considerable benefits can thus be achieved by employers when IAQ is improved. These benefits stem from employees' improved productivity and health status, resulting from general satisfaction from the working environment, lower staff turnover, and more satisfied customers.

In summary, all stakeholders benefit from improved IAQ. These benefits outweigh potential energy and investment costs if only the effects of improved performance are included in the calculations (Wargocki et al. 2006). Despite the possible high economic premiums and rewards, health and productivity benefits are not yet regularly included in conventional financial analyses used during the design and operation of buildings. One reason could be inadequate communication and lack of confidence regarding the benefits of improving air quality, as well as low willingness to pay for these improvements. This is nicely demonstrated by Hamilton et al. (2016), who documented opinions of the US building industry. Their analysis showed that less than half of respondents expected that improving ventilation and filtration of buildings would improve productivity and even less associated these interventions with lower absence rates and health risks. Respondents attributed high costs to the interventions aiming to improve IAQ, which were more significant than the estimated actual costs. In addition, green building owners were less likely to pay for the upgrades.

Health Costs

There are limited estimations regarding the health costs related to poor IAQ. One of the key publications by Fisk and Rosenfeldt (1997) was published nearly 25 years ago. Its summary supplemented by the more recent analyses is presented below.

Fisk and Rosenfeldt (1997) estimated that savings due to reduced respiratory illnesses as a result of improved IAQ could in the US amount to \$6–14 billion annually, assuming that they constitute 10–30% of the total costs of these illnesses estimated to be \$64 billion annually (1990s figures). Using the work of Milton et al. (2000), it may be assumed that the direct costs of respiratory diseases also include the costs of absence from work estimated in the USA to be \$400 per employee per year (2000 figures).

Fisk and Rosenfeldt (1997) estimated that savings due to reduced costs of allergies and asthma as a result of improved IAQ in the USA could amount to \$2–4 billion annually, assuming that they constitute 10–30% of their total costs estimated to be \$12.8 billion annually (1990s figures). A significant portion of these costs reflected the burden of disease in children, including mainly health care and lost school days. In 2016, the new estimate of direct medical costs and wage-related losses in the USA for selected allergy-induced health conditions, including exposure to damp and mold in homes, showed that direct medical expenses related to allergic rhinitis were \$2.26 billion, to asthma were \$ 880 million, and to bronchitis were \$287 million (Mudarri 2016). \$335 million was estimated as the total loss due to sick days (including care for sick children) and reduced labor productivity caused by allergic rhinitis. The corresponding losses were estimated to be \$156 million for asthma and \$56 million for acute bronchitis. These figures do not differ much from the estimates of Fisk and Rosenfeldt (1997).

Fisk and Rosenfeldt (1997) also produced an estimate for the cost of reduced productivity in the USA due to SBS yielding \$50 billion per year (1990 figures). This estimate corresponded to about \$400 per worker annually, being about 2–3 lost working days of each worker per year. In the Finnish offices, similar estimates were obtained: A reduction in the prevalence of SBS symptoms was estimated to result in savings of ca. €330 per worker annually, corresponding to about 1–2 lost working days for each worker per year (Seppänen 1999). However, it must be underlined that some of these costs are not related directly to poor IAQ and are associated with job satisfaction, psychosocial conditions, or personal issues. Nevertheless, assuming that only 10% are attributable to poor IAQ, they would yield nonnegligible costs of \$0.75–2 billion annually.

Recently, the health impact of air pollution was estimated in Europe and the USA using the Disability-Adjusted Life Years (DALYs). DALY estimates the lost healthy life years and combines the effects on premature mortality and morbidity. In economic terms, the cost of one DALY is estimated to be around \$100 k but can vary by a factor of one or two (Boulanger et al. 2017). Logue et al. (2012) estimated that 1.3 to 3.5 million healthy life years could be lost due to premature death or disability to perform work each year in the USA due to poor IAQ in homes. Similar estimations in Europe (EU-26), though for the entire building stock, including public and residential buildings but excluding secondhand tobacco smoke, led to a very similar figure of ca. two million healthy life years lost (Jantunen et al. 2011; Asikainen et al. 2016). For comparison, the estimated DALYs caused by exposure to air pollutants are about seven times lower than DALYs for all noncommunicable nonpsychiatric diseases combined independently of the etiology. Nevertheless, the

two cited estimations clearly illustrate that indoor exposures contribute significantly to the burden of disease in the population and create significant challenges for public health with considerable economic consequences. Such estimations are rare. Those that exist confirm that the socioeconomic costs of poor indoor air quality are very high. For example, a recent estimation of health consequences of exposures to selected indoor air pollutants in France yielded the cost of €20 billion annually (Boulanger et al. 2017).

In estimations of DALYs, PM2.5 was shown to account for a majority of lost healthy life years. The potential health benefits due to installation of particle filtration were estimated to amount annually \$5–\$15/person for the human capital loss and as much for the minor restricted activity days, \$5–\$20/person for work loss days, \$10–\$35/person for the total morbidity, and \$40–\$160/person for the lost value of the statistical life year (Bekö et al. 2008), the size of the benefits depending on the reduction of the exposure to PM indoors. The potential annual total benefits from the reduced adverse effects on health can be estimated to be as high as \$250 per person. This figure is much lower than the potential benefit from the productivity, which can reach a few thousand dollars annually per person depending on productivity (estimated to be $\leq 5\%$) and salary.

The Costs of Reduced Work Performance

Fisk and Rosenfeldt (1997) estimated that direct improvements in worker performance unrelated to illness and health symptoms could be \$12–125 billion per year (1990 figures); this estimate included mainly lighting quality affecting vision and thermal effects and is only partially caused by poor IAQ. Fisk et al. (2011) postulated that up to 20% reduction in SBS could be obtained by improved ventilation resulting in savings of \$5 billion annually. Other estimates more closely related to poor IAQ were presented by Fisk et al. (2012). They simulated the effects of changing ventilation rates in the US offices and showed that benefits due to improved productivity could amount to \$13 billion by increasing minimum ventilation rates to 10 L/s per person, \$38 billion when increased to 15 L/s per person. Filtration can also bring substantial benefits, but they can be offset due to pollutants emitted from used filters that can cause poor IAQ (Bekö et al. 2008).

The Costs of Reduced Learning

Wargocki et al. (2014) presented economic calculations showing that students performing better in primary schools would have higher income in adult life. Using the Danish data, they showed that the socioeconomic consequences of improved air quality in primary schools in Denmark would produce the benefit corresponding to about 1 per million of the Danish GDP (€240 billion in 2011). The benefits were attributed to improved ventilation in schools, improved learning, and shortened stay in school – fewer children took tenth grade in the ninth-grade schooling system in

Denmark and started work earlier, and lower teacher sick leave. However, the most significant effect was seen for improved productivity resulting in the annual growth of €104 million (measured in 2011 prices); the effect is expected to increase steadily with the increasing number of pupils graduating earlier from school.

Another way of estimating the potential benefits of improved IAQ on learning is to relate schoolwork performance with the expenses needed to cover salaries for teachers assuming that any performance improvement can be expected to reduce overtime and extra teaching hours. Simple estimations for Danish conditions suggest that renovations of primary schools leading to improved performance of school performance by 5% and subsequent 5% reduction in the expenses for wages for teachers would result in the net benefit of €0.10 per child per day (2011 data) after deducting the costs of renovations. The breakeven would occur if renovations resulted in the improved performance of schoolwork by 3% and thus a 3% reduction in teachers' wages (Marxen et al. 2011). Studies show that the effects of improved IAQ in schools can be expected to be much higher (Wargocki and Wyon 2013; Wargocki et al. 2020).

Mendell et al. (2013) estimated the benefits of improved ventilation in schools resulting in decreased illness absence in school districts, i.e., increased revenue from the student attendance and reduced costs to families from the lost caregiver wages. These benefits yielded \$33 to \$66 million annually from the increased revenue and \$80 to \$160 million from the reduced losses to caregivers.

Other Costs

In health care facilities, the adverse effects of poor IAQ can be exemplified by a negative impact on the hospital staff, increased risk for nosocomial infections, and extended hospital patient stays (patient recovery time); the 1990s estimates in the USA conditions suggested that they can amount to \$2 billion annually.

In the hospitality industry, including restaurants, bars, lodgings, and casinos, the costs for health and productivity were estimated to be as high as \$19.6 billion per year in the USA (2000s figures); \$1.46 billion were the productivity costs, \$1.65 billion employee medical costs, \$11.37 billion lost sales, and the remaining \$5.12 billion absenteeism, training, sick leave, and dealing with complaints (Dorgan and Dorgan 2006).

The costs in other buildings such as supermarkets, department stores, and fast-food outlets have not been estimated. Still, they can be approximated by the daily turnover resulting from customer behavior and staff performance.

Green Buildings

Recent studies examining the green office buildings' asset value have shown that these buildings generally have a higher market value considering their sale and leasing value than conventional buildings (Harrison and Seiler 2011; Chegut et al.

2013; Eichholtz et al. 2013). The evidence exists of leasing premiums being up to 17% in green buildings compared to conventional buildings (Wiley et al. 2008); the evidence in selling prices shows a bonus of up to 30% (Eichholtz et al. 2013; Newell et al. 2011). In addition, there is supporting evidence of higher sale yields (Sayce et al. 2010), higher occupancy rates, and lower operating expenses in green buildings than conventional buildings (Wiley et al. 2008; Eichholtz et al. 2013).

Working from Home

Working from home (teleworking or telecommuting) has become an increasingly popular work mode, boosting significantly during the COVID-19 pandemic in 2020–2021. Before the pandemic, it was estimated at the level of 3% for EU workers (Eurofound 2016). Dingel and Neiman (2020) estimated that 37% of all US jobs could be performed from home.

Working from home may result in a radical change of the working environment, including ergonomic aspects and communication and other conditions related, among others, to IAQ. For example, Morawska et al. (2017) suggested that, in general, office air is less polluted with particles than the air in homes (and schools). Zhao et al. (2015) estimated the economic consequences of improved air filtration in US homes and showed that application of filters with an efficiency higher than MERV5 would reduce premature mortality by 0.002–2.5% and extend life expectancy by 0.02–1.6 months, yielding annual economic benefits ranging from \$1 to \$1348; the benefits increased with a higher filtration class. The earlier presented estimates of Logue et al. (2012) can also be recalled here, showing 1.3 to 3.5 million healthy life years lost potentially due to poor IAQ in homes which could cost the society an astronomical \$1.3–3.5 trillion annually.

An Example of a Model Used to Estimate the Costs

When the economic estimates are made, different approaches are used, including:

- Simple balance methods
- Optimization methods
- Methods based on Bayesian Network

The applied model should include the costs of building and productivity of the company staff and the changes in the monetary value over time. In addition, models contain some constraints such as boundary conditions for thermal comfort or indoor air quality. For example, Petersen and Knudsen (2017) described yearly productivity loss with work performance treated as an indicator of productivity using two components: overall thermal comfort sensation and perceived air quality. Jensen et al. (2009) presented a Performance Index (P) determined with a Bayesian Network that can be used to compare different building designs in terms of their estimated

economic consequences when the effects on occupant performance and energy use are taken into account. The overview of the various methods of calculation of economic costs used in practice is presented in the REHVA Guidebook 6 (Wargocki et al. 2006).

From the company perspective, the annual profit depends on annual production revenues decreased by annual labor costs and costs related to a building (Skåret 1992; Hanssen 1997). The annual profit can be calculated from the simplified equation that also considers the variable value of the money over time.

$$G = P - S - (B \cdot a + E + M + C)$$

where:

G = annual profit

P = annual production revenue

B = investment capital cost-related building, furnishing, equipment, and installations per floor area

a = annuity factor

E = annual energy costs

M = annual operation and maintenance cost

C = annual cleaning costs

S = annual salaries including related costs

The annuity factor that allows converting the investment cost over n years when the annual interest rate is r can be calculated using the following formula

$$a = \frac{r \cdot (1 + r)^n}{(1 + r)^n - 1}$$

It is more convenient to analyze the profitability of the investment in improving indoor environmental quality in slightly modified form by relating some costs to the floor area (subscript F) or the number of employees (subscript P). The average floor area per person is denoted as y.

$$G_F = \frac{P_p}{y} - S_F - (B_F \cdot a + E_F + M_F + C_F)$$

The investment can be regarded as profitable when the increase of production revenue (due to increased productivity) exceeds the increase of costs related to buildings.

$$\Delta P_P \geq y \cdot (\Delta B_F \cdot a + \Delta E_F + \Delta M_F + \Delta C_F)$$

Generally, in the methods presented above, due to the predominating share of annual salaries (with the related costs), even a slight increase in productivity by a few percent increases the company profit.

Conclusion

Poor IAQ has been shown to result in considerable economic costs related to health, reduced productivity, absence from work, and the presence when sick. The benefits from improved IAQ will significantly outweigh the costs necessary for achieving high IAQ. The estimates suggest the returns being 3–6 times higher than the costs for increased ventilation, 8 times higher for increased filtration, and up to 60 times higher when all improvements and related benefits are taken into account (Hawkins et al. 2020).

Crude estimates suggest that 2 million healthy life years can be saved in Europe by improving IAQ in nonindustrial buildings while up to 3.5 million in the USA when residential buildings are considered. This will result in massive economic benefits considering that one healthy life year costs about \$100k.

The potential annual savings and productivity gains from the improved IAQ were estimated to be \$168 billion in the USA (1997 data) and €330 per worker in Europe (2000 data); reduced absenteeism was estimated to be \$400 per employee per year (2000 data). There are also significant economic benefits of improved learning when IAQ in schools is improved.

Despite the obvious economic and societal benefits, the effects of improved IAQ have not yet been integrated into the conventional financial calculations pertaining to building design and operation.

Abstract

This chapter reviews and discusses the World Health Organization (WHO) guidelines related to indoor air quality (IAQ). The WHO IAQ health guidelines are developed and published after systematic reviews of evidence from medical and public health studies, and through extensive panel discussion and expert consultation, which provide an important basis for countries to develop your national indoor air standards. First, a general background is provided for establishing health-based air quality guidelines, followed by a summary of the criteria for the inclusion and exclusion of specific pollutants in these documents and a summary of the values of the numerical guidelines for IAQ. The following

is a summary of existing or planned national standards or guidelines for IAQ management, including monitoring, in countries around the world, and discussed in the context of the WHO IAQ guidelines. Globally, only several countries have enacted national indoor air quality standards or health guidelines. The importance of developing a national standard or guideline for indoor air quality based on health evidence is discussed as a measure to reduce indoor exposure.

Keywords

Indoor air quality · Indoor air quality guidelines · Indoor air quality standards · WHO indoor air quality guidelines

Introduction

In this chapter, guidelines and standards for indoor air quality are reviewed and discussed. While the terms “guidelines” and “standards” are often used interchangeably, these are different types of documents, which we explain first. Secondly, we define indoor air quality for the purpose of this discussion. Finally, we outline the scope of this chapter.

An air quality health guideline is any kind of recommendation or guideline on the protection of a human population or receptors in the environment from the adverse effects of air pollution. The guidelines, which are globally considered to be the foundation for the prevention of health effects in relation to air pollution, are those developed by the World Health Organization (WHO). In 1979, the WHO published a criteria document focused on sulfur dioxide (SO_2) and particulate matter (WHO 1979), but the first edition of the guidelines was published by the WHO European Office in 1987 (WHO 1987). Following this, a global edition of the guidelines was published in 2000 (WHO 2000), with the most recent update published in 2021 (WHO 2021). The first edition of the guidelines (1987) included carbon monoxide (CO), lead, nitrogen dioxide (NO_2), ozone (O_3), sulfur dioxide (SO_2), and total suspended particulate (TSP) matter. The Global and European guidelines published in 2000, as well as the Global guidelines published in 2006, included the same pollutants; however, in 2000, TSP was replaced by $\text{PM}_{2.5}$ and PM_{10} , (particulate matter with aerodynamic diameter $<2.5\ \mu\text{m}$ and $10\ \mu\text{m}$, respectively), albeit without the provision of numerical guideline levels. In addition, the 2000 Global and European guidelines also included the following pollutants: cadmium, carbon disulfide, carbon monoxide, 1,2-dichloroethane, dichloromethane, formaldehyde, hydrogen sulfide, manganese, mercury, platinum, styrene, tetrachloroethylene, toluene, and vanadium. These pollutants were not included in the 2006 updated WHO AQG due to the limited resources available for the project, and therefore their values from the 2000 remain in effect. The new edition of the guidelines includes particulate matter: ($\text{PM}_{2.5}$ and PM_{10}), ozone, nitrogen dioxide, sulfur dioxide, and carbon monoxide (WHO 2021). As a general comment, the concept in WHO air quality guidelines has evolved over the years, to include in terms of the method used and environmental protection considerations (WHO 2017).

Health guidelines published by WHO are adopted based on expert panel agreements, following consideration of evidence from medical and public health studies. As stressed in the latest edition of the guidelines, “*The overall objective of these guidelines is to offer quantitative health-based recommendations for air quality, expressed as long- or short-term concentrations of a number of key air pollutants*” (WHO 2021).

Health guidelines are exclusively based on exposure (concentration)-response relationships found in epidemiological, toxicological, and environment-related studies. In general, they are not restricted to a numerical value but can be expressed in different ways. However, air quality guideline values are fixed numerical values corresponding to a defined averaging time. They could be expressed as: pollutant concentration in ambient air, a pollutant deposition level, other physical-chemical value, or a unit risk. In relation to human health, the air quality guideline is a concentration below which no adverse effects are expected, albeit a small individual risk always exists.

Over decades, there have been continued improvements to the meaning of the term “adverse health effects,” and improved in the understanding of the distinction between adverse and nonadverse effects (WHO 1972, 1978). These improvements came with the expansion of medical knowledge, including a higher sensitivity of research approaches and the application of biomarkers that can detect even the most subtle perturbation in the human biological system resulting from exposure to air pollution. These expansions were discussed and utilized in the Official Statement of the American Thoracic Society as to “What Constitutes an Adverse Health Effect of Air Pollution,” released in 2000 (Samet et al. 2000), thus modifying the previous statement of the Society released in 1985 (Andrews et al. 1985).

The above example illustrates many steps, which need to be taken before initiating the process of establishing air quality health guidelines – which are “*rigorous scientific tool that can be used by regulatory authorities as a basis for setting standards, taking into account local sociopolitical and economic conditions and prevailing ambient concentrations of air pollutants*” (WHO 2017) – as discussed in section “**National Standards**,” below. The quantification of risk due to environmental exposure to a particular pollutant is always a complex process, since there are numerous other pollutants and environmental factors, which have an impact on the individual at the same time, and the particular exposure investigated is only one of those factors. Such a process is normally initiated when evidence emerges that exposure to the pollutant constitutes a risk to human health. Some of the key subsequent steps in the process include the quantification of both the exposure-response relationship, as well as the impact of the proposed regulations or policy measures on the actual reduction in exposure. The entire process of risk assessment, for the purpose of risk management, encompasses several more steps, in particular, establishing the exposure-dose and dose-response relationships (these two are not always conducted, instead concertation-response is considered), the lifetime individual risk, and the risk to the exposed population (Naugle and Pierson 1991).

By contrast to air quality health guideline, an air quality standard is a level of air pollution (concentration, deposition, etc.), which is promulgated by a regulatory

authority and adopted as enforceable. The key elements in formulation of a standard are: (i) effect-based level, (ii) averaging time, (iii) measurement procedure, (vi) definition of compliance parameters corresponding to the averaging times, and (vii) permitted number of exceeding. Ideally, national (state, provincial, etc.) standards should be set at the level (or below) recommended by WHO guidelines. For a range of reasons this is often not possible and a higher-standard values are decided upon and set. Unlike WHO air quality guidelines that are exclusively based on exposure-response relationships, there are two key aspects that are considered by public health regulators when setting standards, which are acceptability of risk and cost-benefits analysis. Acceptability of the risk and thus the standard value selected depend on: (i) the expected incidence and severity of the potential health effects; (ii) the size of the population at risk; and (iii) the degree of scientific uncertainty that the health effect will occur at any given level of air pollution. The acceptability of risk may vary among countries (or even among administrative regions within the countries), because of differences in social norms, degree of adversity, risk perception in the general population and various stakeholders, and how the risk associated with air pollution compares with other risks. Therefore, approaches to derivation of air quality standards from air quality guideline have the objectives of: (i) reducing the risk of adverse effects to a socially acceptable level and (ii) identification of the control actions that achieve greatest net economic benefit or is most economically efficient.

It is important to keep in mind these broad aspects characterizing indoor air quality (IAQ) guidelines and standards when considering these two types of documents. In principle, we compare different national standards and discuss how they relate to WHO IAQ guidelines.

IAQ is an element of indoor environment quality (IEQ) and is characterized in terms of concentration of pollutants that affect health (discussed in more detail below). IEQ is concerned, in addition to airborne pollutant concentrations, with several other factors, including thermal comfort, lighting, and acoustics. Another critical factor characterizing IEQ is ventilation for acceptable IAQ. Its role in the first instance is to remove from indoor air, and thus lower below acceptable levels (set by guidelines or standards), pollutants generated within the indoor environment. The pollutants are generated by the occupants and sources existing within the indoor environment (for example, mould or wall paint) or operating there (for example, combustion sources). Carbon dioxide (CO_2) requires a specific mention, as it is produced by combustion processes in indoor and outdoor environments but is a by-product of the natural metabolism of living organisms. Sampling for CO_2 is often used as a means for screening areas where potential IEQ problems may exist. Importantly, CO_2 , that is an indoor pollutant generated by humans, is commonly considered as a measure of perceived air quality, or a proxy for ventilation (Khovalyg et al. 2020).

Considering the above background, the scope of this chapter is:

1. WHO IAQ guidelines: (i) WHO guidelines related to indoor environment – background: (i) criteria for inclusion and exclusion of the specific pollutants and (ii) a summary of the IAQ numerical guideline values.

-
2. National IAQ standards: summary of the existing numerical national IAQ standards available in English language; (ii) summary of the rationale for selecting specific pollutants and their numerical values by the national health authorities; and (iii) discussion on the relation between national standards and WHO IAQ guidelines.

Outside the scope of the chapter are: (i) any qualitative IAQ guidelines or recommendations; and (ii) analysis of any broader IEQ aspects, in particular ventilation guidelines or standards. The later are critically reviewed, by, for example (Khovalyg et al. 2020).

WHO Indoor Air Quality Guidelines

WHO Guidelines Related to Indoor Environment: Background

There is an added complexity to indoor air pollution, compared to outdoor air pollution, since indoor air contains a mix of pollutants that penetrated from outside and those that were emitted inside; it is the mix of the pollutants that affects human health. This added complexity of relating indoor air quality and health, when compared to the impact of outdoor air, reflected in the WHO approach to develop health guidelines related to both of these environments. While, in relation to the outdoor air, there are two current documents, *WHO Global Air Quality Guidelines: particulate matter (PM_{2.5} and PM₁₀), ozone, nitrogen dioxide, sulfur dioxide, and carbon monoxide* (WHO 2021) and for some pollutant and averaging times (WHO 2006), indoor air is covered by three documents. Recommendation for developing separate indoor air quality guidelines came from the working group of the *WHO Air Quality Guidelines: Global Update 2005: particulate matter, ozone, nitrogen dioxide, and sulfur dioxide* (WHO 2006), in recognition that the management of indoor air quality requires approaches different from those used for outdoor air. In the subsequent work, it was acknowledged that while the existing WHO air quality guidelines are applicable to indoor air, a number of chemical substances were also identified for which specific indoor air guidelines were recommended. This led to the development of *WHO Guidelines for Indoor Air Quality, Selected Pollutants* (WHO 2010) – discussed below. In addition, guidelines on two other categories of health risk in indoor environments were also developed: biological agents and indoor combustion of solid fuels. The WHO guidelines on *Dampness and Mould* were published in 2009 (WHO 2009) and later, the *WHO Guidelines for Indoor Air Quality: Household Fuel Combustion* (WHO 2014). These two sets of WHO guidelines do not, however, provide limit values in indoor air but provide qualitative recommendations to manage mould and dampness in buildings and best approaches to reducing household air pollution, respectively. Given our objective is to provide to the reader an overview of existing numerical guideline values for indoor air (regulatory or voluntary), the WHO guidelines on dampness and combustion of solid fuels are out of the scope of this chapter.

Criteria for Inclusion and Exclusion of the Specific Pollutants

The criteria, which were defined for selecting the compounds to be included in the WHO guidelines for indoor air were:

- The existence of indoor sources.
- The availability of toxicological and epidemiological data.
- Indoor levels exceeding the levels of health concern (NOAEL – no observed adverse effect level and/or LOAEL – lowest observed adverse effect level).

The substances initially selected based on these criteria as requiring specific attention in relation to the indoor environment were: benzene, carbon monoxide, formaldehyde, naphthalene, nitrogen dioxide, particulate matter ($PM_{2.5}$ and PM_{10}), polycyclic aromatic hydrocarbons (especially benzo-[*a*]-pyrene), radon, tetrachloroethylene, and trichloroethylene. Later, however, particulate matter – $PM_{2.5}$ and PM_{10} – was included in the list of the pollutants covered by the same outdoor and indoor air quality guidelines. In this chapter we discuss all these pollutants, including particulate matter, since exposure to particulate matter is one of the most significant environmental risks factors (GBD 2019).

The pollutants covered by the WHO *Air Quality Guidelines: Global Update 2005: particulate matter, ozone, nitrogen dioxide, and sulfur dioxide* (WHO 2006) are regarded as not requiring specific attention in regard to indoor air: O₃, lead, and SO₂. Therefore, the same numerical health guidelines apply to both outdoor and indoor environments in relation to these pollutants (now provided by [WHO 2021]). While all three of these pollutants also originate from indoor sources, outdoor air is typically their main source in indoor environments, and the chemical structure of their molecules is the same, whether originating from indoor or outdoor sources.

Organic Indoor Air Pollutants

In relation to the impact of the organic air pollutants (benzene, formaldehyde, naphthalene, and polycyclic aromatic hydrocarbons, including especially benzo-[*a*]-pyrene, tetrachloroethylene, and trichloroethylene), the list of effects includes: carcinogenicity, co-carcinogenicity, mucus coagulation, cilia toxicity, increased allergic sensitization, increased airway reactivity, eye, throat or nose irritation, headache, cough, and fatigue. While it is outside the scope of this chapter to discuss these effects in more detail, they are comprehensively covered by the guideline document. The indoor sources of these pollutants include – *benzene*: tobacco smoke, solvents used for hobbies or cleaning, or using building materials that off-gas benzene; *formaldehyde*: particleboard, insulation, furnishing, tobacco smoke, gas stoves, and consumer products; *naphthalene*: naphthalene mothballs, but also the combustion of biomass; *polycyclic aromatic hydrocarbons*: mainly combustion, including cooking smoking, candle burning, etc; *trichloroethylene*: using wood stains, varnishes, lubricants, paint removers, etc; and *tetrachloroethylene*: cleaning solvent and dry cleaning agents.

Inorganic Indoor Gaseous Pollutants: CO and NO₂ and Radon

In contrast, CO was included in the WHO Air Quality Guidelines for Europe, 2nd ed. (WHO 2000), and NO₂ was included in the WHO *Air Quality Guidelines: Global Update 2005: particulate matter, ozone, nitrogen dioxide, and sulfur dioxide* (WHO 2006). The two pollutants were in turn included in the WHO *Guidelines for Indoor Air Quality, Selected Pollutants* (WHO 2010), considering the different nature of exposure to these gases in indoor environments. Briefly, exposure to CO results in a reduction of oxygen delivery to tissues, owing to the formation of carboxyhemoglobin, and its indoor sources include tobacco smoke, faulty appliances (e.g., furnaces and hot water heaters), clogged chimneys, and automobile exhaust in houses with attached garages. Chronic health effects may be present for low concentrations of CO and sudden death can occur at high levels of the gas. Nitrogen dioxide exposure may lead to the occurrence of respiratory health effects, including short-term effects due to peak concentrations, particularly in susceptible individuals (asthmatics), as well as long-term effects on the incidence and prevalence of respiratory disease, primarily among children. Its indoor sources mainly include unvented combustion appliances, such as gas stoves, kerosene heaters, etc.

Radon, mainly ²²²Rn, is a naturally occurring noble radioactive gas which is classified by the International Agency for Research on Cancer (IARC) as a human carcinogen, which emanates and penetrates to indoor air from rocks, soil, groundwater, and also building materials. The radiation released, mainly from alpha decay of short-lived decay products within the lungs, imparts on the lung a dose to which an increased risk of lung cancer can be attributed. The WHO has identified radon as the highest priority area for reducing environmental radiation risk and in 2009 they launched the *WHO Radon Handbook* which gives a comprehensive overview on the radon problem (Zeeb et al. 2009).

Particulate Matter: PM_{2.5} and PM₁₀

There are still many questions remaining regarding PM, with one of them being whether there is convincing evidence for a difference in risk caused by PM from indoor sources, as compared with those from outdoors. One complexity is that ambient air is a significant contributor to indoor PM, whereby indoor concentrations are of the order of 50% of ambient concentrations, in the absence of any indoor sources. However, when indoor sources are present, the indoor levels of PM are usually higher than the outdoor levels. A large number of indoor particle sources were identified and emissions from these sources were investigated by many studies reported in the literature, e.g., He et al. (2004). Combustion processes are the main indoor sources of smaller particles, with the majority of them (in terms of number) in the ultrafine size range (<0.1 µm), containing a host of organic and inorganic material (Morawska and Zhang 2002). Other sources or human activities contributing to elevated levels of indoor ultrafine particles include vacuuming, cleaning using detergents, showering, operation of electric motors, and operation of printing and photocopying devices (Monn et al. 1995; Tucker 2000). Resuspension of particles by human movement, on the other hand, contributes to the coarse mode of indoor

particles, usually in the supermicrometer size (He et al. 2004). Contributions of different sources to different particle metrics (particle mass or particle number concentration), and different particle size ranges, were reviewed and summarized by Morawska et al. (2017). The analysis of the data available in literature showed that the key source contribution varies between different indoor environments. In particular, the main source of residential PM₁₀ and PM_{2.5} is outdoor; ultrafine particles (measured as particles number concentration) are generated predominantly by indoor sources, which is opposite to schools and day cares, for which ultrafine particles originate from outside, but PM₁₀ and PM_{2.5} originate from indoor sources, and for offices, particles of all sizes originate mainly from outdoors.

Health effects due to exposure to particulate matter include: decreased lung function, increased respiratory symptoms, increased chronic obstructive pulmonary disease, increased cardiovascular and cardiopulmonary disease, and increased all cause and cause-specific mortality. A large body of evidence on health effects associated with exposure to PM₁₀ and PM_{2.5} since publication of WHO *Air Quality Guidelines: Global Update 2005: particulate matter, ozone, nitrogen dioxide, and sulfur dioxide* (WHO 2006), which was used in the current update of the WHO *Global Air Quality Guidelines: particulate matter (PM_{2.5} and PM₁₀), ozone, nitrogen dioxide, sulfur dioxide, and carbon monoxide* (WHO 2021).

Summary of the IAQ Numerical Guideline Values

Table 1 summarizes WHO IAQ guideline values based on WHO *Guidelines for Indoor Air Quality, Selected Pollutants* (WHO 2010). Included in the table are also guideline values for PM_{2.5} and PM₁₀, NO₂, and CO based on the WHO *Global Air Quality Guidelines: particulate matter (PM_{2.5} and PM₁₀), ozone, nitrogen dioxide, sulfur dioxide, and carbon monoxide* (WHO 2021), as well as NO₂ and CO for the averaging times that are covered by WHO *Air Quality Guidelines: Global Update 2005: particulate matter, ozone, nitrogen dioxide, and sulfur dioxide* (WHO 2006).

National Standards

National air quality standards are enacted based on the potential for health and economic effects of the identified pollutants. We conducted a comprehensive Internet search to identify any existing indoor air quality national standards or guidelines. Unlike literature searches for referred journal papers, we could not use databases such as Web of Science, Scopus, etc. to identify national standards. Our search was also limited to English and Chinese language published documents; countries in which English is not spoken will not necessarily have their standards published in English (but some European Union [EU] countries have). While our search was comprehensive, we cannot exclude that we missed some countries' national regulations due to, for example, different terminology used or the indoor air regulations being imbedded into other types of broader regulations.

Table 1 Guideline values, as well as critical health outcomes of the indoor air pollutants included in the WHO *Guidelines for Indoor Air Quality, Selected Pollutants* (WHO 2010)⁽¹⁾, on particulate matter, NO₂, and CO averaging times based on the WHO Global Air Quality Guidelines: particulate matter ($PM_{2.5}$ and PM_{10}), ozone, nitrogen dioxide, sulfur dioxide, and carbon monoxide (WHO 2021)⁽²⁾, and on NO₂ and CO that are covered by WHO Air Quality Guidelines: Global Update 2005: particulate matter, ozone, nitrogen dioxide, and sulfur dioxide (WHO 2006)⁽³⁾

Pollutant	Guideline value	Critical outcome ^a
Benzene ⁽¹⁾	No safe level of exposure can be recommended Unit risk of leukaemia per 1 $\mu\text{g}/\text{m}^3$ air concentration is 6×10^{-6} The concentrations of airborne benzene associated with an excess lifetime risk of 1/10,000, 1/100,000 and 1/1,000,000 are 17, 1.7, and 0.17 $\mu\text{g}/\text{m}^3$, respectively	Acute myeloid leukemia (sufficient evidence on causality) Genotoxicity
Carbon ⁽¹⁾ monoxide Carbon ⁽²⁾ monoxide	15 min – 100 mg/m^3 1 h – 35 mg/m^3 8 h – 10 mg/m^3	Acute exposure-related reduction of exercise tolerance and increase in symptoms of ischemic heart disease (e.g., ST-segment changes)
	24 h – 4 mg/m^3	Association with hospital admissions and mortality from myocardial infarction
Formaldehyde ⁽¹⁾	0.1 mg/m^3 –30-min average	Sensory irritation
Naphthalene ⁽¹⁾	0.01 mg/m^3 – annual average	Respiratory tract lesions leading to inflammation and malignancy in animal studies
Nitrogen dioxide ⁽³⁾ Nitrogen dioxide ⁽²⁾	200 $\mu\text{g}/\text{m}^3$ –1 h average	Respiratory symptoms, bronchoconstriction, increased bronchial reactivity, airway inflammation, and decreases in immune defence, leading to increased susceptibility to respiratory infection
	10 $\mu\text{g}/\text{m}^3$ – annual average 25 $\mu\text{g}/\text{m}^3$ –24-h average	Nonaccidental mortality, cause-specific, and respiratory mortality
Polycyclic aromatic hydrocarbons ⁽¹⁾	No threshold can be determined, and all indoor exposures are considered relevant to health Unit risk for lung cancer for PAH mixtures is estimated to be 8.7×10^{-5} per ng/m^3 of B[a]P The corresponding concentrations for lifetime exposure to B[a]P producing excess lifetime cancer risks of 1/10,000, 1/100,000, and 1/1,000,000 are approximately 1.2, 0.12, and 0.012 ng/m^3 , respectively	Lung cancer

(continued)

Table 1 (continued)

Pollutant	Guideline value	Critical outcome ^a
Radon ⁽¹⁾	The excess lifetime risk of death from radon-induced lung cancer (by the age of 75 years) is estimated to be 0.6×10^{-5} per Bq/m ³ for lifelong nonsmokers and 15×10^{-5} per Bq/m ³ for current smokers (15–24 cigarettes per day); among ex-smokers, the risk is intermediate, depending on time since smoking cessation The radon concentrations associated with an excess lifetime risk of 1/100 and 1/1000 are 67 and 6.7 Bq/m ³ for current smokers and 1670 and 167 Bq/m ³ for lifelong nonsmokers, respectively	Lung cancer suggestive evidence of an association with other cancers, in particular leukemia and cancers of the extra thoracic airways
Trichloroethylene ⁽¹⁾	Unit risk estimate of 4.3×10^{-7} per µg/m ³ The concentrations of airborne trichloroethylene associated with an excess lifetime cancer risk of 1:10,000, 1:100,000, and 1:1,000,000 are 230, 23, and 2.3 µg/m ³ , respectively	Carcinogenicity (liver, kidney, bile duct, and non-Hodgkin's lymphoma), with the assumption of genotoxicity
Tetrachloroethylene ⁽¹⁾	0.25 mg/m ³ – annual average	Effects in the kidney indicative of early renal disease and impaired performance
PM _{2.5} ⁽²⁾	1 year, 5 µg/m ³ 24 h, 15 µg/m ³	All-cause, cardiovascular, respiratory, and lung cancer mortality
PM ₁₀ ⁽²⁾	1 year, 15 µg/m ³ 24 h, 45 µg/m ³	All-cause, cardiovascular, respiratory, and lung cancer mortality

^aBesides these outcomes, there are other health effects of the exposure to each of the considered pollutants. The critical outcomes were selected for the risk assessment of the exposure to given pollutant with the assumption (based on available evidence) that the reduction of exposure to prevent this critical health outcome prevents other health outcomes of the exposure as well

Based on the Internet search, we found that not all countries have their own national standards or guidelines. There is no directive guideline or standard at the EU level, but there are national guidelines in some European countries, including the guideline or target values in the UK (Shrubsole et al. 2019), France (France 2020), Germany (Bundesamt 2021), and Belgium (De Brouwere et al. 2020). Table 2 presents a summary of national standards or guidelines for IAQ management or monitoring and Table 3 tabulates pollutants and their limit values for the countries that have national standards, guidelines, or targets.

We have also separately listed the countries which state that they do not have national standards. Those countries in alphabetic order include: Albania, Algeria, Andorra, Angola, Argentina, Armenia, Australia, Austria, Azerbaijan, Bahrain, Bangladesh, Bahamas, Barbados, Belarus, Benin, Bhutan, Bolivia, Bosnia and Herzegovina, Botswana, Brunei, Bulgaria, Burkina Faso, Burundi, Cambodia, Cameroon, Capo Verde, Central African Republic, Chad, Chile, Colombia, Comoros, Congo, Cote d'Ivoire, Croatia, Cyprus, Czech Republic, Democratic Republic of Congo, Denmark, Djibouti, Ecuador, Egypt, Equatorial Guinea, Eritrea, Estonia, Eswatini, Ethiopia, Falkland Islands, Finland, French Guiana, Gabon, Gambia, Georgia, Ghana, Greece, Guinea, Guyana, Iceland, Iran, Ireland, Italy, Jamaica, Jordan, Kazakhstan, Kenya, Kyrgyzstan, Latvia, Laos, Lebanon, Lesotho, Liberia, Libya, Liechtenstein, Lithuania, Luxembourg, Madagascar, Malawi, Maldives, Mali, Malta, Mauritania, Mauritius, Mayotte, Moldova, Monaco, Mongolia, Montenegro, Morocco, Mozambique, Myanmar, Namibia, the Netherlands, New Zealand, Niger, Nigeria, North Macedonia, Oman, Pakistan, Paraguay, Peru, Philippines, Qatar, Réunion, Romania, Rwanda, Saint Helena, San Marino, Sao Tome and Principe, Senegal, Serbia, Seychelles, Sierra Leone, Singapore, Slovakia, Slovenia, Somalia, South Africa, South Sudan, Sri Lanka, State of Palestine, Sudan, Suriname, Switzerland, Syria, Tajikistan, Tanzania, Thailand, Timor-Leste, Togo, Trinidad and Tobago, Tunisia, Turkmenistan, Turkey, Uganda, Ukraine, United Arab Emirates, Uruguay, Venezuela, Vietnam, Western Sahara, Zambia, Zimbabwe, etc.

Although there are no specific policies in these countries, in some of the countries actions are being taken to comply with other countries' air quality standards or other type of indoor air regulations. For example, in Singapore, building owners, facility managers, and occupants all have liability in maintaining indoor air quality for the health and comfort of occupants in buildings. In Bahamas, the government regularly compare local air quality levels with the US air quality index values.

Different environments in different countries, as well as different factors considered in health and economic assessments of the impact of indoor air pollution, can result in different pollutants to be included in national standards or guidelines across countries. Most national guideline or standard threshold values are enacted in consideration with exposure level that is undesirable for health; however, the numerical values for the same pollutant can be different across countries. For example, in Germany, Guide value II (RW II) is an effect-related value based on current toxicological and epidemiological evidence of a substance's effect threshold with uncertainty factors considered. Guide value I (RW I) represents the concentration of a substance in indoor air for which, when considered individually, there is no evidence at present that even lifelong exposure is expected to bear any adverse health impacts. In India, three levels of threshold values have been defined as aspirational (Class A), acceptable (Class B), and marginally acceptable (Class C).

An important question is how the national indoor air quality guideline or standard values for individual pollutants relate to the WHO guideline values for these pollutants. To answer this question, in Fig. 1a, b, we compare national threshold values to the WHO ones, for PM ($PM_{2.5}$ and PM_{10}) and CO, respectively. An interesting observation from Fig. 1a is that while for PM_{10} the regulatory threshold

for four out of six countries that have regulations, significantly exceed the WHO values, for PM_{2.5} by contrast, only in one out of six countries the national threshold value exceeded this of WHO, while in four countries, the national thresholds are lower than the WHO ones. However, CO national guideline/standard values are all one (out of nine countries) higher than WHO guideline levels.

Another important question is the enforcement of indoor air quality national regulations. The first element of enforcement is compliance monitoring of the concentration levels of the regulated pollutants. Compliance monitoring of ambient air pollution is conducted at networks of air monitoring stations, usually operated by the relevant authorities, or by organizations mandated to do so. Measurements from a set number of central monitoring stations are considered for this purpose as representative of the entire area the network covers. In contrast, compliance monitoring of indoor air quality would require monitoring to be conducted in every building or in several locations within the building, as no central indoor monitoring would be representative of air quality in the entire local building stock. Therefore, indoor air monitoring is usually not conducted on a routine manner, which means there is no enforcement of indoor air quality regulations (UNEP 2021). A particularly difficult case regarding enforcement is, if the pollutant in question is generated predominantly outdoors, from where it penetrates indoors. This is the case in relation to PM_{2.5} and PM₁₀, in homes, and offices, as discussed above, based on a review by Morawska et al. (2017). This is also the case in many air pollution episodes, such as bushfires are haze episodes. In such situations controlling indoor air quality may be difficult or impossible, if the building does not have an efficient mechanical ventilation system.

It is somewhat easier to compare regulatory values and the averaging times for the so-called criteria pollutants (PM and gaseous pollutants: CO, NO_x, O₃, and SO₂), then for organic compounds. Due to the complex structure and toxicity of organic matter in indoor environments, we have summarized national standards of major

Table 3 Summary on threshold or guideline values for common pollutants in National Indoor Air Quality Standards or Guidelines^a

Country	PM _{2.5}	Ozone, O ₃	Nitrogen dioxide, NO ₂	Sulfur dioxide, SO ₂	Carbon dioxide, CO ₂	Carbon monoxide, CO

between countries. However, it is outside the scope of this work to analyze in detail the differences and the rationale of different countries to select specific values.

Summary

Health guidelines for indoor air quality that developed and published by WHO following systematic reviews on evidence from medical and public health studies and through extensive expert panel discussion and consultation have provided an important foundation for countries to develop their national indoor air standards. Nevertheless, globally, only several countries have promulgated national indoor air quality standards or health guidelines, and in many cases the threshold values are higher than the current WHO guideline levels. Given the importance of air quality in indoor environments where people spend most of their time, developing health evidence-based national indoor air quality standard or guideline development to reduce indoor exposure is of paramount significance in terms of public health protection, particularly in low- and middle-income countries (LIMCs) with poorer indoor air quality.

Abstract

With the rapid development of high technology and indoor health problems in the modern world, indoor air quality (IAQ) becomes a matter of great concern to building occupants, building industry, manufacturers, national, state, and local government agencies, and other relevant entities. Utilizing harmonized consensus test standards is essential to characterize indoor pollutants and investigate indoor environmental conditions for assessing and improving IAQ and reducing occupants' risk of exposure and adverse health effects. This chapter elaborates on

X. Liu (✉)

Office of Research and Development, Center for Environmental Measurement & Modeling,
U.S. Environmental Protection Agency, Research Triangle Park, NC, USA
e-mail: liu.xiaoyu@epa.gov

consensus test standards that are widely used in the USA to assess IAQ-related issues, specifically highlighting the standards from ASTM International and Standard 62.1 and 62.2 of the American Society of Heating, Refrigerating, and Air-Conditioning Engineers (ASHRAE). ASTM methods help source control of indoor air pollutants for IAQ, whereas ASHRAE standards address the control and assessment of IAQ and ventilation of commercial and residential buildings for IAQ management. Primary focuses of this chapter are ASTM methods for indoor air sampling and analysis, emission and material testing, IAQ evaluation and exposure assessment, and the ventilation calculation methods and procedures in ASHRAE Standards 62.1 and 62.2. The IAQ acceptable limits and ventilation requirements are out of the scope of this chapter. Other standards discussed include US Environmental Protection Agency methods, International Organization for Standardization standards, and others. Recommendations of future standardization efforts comprises standards for exposure test protocols, new and advanced sampling and analysis methods, emerging contaminant measurements, indoor air modeling, and updates of ASHRAE standards.

Keywords

ASTM standard · ASHRAE standard · Consensus standards · Emission testing · Ventilation

Introduction

In the modern world, green building movements to improve energy efficiency, advances in construction technology using synthetic materials, and increase use of varied chemicals in building materials and consumer products have contributed to a more comfortable life while at the same time potentially producing high concentrations of indoor air pollutants (Liu 2018). Indoor air pollutants and indoor environment have significant impacts on human health since people spend nearly 90% of their time indoors. Human exposure to indoor air pollution has the potential to cause acute and chronic adverse health effects, especially for sensitive populations like children and the elderly. In addition, poor indoor air quality (IAQ) directly affects occupant quality of life and productivity. IAQ includes consideration of both indoor air pollution levels and thermal environmental parameters (ASHRAE 2009). This potential increase on indoor pollution and its greater health impact invokes the desire for better IAQ through control of temperature, humidity, ventilation, and airborne contaminants in the indoor environment. Emissions from building materials, furnishings, consumer products, and indoor equipment, and entry of outdoor contaminants along with human activities, airborne particles, settled dust, and indoor radon are all major causes of IAQ problems. Poor air ventilation and inadequate supply of outdoor air to the indoor environment increase indoor pollution. Extreme temperature and humidity could elevate air pollution levels and accelerate growth of bacteria and viruses. During the development of relevant IAQ regulations, guidelines, and

labeling systems, consensus standards play an important role in helping understand the indoor environments in buildings, improving IAQ, and ensuring greener and healthier buildings and indoor environments. This chapter provides an overview of indoor air test standards with the focus on standards of ASTM International and guidance on ventilation from the American Society of Heating, Refrigerating, and Air-Conditioning Engineers (ASHRAE) used by the indoor air research community for the assessment and control of IAQ.

The word “consensus” is defined by the US Office of Management and Budget (OMB) in the OMB Circular A-119 Section 5e as “*general agreement, but not necessarily unanimity. During the development of consensus, comments and objections are considered using fair, impartial, open, and transparent processes*” (OMB 2016). This definition aligns closely to the definition given by American National Standards Institute (ANSI), which is “*substantial agreement reached by directly and materially affected interest categories. This signifies the concurrence of more than a simple majority, but not necessarily unanimity. Consensus requires that all views and objections be considered, and that an effort be made toward their resolution*” (ANSI 2020a). Measurements undertaken using consensus test standards ensure that the data is collected based upon agreed best practice with data quality and uncertainty taken into account, such that they be used nationally and internationally by product manufacturers, consumers, and researchers allowing data comparability. Consensus test standards can help business and industry manufacture safe, reliable, and good quality products while also safeguarding consumers and the end users to minimize potential harm, hazardous exposure, and adverse health effects. Consensus test standards are not mandatory for regulatory compliance, but they could become mandatory if they are incorporated by the government or law enforcement for technical details into a legislation. There are a few voluntary consensus standards bodies in the USA and around the world that oversee or develop voluntary consensus test standards related to IAQ. The following organizations and institutions (in alphabetical order) are well recognized in the development, use, and distribution of test standards related to IAQ issues in the USA.

American Conference of Governmental Industrial Hygienists (ACGIH), (ACGIH 2020a), founded in 1938, is an organization whose members are industrial hygienists or other occupational health and safety professionals. ACGIH is not a standards-setting body. It publishes guidelines based on scientific literature review, known as threshold limit values (TLVs) and biological exposure indices (BEIs), for use by industrial hygienists each year. TLVs for over 700 chemical substances and physical agents and BEIs for more than 50 selected chemicals are currently available for use. TLVs and BEIs are not consensus standards per se, but they are guidelines for safe levels of chemical and physical agents’ exposure in the workplace (ACGIH 2020b).

American Industrial Hygiene Association (AIHA), (AIHA 2020), founded in 1939, is the association for scientists and professionals of occupational and environmental health and safety in the workplace and community. AIHA supports the development and harmonization of national and international industrial/occupational hygiene-related standards.

American National Standards Institute (ANSI), (ANSI 2020b), founded in 1918, oversees the development of voluntary consensus standards for products, services, processes, systems, and personnel in the USA. ANSI itself does not develop standards but accredits the procedures of standards developing organizations (SDOs) and approve documents developed by SDOs as American National Standards. ANSI coordinates US standards with international standards and plays an important role in the US voluntary standards community.

American Society of Heating, Refrigerating, and Air-Conditioning Engineers (ASHRAE), (2020a), was founded in 1894. The current name and organization came from the 1959 merger of the American Society of Heating and Air-Conditioning Engineers (ASHAE) and the American Society of Refrigerating Engineers (ASRE). The society develops and publishes standards and guidelines relating to heating, ventilation, and air-conditioning (HVAC) systems to improve building service engineering, energy efficiency, and IAQ.

ASTM International (ASTM), (2020a), founded in 1898, was formerly known as American Society for Testing and Materials. It is an international standards organization that develops and publishes over 12,000 voluntary consensus technical standards for a variety of systems, services, materials, and products. There are over 140 technical committees within ASTM, among which D22 is the air quality committee with 13 subcommittees including D22.05, the indoor air subcommittee.

Business and Institutional Furniture Manufacturers Association (BIFMA), (2020), founded in 1973, is the not-for-profit trade association for business and institutional furniture manufacturers, which develops, maintains, and publishes safety and performance standards for commercial furniture products.

California Department of Public Health (CDPH), (2020), is a subdivision of the California Health and Human Services Agency. CDPH developed a standard test method, known as the CDPH Standard Method, V1.2-2017. This test method expanded on requirements of the California 01350 Specification developed by the State of California to address IAQ problems related to emissions from building materials (California Department of Resources Recycling and Recovery (CalRecycle) 2019).

US Consumer Product Safety Commission (CPSC), (2020), formed in 1972, is a US federal regulatory agency for consumer product safety. CPSC collaborates with other standard bodies such as Underwriters Laboratories Inc. (UL), ASTM, and others to develop safety standards for consumer products.

International Organization for Standardization (ISO), (2020a), founded in 1947, is the world's largest developer of voluntary international standards composed of 165 national standards bodies and headquartered in Geneva, Switzerland. ISO standards are developed by ISO technical committees (TC) and subcommittees (SC). The organization has published more than 20,000 international standards covering almost every industry.

National Institute for Occupational Safety and Health (NIOSH), (2018) established in 1971, is part of the Centers for Disease Control and Prevention (CDC) within the US Department of Health and Human Services. The institute is a research agency focusing on the study of worker safety and health. NIOSH

publishes the Manual of Analytical Methods (NMAM), which is a frequently updated living document that provides evaluated methods for sampling and analysis of contaminants at workplaces (NIOSH 2020)

Underwriters Laboratories Inc. (UL), (2020a) established in 1894, is an accredited standards developer in the USA and Canada. It has produced over 1500 standards that are used to test and evaluate products, systems, and innovative technologies (UL 2020b).

United States Environmental Protection Agency (US EPA), (2020a) established in 1972, is a US federal agency whose mission is to protect human health and the environment. EPA offices and laboratories develop test methods for the analysis of various environmental media. EPA developed Test Methods for Evaluating Solid Waste: Physical/Chemical Methods, also known as SW-846 (US EPA 2020b), which includes over 200 analytical methods for hazardous and environmental pollutants. EPA also published Compendium of Methods for the Determination of Toxic Organic (TO) Compounds in Ambient Air, which include a set of 17 peer-reviewed, standardized methods for the determination of volatile, semivolatile, and selected toxic organic pollutants in the air (US EPA 2020c).

IAQ Test Standards

Overview

Poor IAQ is often considered to result in human exposure to adverse levels or mixtures of indoor air pollutants or adverse indoor environmental conditions. Indoor air pollutants can be categorized by (1) organic chemicals, including volatile organic compounds (VOCs) and semivolatile organic compounds (SVOCs), emitted from building materials, furnishings, consumer products, and human activities such as cooking, smoking, and cleaning; (2) inorganic gases and other chemicals, e.g. carbon monoxide, nitrogen oxides, and lead; (3) airborne particles and dust; (4) microorganisms such as bacteria, fungi, and viruses; and (5) outdoor sources, such as radon and chemicals entering through vapor intrusion and penetration. Additional environmental conditions contributing to IAQ include temperature, humidity, building pressures induced by air infiltration and/or stack effect, and the presence of natural and/or mechanical ventilation. The IAQ consensus test standards summarized in this section are used by government regulators, industry, consumer groups, and others for IAQ assessment and/or potential remediation. They are also effective tools used for building codes and product labeling.

ASTM Methods Developed by Subcommittee on Indoor Air

The standards listed below were developed by the ASTM Subcommittee D22.05 on Indoor Air (ASTM 2020b). All the ASTM standards cited in this chapter are reprinted with permission from ASTM, copyright ASTM International, 100 Barr

Harbor Drive, and West Conshohocken, PA 19428. A copy of the complete standard may be obtained from ASTM international, <http://www.astm.org>.

- D4861 Standard Practice for Sampling and Selection of Analytical Techniques for Pesticides and Polychlorinated Biphenyls in Air
- D5075 Standard Test Method for Nicotine and 3-Ethenylpyridine in Indoor Air
- D5116 Standard Guide for Small-Scale Environmental Chamber Determinations of Organic Emissions from Indoor Materials/Products
- D5157 Standard Guide for Statistical Evaluation of Indoor Air Quality Models
- D5197 Standard Test Method for Determination of Formaldehyde and Other Carbonyl Compounds in Air (Active Sampler Methodology)
- D5438 Standard Practice for Collection of Floor Dust for Chemical Analysis
- D5466 Standard Test Method for Determination of Volatile Organic Compounds in Atmospheres (Canister Sampling Methodology)
- D5791 Standard Guide for Using Probability Sampling Methods in Studies of Indoor Air Quality in Buildings
- D5955 Standard Test Methods for Estimating Contribution of Environmental Tobacco Smoke to Respirable Suspended Particles Based on UVPM and FPM
- D6177 Standard Practice for Determining Emission Profiles of Volatile Organic Chemicals Emitted from Bedding Sets
- D6178 Standard Practice for Estimation of Short-Term Inhalation Exposure to Volatile Organic Chemicals Emitted from Bedding Sets
- D6196 Standard Practice for Choosing Sorbents, Sampling Parameters and Thermal Desorption Analytical Conditions for Monitoring Volatile Organic Chemicals in Air
- D6245 Standard Guide for Using Indoor Carbon Dioxide Concentrations to Evaluate Indoor Air Quality and Ventilation
- D6271 Standard Test Method for Estimating Contribution of Environmental Tobacco Smoke to Respirable Suspended Particles Based on Solanesol
- D6306 Standard Guide for Placement and Use of Diffusive Samplers for Gaseous Pollutants in Indoor Air
- D6327 Standard Test Method for Determination of Radon Decay Product Concentration and Working Level in Indoor Atmospheres by Active Sampling on a Filter
- D6330 Standard Practice for Determination of Volatile Organic Compounds (Excluding Formaldehyde) Emissions from Wood-Based Panels Using Small Environmental Chambers Under Defined Test Conditions
- D6332 Standard Guide for Testing Systems for Measuring Dynamic Responses of Carbon Monoxide Detectors to Gases and Vapors
- D6333 Standard Practice for Collection of Dislodgable Pesticide Residues from Floors
- D6399 Standard Guide for Selecting Instruments and Methods for Measuring Air Quality in Aircraft Cabins
- D6485 Standard Guide for Risk Characterization of Acute and Irritant Effects of Short-Term Exposure to Volatile Organic Chemicals Emitted from Bedding Sets
- D6669 Standard Practice for Selecting and Constructing Exposure Scenarios for Assessment of Exposures to Alkyd and Latex Interior Paints

- D6670 Standard Practice for Full-Scale Chamber Determination of Volatile Organic Emissions from Indoor Materials/Products
- D6803 Standard Practice for Testing and Sampling of Volatile Organic Compounds (Including Carbonyl Compounds) Emitted from Architectural Coatings Using Small-Scale Environmental Chambers
- D7034 Standard Guide for Deriving Acceptable Levels of Airborne Chemical Contaminants in Aircraft Cabins Based on Health and Comfort Considerations
- D7143 Standard Practice for Emission Cells for the Determination of Volatile Organic Emissions from Indoor Materials/Products
- D7297 Standard Practice for Evaluating Residential Indoor Air Quality Concerns
- D7339 Standard Test Method for Determination of Volatile Organic Compounds Emitted from Carpet Using a Specific Sorbent Tube and Thermal Desorption/Gas Chromatography
- D7706 Standard Practice for Rapid Screening of VOC Emissions from Products Using Microscale Chambers
- D7859 Standard Practice for Spraying, Sampling, Packaging, and Test Specimen Preparation of Spray Polyurethane Foam (SPF) Insulation for Testing of Emissions Using Environmental Chambers
- D7911 Standard Guide for Using Reference Material to Characterize Measurement Bias Associated with Volatile Organic Compound Emission Chamber Test
- D8141 Standard Guide for Selecting Volatile Organic Compounds (VOCs) and Semivolatile Organic Compounds (SVOCs) Emission Testing Methods to Determine Emission Parameters for Modeling of Indoor Environments
- D8142 Standard Test Method for Determining Chemical Emissions from Spray Polyurethane Foam (SPF) Insulation Using Microscale Environmental Test Chambers
- D8283 Standard Practice for Cleaning and Certification of Specially Prepared Canisters

There are currently seven proposed new standards under the jurisdiction of D22.05:

- WK52095 Determination of an Emission Parameter for Phthalate Esters and Other Non-Phthalate Plasticizers from Planar Polyvinyl Chloride Indoor Materials for Use in Mass Transfer Modeling Calculations
- WK58354 Measuring Chemical Emissions from Spray Polyurethane Foam (SPF) Insulation Samples in a Large-Scale Spray Room
- WK58356 Conducting Emission and Fate Modeling for Spray Polyurethane Foam (SPF) Insulation in An Indoor Environment
- WK72782 Environmental Odor Assessment Using Odorant Prioritization with Solid Phase Microextraction (SPME) Air Sampling, Multidimensional Gas Chromatography-Mass Spectrometry (MDGC-MS) Olfactometry Analysis, and Synthetic Odor-Matching Validation
- WK62732 Evaluating PM_{2.5} Sensors or Sensor Systems Used in Indoor Air Applications

WK71196 Measurement Techniques for Formaldehyde in Indoor Air
WK74360 Evaluating CO₂ Indoor Air Quality Sensors or Sensor Systems Used in Indoor Applications

ASTM Methods Developed by Other Subcommittees

The ASTM standards listed below are regularly used for IAQ testing and assessments but were generated by subcommittees other than Subcommittee D22.05, such as Subcommittee D22.01 on Quality Control (ASTM 2020c), Subcommittee D22.08 on Assessment, Sampling, and Analysis of Microorganisms (ASTM 2020d), Subcommittee E06.41 on Air Leakage and Ventilation Performance (ASTM 2020e), Subcommittee D07.03 on Panel Products (ASTM 2020f), Subcommittee D01.28 on Biodeterioration (ASTM 2020g), and Subcommittee C16.31 on Chemical and Physical Properties (ASTM 2020h).

- D1356 Standard Terminology Relating to Sampling and Analysis of Atmospheres (Subcommittee D22.01)
- D6329 Standard Guide for Developing Methodology for Evaluating the Ability of Indoor Materials to Support Microbial Growth Using Static Environmental Chambers (Subcommittee D22.08)
- D7338 Standard Guide for Assessment of Fungal Growth in Buildings (D22.08)
- D7391 Standard Test Method for Categorization and Quantification of Airborne Fungal Structures in an Inertial Impaction Sample by Optical Microscopy (D22.08)
- D7658 Standard Test Method for Direct Microscopy of Fungal Structures from Tape (D22.08)
- D7788 Standard Practice for Collection of Total Airborne Fungal Structures via Inertial Impaction Methodology (D22.08)
- D7789 Standard Practice for Collection of Fungal Material from Surfaces by Swab (D22.08)
- D7910 Standard Practice for Collection of Fungal Material from Surfaces by Tape Lift (D22.08)
- D3273 Standard Test Method for Resistance to Growth of Mold on the Surface of Interior Coatings in an Environmental Chamber (Subcommittee D01.28)
- C1338 Standard Test Method for Determining Fungi Resistance of Insulation Materials and Facings (Subcommittee C16.31)
- E741 Standard Test Method for Determining Air Change in a Single Zone by Means of a Tracer Gas Dilution Active Standard (Subcommittee E06.41)
- E1333 Standard Test Method for Determining Formaldehyde Concentrations in Air and Emission Rates from Wood Products Using a Large Chamber (Subcommittee D07.03)
- D6007 Standard Test Method for Determining Formaldehyde Concentrations in Air from Wood Products Using a Small-Scale Chamber (D07.03)
- E241 Standard Guide for Limiting Water-Induced Damage to Buildings (E06.41 Subcommittee)

-
- E779 Standard Test Method for Determining Air Leakage Rate by Fan Pressurization (E06.41)
- E1827 Standard Test Methods for Determining Airtightness of Buildings Using an Orifice Blower Door (E06.41)

ISO Methods Developed by ISO TC 146/SC 6 Indoor Air Subcommittee

ISO TC 146 (air quality) and specifically subcommittee (SC) 6 (indoor air) have published 50 standards, nine of which (ISO12219:1 to 12219:9) are standards about emission testing for interior parts and materials of road vehicles. The ISO 16000 standards listed here are the standards focusing on indoor air quality issues only (ISO 2020b). They are measurement methods for characterizing emissions in indoor air and procedures for quality assurance/quality control (QA/QC).

- ISO16000-1:2004 Indoor Air – Part 1: General Aspects of Sampling Strategy
- ISO16000-2:2004 Indoor Air – Part 2: Sampling Strategy for Formaldehyde
- ISO16000-3:2011 Indoor Air – Part 3: Determination of Formaldehyde and Other Carbonyl Compounds in Indoor Air and Test Chamber Air – Active Sampling Method
- ISO16000-4:2011 Indoor Air – Part 4: Determination of Formaldehyde – Diffusive Sampling Method
- ISO16000-5:2007 Indoor Air – Part 5: Sampling Strategy for Volatile Organic Compounds (VOCs)
- ISO16000-6:2011 Indoor Air – Part 6: Determination of Volatile Organic Compounds in Indoor and Test Chamber Air by Active Sampling on Tenax TA Sorbent, Thermal Desorption and Gas Chromatography using MS or MS-FID
- ISO16000-7:2007 Indoor Air – Part 7: Sampling Strategy for Determination of Airborne Asbestos Fiber Concentrations
- ISO16000-8:2007 Indoor Air – Part 8: Determination of Local Mean Ages of Air in Buildings for Characterizing Ventilation Conditions
- ISO16000-9:2006 Indoor Air – Part 9: Determination of the Emission of Volatile Organic Compounds from Building Products and Furnishing – Emission Test Chamber Method
- ISO16000-10:2006 Indoor Air – Part 10: Determination of the Emission of Volatile Organic Compounds from Building Products and Furnishing – Emission Test Cell Method
- ISO16000-11:2006 Indoor Air – Part 11: Determination of the Emission of Volatile Organic Compounds from Building Products and Furnishing – Sampling, Storage of Samples, and Preparation of Test Specimens
- ISO16000-12:2008 Indoor Air – Part 12: Sampling Strategy for Polychlorinated Biphenyls (PCBs), Polychlorinated Dibenz-p-dioxins (PCDDs), Polychlorinated Dibenzofurans (PCDFs), and Polycyclic Aromatic Hydrocarbons (PAHs)
- ISO16000-13:2008 Indoor Air – Part 13: Determination of Total (gas and particle-phase) Polychlorinated Dioxin-like Biphenyls (PCBs) and Polychlorinated

- Dibenzo-p-dioxins/dibenzofurans (PCDDs/PCDFs) – Collection on Sorbent-backed Filters
- ISO16000-14:2009 Indoor Air – Part 14: Determination of Total (gas and particle-phase) Polychlorinated Dioxin-like Biphenyls (PCBs) and Polychlorinated Dibenzo-p-dioxins/dibenzofurans (PCDDs/PCDFs) – Extraction, Clean-up, and Analysis by High-resolution Gas Chromatography and Mass Spectrometry
- ISO16000-15:2008 Indoor Air – Part 15: Sampling Strategy for Nitrogen Dioxide (NO_2)
- ISO16000-16:2008 Indoor Air – Part 16: Detection and Enumeration of Moulds – Sampling by Filtration
- ISO16000-17:2008 Indoor Air – Part 17: Detection and Enumeration of Moulds – Culture-based Method
- ISO16000-18:2011 Indoor Air – Part 18: Detection and Enumeration of Moulds – Sampling by Impaction
- ISO16000-19:2012 Indoor Air – Part 19: Sampling Strategy for Moulds
- ISO16000-20:2014 Indoor Air – Part 20: Detection and Enumeration of Moulds – Determination of Total Spore Count
- ISO16000-21:2013 Indoor Air – Part 21: Detection and Enumeration of Moulds – Sampling from Materials
- ISO16000-23:2018 Indoor Air – Part 23: Performance Test for Evaluating the Reduction of Formaldehyde and Other Carbonyl Compounds Concentrations by Sorptive Building Materials
- ISO16000-24:2018 Indoor Air – Part 24: Performance Test for Evaluating the Reduction of Volatile Organic Compound Concentrations by Sorptive Building Materials
- ISO16000-25:2011 Indoor Air – Part 25: Determination of the Emission of Semivolatile Organic Compounds by Building Products – Microchamber Method
- ISO16000-26:2012 Indoor Air – Part 26: Sampling Strategy for Carbon Dioxide (CO_2)
- ISO16000-27:2014 Indoor Air – Part 27: Determination of Settled Fibrous Dust on Surfaces by SEM (scanning electron microscopy) (direct method)
- ISO16000-28:2012 Indoor air – Part 28: Determination of Odor Emissions from Building Products using Test Chambers
- ISO16000-29:2014 Indoor Air – Part 29: Test Methods for VOC Detectors
- ISO16000-30:2014 Indoor Air – Part 30: Sensory Testing of Indoor Air
- ISO16000-31:2014 Indoor Air – Part 31: Measurement of Flame Retardants and Plasticizers Based on Organophosphorus Compounds – Phosphoric Acid Ester
- ISO16000-32:2014 Indoor Air – Part 32: Investigation of Buildings for the Occurrence of Pollutants
- ISO16000-33:2017 Indoor Air – Part 33: Determination of Phthalates with Gas Chromatography/Mass Spectrometry (GC/MS)
- ISO16000-34:2018 Indoor Air – Part 34: Strategies for the Measurement of Airborne Particles
- ISO16000-36:2018 Indoor Air – Part 36: Standard Method for Assessing the Reduction Rate of Culturable Airborne Bacteria by Air Purifiers using a Test Chamber

- ISO16000-37:2019 Indoor Air – Part 37: Measurement of PM_{2.5} Mass Concentration
- ISO16000-38:2019 Indoor Air – Part 38: Determination of Amines in Indoor and Test Chamber Air – Active Sampling on Samplers Containing Phosphoric Acid Impregnated Filters
- ISO16000-39:2019 Indoor Air – Part 39: Determination of Amines – Analysis of Amines by (ultra-) High-performance Liquid Chromatography Coupled to High-resolution or Tandem Mass Spectrometry
- ISO16000-40:2019 Indoor Air – Part 40: Indoor Air Quality Management System

US EPA Methods

US EPA has developed the well-known compendium of methods for characterizing organic pollutants in the ambient air (US EPA 2020c) and for sampling and analysis of organic and inorganic chemicals in waste and other metrics in the environment (US EPA 2020b). The EPA methods presented here are closely related to indoor air sampling and analysis and have been widely accepted and employed by the IAQ community.

EPA Compendium Method TO-1 Method for the Determination of Volatile Organic Compounds in Ambient Air Using Tenax® Adsorption and Gas Chromatography/Mass Spectrometry (GC/MS)

EPA Compendium Method TO-11A Determination of Formaldehyde in Ambient Air Using Adsorbent Cartridge Followed by High Performance Liquid Chromatography (HPLC) (Active Sampling Methodology)

EPA Compendium Method TO-14A Determination of Volatile Organic Compounds (VOCs) in Ambient Air Using Specially Prepared Canisters with Subsequent Analysis by Gas Chromatography

EPA Compendium Method TO-15A Determination of Volatile Organic Compounds (VOCs) In Air Collected in Specially-prepared Canisters and Analyzed by Gas Chromatography/Mass Spectrometry (GC/MS)

EPA Compendium Method TO-17 Determination of Volatile Organic Compounds in Ambient Air Using Active Sampling onto Sorbent Tubes

EPA SW-846 Test Methods for Evaluating Solid Waste Physical Chemical Methods

Government Regulations

The Code of Federal Regulations (CFR) is frequently referenced in the test standards. CFR is the codification of the federal regulations published in the Federal Register by the US federal government (GPO 2020). CFR Title 29 (29 CFR) – Labor and CFR Title 40 (40 CFR) – Protection of Environment are 2 of 50 titles comprising CFRs. Twenty-nine CFR includes federal rules and regulations regarding labor,

including occupational safety and health. Forty CFR are environmental regulations that are promulgated by the US EPA. The following CFR items are cited in the ASTM methods listed previously:

- 29 CFR Part 1910 Occupational Safety and Health Standards
- 29 CFR 1910.1450 Occupational Exposure to Hazardous Chemicals in Laboratories
- 40 CFR Part 50 National Primary and Secondary Ambient Air Quality Standards
- 40 CFR Part 53 Ambient Air Monitoring Reference and Equivalent Methods
- 40 CFR Part 60 Standards of Performance for New Stationary Sources – Appendix A: Test Methods
- 40 CFR Part 136 Guidelines Establishing Test Procedures for the Analysis of Pollutants
- 40 CFR Part 136 Guidelines Establishing Test Procedures for the Analysis of Pollutants Appendix B: Definition and Procedure for the Determination of the Method Detection Limit

Other Frequently Used Standards

Standards developed by other government agency and standard bodies not listed above and commonly used for compliance with regulations include below. It is to point out that ASHRAE Standard 52.2 is not generally used for compliance with regulations, but it prescribes the test method forming the basis of the minimum efficiency reporting values (MERVs) rating system to address particulate matter for the majority of centrally ducted HVAC systems.

CDPH Standard Method v1.2 ([CDPH 2017](#)), Standard Method for the Testing and Evaluation of Volatile Organic Chemicals Emission from Indoor Sources using Environmental Chamber (Emission Testing Method for California Specification 01350) ([CDPH 2017](#))

California 01350 Specification, a special environmental requirements standard specification developed by the State of California to cover key environmental performance issues related to the selection and handling of building materials (California Department of Resources Recycling and Recovery (CalRecycle) [2019](#)).

ANSI/BIFMA M7.1-2011(R2016), Standard Test Method for Determining VOC Emissions from Office Furniture Systems, Components, and Seating ([BIFMA 2016a](#))

ANSI/BIFMA X7.1-2011(R2016), Standard for Formaldehyde and TVOC Emissions of Low-emitting Office Furniture and Seating ([BIFMA 2016b](#))

ANSI/ASHRAE Standard 52.2-2017, Method of Testing General Ventilation Air-Cleaning Devices for Removal Efficiency by Particle Size ([ASHRAE 2017a](#))

ANSI/ASHRAE Standard 55-2017, Thermal Environmental Conditions for Human Occupancy ([ASHRAE 2017b](#))

ANSI/ASHRAE Standard 62.1-2019, Ventilation for Acceptable Indoor Air Quality ([ASHRAE 2019a](#))

ANSI/ASHRAE Standard 62.2-2019, Ventilation and Acceptable Indoor Air Quality in Residential Buildings (ASHRAE 2019b)

ANSI/ASHRAE Standard 189.1-2017, Standard for the Design of High-Performance Green Buildings (ASHRAE 2017c)

CAN/ULC-S774-09 (R2014), Standard Laboratory Guide for the Determination of Volatile Organic Compound Emssions from Polyurethane Foam (ULC 2020)

CPSC-CH-C1001-09.4, Standard Operating Procedure for Determination of Phthalates (CPSC 2018)

ASTM Test Standards

ASTM standards are classified into three types: test method, guide, and practice. By ASTM definitions (2018), test method is “*a definitive procedure that produces a test result,*” guide is “*a compendium of information or series of options that does not recommend a specific course of action,*” and practice is “*a set of instructions for performing one or more specific operations that does not produce a test result.*” In general, ASTM standards prescribe procedures in sufficient detail for users to perform tests and collect data successfully and at the same time with flexibility through informative notes and annexes. The existing ASTM standards are reviewed and updated as needed and at a minimum every 5 years.

ASTM D22.05 Indoor Air Subcommittee currently maintains 34 active standards and is developing several new standards as listed above. The standards are on topics related to indoor air and dust sampling and analysis, emission testing for air pollutants from consumer products and building materials, ventilation, determination of uncertainty in chamber testing and indoor air modeling, and IAQ evaluation and exposure. They exclude the establishment of IAQ limit values. It is notable that these ASTM standards measure IAQ parameters in buildings and chemical emissions from materials, but not for automobiles. For individual pollutants there may be different sampling and analytical procedures in separate standards. The ASTM D22.08 Assessment, Sampling, and Analysis of Microorganisms Subcommittee also maintains and develops standards related to IAQ and focuses on indoor microorganisms. The ASTM standards and other relevant standards are categorized in Table 1.

In addition to the test standards, the ASTM standard terminology D1356 developed by Subcommittee D22.01 on Quality Control harmonizes definitions of terms commonly used in the air quality standards. There are also definitions of terms specific to individual ASTM standards when applicable. The following listing contains most frequently used terminologies that are not only referenced in the ASTM standards but also very often cited in other IAQ standards and publications. These terminologies are alphabetically adopted from ASTM D22 standards. The numbers in the parentheses are the ASTM standard numbers. All the ASTM terminology cited in this chapter are reprinted with permission from ASTM, copyright ASTM International.

Table 1 ASTM indoor air test standards by field applications

Field	Subfield	ASTM standard	Other relevant standard
Samplings/ Analysis	Microorganism	D7391, D7658, D7788, D7789, D7910	ISO16000-16, 17, 18, 19, & 20
	Pesticides and SVOCs	D4861, D5075, D6333	ISO16000-12, 13, 14, 31, & 33; TO-11A, SW-846, NIOSH Method, CPSC-CH-C1001-09.4
	Formaldehyde	D5197	ISO16000-2, 3, & 4; TO-11A
	Dust and particles	D5438	ISO16000-27, 34, & 37
	VOCs	D5466, D6196, D6306, D8283	ISO16000-5, 6, 38, & 39; TO-14A, 15A, &17;
	Tobacco smoke	D5955, D6271	
	Radon	D6327	
	Inorganic gas	D6332	ISO16000-15 & 26
Emission and material test	General	D5116, D6670, D7143, D7706, D7911, D8141	ISO16000-9, 10, 11, 23, 24, & 25; CDPH Standard Method v1.2
	Bedding set	D6177	
	Wood products	D6330, E1333, D6007	ANSI/BIFMA M7.1 & X7.1
	Coating	D6803	
	Carpet	D7339	
	SPF	D7859, D8142	CAN/ULC-S774-09
	Microbial ^a	D6329, D3273, C1338	ISO16000-21,
	Odor	Under development	ISO16000-28 & 30
Ventilation	Air change	E741, E779, E1827	
	Evaluation	D6245	ISO16000-8, ASHRAE Standard 62.1& 62.2
Indoor air modeling	Evaluation	D5157	
IAQ evaluation and exposure	Exposure	D6178, D6485, D6669	
	Aircraft cabins	D6399, D7034	
	IAQ	D5791, D7297	ISO16000-32
	Microorganism	D7338	ISO16000-36
	Moisture	E241	

^aD6329, D3273, and C1338 are not emission or material test standards of microbial, they are standards of material testing for microbial growth

Air change rate, the volumetric flow rate (volume per unit time) of air entering a space or enclosure divided by the net volume of air in that space or enclosure (1/s, 1/h) (D1356, D6177).

Chamber loading ratio, the total amount of test specimen exposed in the chamber divided by the net or corrected internal air volume of the chamber (D5116, D6670).

Clean air, air that does not contain any airborne contaminants in excess of defined limits (D6803).

Emission factor, the mass of a VOC or total VOC emitted per unit time and per unit amount of source tested. Depending on the type of source, the amount of source may be expressed by its exposed surface area (that is, an area source such as a painted gypsum wallboard surface), its dominant dimension (that is, a line source such as a caulk or sealant), its mass, or its standard setup (that is, a “unit” source such as a predefined work station system). As a result, the unit for the emission factor will be mg/h, mg/(m² h), mg/(m³ h), mg/(kg h), and mg/(m³ h) for the “unit,” line, area, mass, and volume emission sources, respectively (D6670).

Emission profile, a time series of emission rates of one or more chemicals (D6177, D6669, D6485).

Emission rate, the mass emitted per unit of time from a source or, alternatively, per unit of material or energy produced or consumed by a process (D1356).

Nonvolatile organic chemical, an organic compound with a saturation vapor pressure less than 10⁻⁸ kPa at 25 °C (D1356, D6177).

Semivolatile organic chemical (SVOC), an organic compound with a saturation vapor pressure between 10⁻² and 10⁻⁸ kPa at 25 °C (D1356).

Test chamber, an enclosed test volume constructed of chemically inert materials with a clean air supply and exhaust (D5116).

Total volatile organic compounds (TVOC), the summed concentration of all the individual volatile organic compounds (VOCs) quantifiable in an air sample by both a precisely specified sampling protocol and a precisely defined analytical method (D1356).

Tracer gas, a gaseous compound that can be used to determine the mixing characteristics of the test chamber and be a cross-check of the air change rate. The tracer gas must not be emitted by the test specimen and must not be contained in the supply air (D6670).

Volatile organic chemical (VOC), an organic compound with a saturation vapor pressure greater than 10⁻² kPa at 25 °C (D1356).

There are also commonly used terms and definitions for IAQ health, exposure, and risk assessment in ASTM D22.05 standards. They are:

Acute exposure guideline levels (AEGLs), represent short-term threshold or ceiling exposure values intended for the protection of the general public, including susceptible or sensitive individuals, but not hypersusceptible or hypersensitive individuals (D6485).

Ceiling limit, a maximum allowable air concentration, established by the Occupational Safety and Health Administration (OSHA), that must not be exceeded during any part of the workday (D6399, D6485).

Inhalation reference concentration (RfC), an estimate (with uncertainty spanning an order of magnitude) of the daily exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects (D6485).

Lethal concentration 50 (LC_{50}), a calculated concentration of a chemical in air to which exposure for a specific length of time is expected to cause death in 50% of a defined experimental animal population (D6485).

Lethal concentration low (LCL_o), the lowest calculated concentration of a chemical in air to which exposure over any period of time is reported to have caused death in humans or animals (D6485).

Level of concern, an exposure level or concentration that is not to be exceeded by regulation or, for unregulated pollutants, an exposure level or concentration that is believed to be associated with odor, sensory irritation, and other adverse health or toxic effects (D6399).

Lowest-observed-adverse-effect level (LOAEL), the lowest dose of a chemical in a study or group of studies that produce statistically or biologically significant increases in frequency or severity of adverse effects between the exposed population and its appropriate control (D6399, D6485).

Minimal risk level (MRL), an estimate of the daily human exposure to a hazardous substance that is likely to be without appreciable risk of adverse noncancer health effects over a specified duration of exposure (D6485).

No-observed-adverse-effect level (NOAEL), the dose of chemical at which there are no statistically or biologically significant increases in frequency or severity of adverse effects seen between the exposed population and its appropriate control (D6399, D6485).

Permissible exposure limit (PEL), an OSHA defined term meaning the limit of OSHA permitted exposure to a specific contaminant as required in the applicable regulation. This limit is an 8 h time weighted average (TWA), determined in the worker's breathing zone, and is expressed in a number of units of measure (D1356).

Potential inhaled dose, the estimated dose of an airborne chemical that an individual is likely to have inhaled within a specified period of time (D6485).

Short-term exposure limit (STEL), the airborne concentration of a substance in a continuous 15-min time period which should not be exceeded at any time during a workday (D1356).

Threshold limit value (TLV), Threshold limit value-time weighted average (TLV-TWA), the time-weighted average concentration for a conventional 8-h workday and 40-h workweek, to which it is believed that nearly all workers may be repeatedly exposed, day after day, without adverse effect (D1356).

Toxic concentration low (TCL_o), the lowest air concentration of a substance introduced by the inhalation route over any period of time that is reported to have produced any significant toxic effects in animals or humans (D6485).

As mentioned at the beginning of this chapter, even though these standards are a consensus on test methods and measurement practices, they do not provide specific criteria on concentrations and limits of material and product emissions. Nevertheless, they could be appropriate or adaptable by regulatory agencies in the laws or regulations. The Public Law 104-113 National Technology Transfer and Advancement Act (NTTAA) of 1995 (NIST 2019) was signed into law on March 7, 1996. The law supports interaction and cooperation between the private and public sectors

in developing and adopting standards that serve the government's purposes and support trade. The NTTAA § 12(d)(1) directs federal agencies and departments to use voluntary consensus standards with the two exceptions in bold below:

[A]ll Federal agencies and departments shall use technical standards that are developed or adopted by voluntary consensus standards bodies, using such technical standards as a means to carry out policy objectives or activities determined by agencies and departments . . . [except where] **inconsistent with applicable law or otherwise impractical.** [emphasis added]

Also, Section 12(d)(2) of the NTTAA directs federal agencies and departments to participate in the development of voluntary consensus standards:

[F]ederal agencies and departments shall consult with voluntary, private sector, consensus standards bodies and shall, when such participation is in the public interest and is compatible with agency and departmental missions, authorities, priorities, and budget resources, participate with such bodies in the development of technical standards.

As an example, ASTM D6007 (secondary method) and E1333 (primary method) are compliance test methods for chamber testing of composite wood products in the US Formaldehyde Standards for Composite Wood Products Act (GovTrack.us 2020). California (which is not subject to NTTAA) has also elected to base the California regulation 17 CCR §93120 Airborne Toxic Control Measure to Reduce Formaldehyde Emissions from Composite Wood Products (CARB 2007) on ASTM D6007 and E1333, which have many benefits to regulators and their stakeholders. These regulations limit formaldehyde emissions from composite wood products, e.g., hardwood plywood, particleboard, and medium-density fiberboard panels, and finished goods, manufactured domestically or imported into the USA. The CDPH Standard Method v1.2 is the emission test method for California Specification 01350. It incorporates ANSI/BIFMA M7.1, ASTM D5116 for small chamber testing procedures and data analysis, ASTM Standards D5197, D6196, D6345, D7339, and EPA methods TO-1 and TO 17 for sampling and analysis. Of note, California Specification 01350 is the only health-based building material specification and one of the most widely recognized US standards for restricting VOC emissions from building materials and products in the indoor environment. It has been referenced or required in criteria by numerous manufacturers and various certification and labeling schemes, such as US Green Building Council's (USGBC) Leadership in Energy and Environmental Design (LEED) program, EPA Indoor airPLUS program, UL GREENGUARD certification, the National Green Building Standard (NGBS), and Carpet and Rug Institute (CRI) Green Label Plus program.

ASHRAE Standards

Ventilation plays an important role in IAQ. Inadequate ventilation poses health-related problems due to increased levels of indoor air pollutants. This section addresses ANSI/ASHRAE Standard 62.1, ventilation for acceptable indoor air

quality, and Standard 62.2, ventilation and acceptable indoor air quality in residential buildings, which are consensus standards of practice regarding ventilation and IAQ in commercial buildings (62.1) and residential buildings (62.2). These two standards focus on IAQ and specify the ventilation criteria and other measurements to minimize adverse occupant health effects. ANSI/ASHRAE 62.1-2019 defines acceptable IAQ as: “air in which there are no known contaminants at harmful concentrations, as determined by cognizant authorities, and with which a substantial majority (80% or more) of the people exposed do not express dissatisfaction.” Both standards are accredited by ANSI and serve the building industry and the public as the most prescriptive standards on ventilation for IAQ.

In 1973, ASHRAE published Standard 62 for the first time to help engineers and other professionals on ventilation system design and operation practices for buildings with the IAQ procedure (IAQP) being initiated (ASHRAE 1973). The standard was then revised in 1981, 1989, 1999, and 2001, and split into Standards 62.1 and 62.2 in 2004 with significant modifications. The original edition of the standard was renamed to ASHRAE 62.1 in the 2004 edition. Since then the two standards have been continually reviewed and updated every 3 years. The latest versions of the standards are ASHRAE Standard 62.1-2019 and ASHRAE Standard 62.2-2019. ASHRAE standards are dynamic documents. A noteworthy foreword in each version of the standards informs the historical perspective on the development of the standards and describes the detailed changes compared to the previous version. In addition to the review process, official and unofficial interpretation documents for some of the editions exist (Standard 62-1989, 1999, 2001; Standard 62.1-2004, 2007, 2010, 2013, 2016, 2019; Standards 62.2-2004, 2007, 2010, 2013, 2016, 2019) (ASHRAE 2020b). An official interpretation is a written response to a request for an explanation of the meaning of a standard by the cognizant project committee or interpretation committee, whereas an unofficial interpretation is addressed by the manager of technical services, the chair of the cognizant project committee, or the manager of standards (ASHRAE 2020b).

ASHRAE 62.1

ASHRAE 62.1 is best recognized for its ventilation airflow requirements for the design of ventilation systems in various commercial and institutional buildings, which includes new buildings and additions and renovations to existing buildings. It is also used as a guide to improve IAQ in existing buildings. Over the years, most notable revisions to this standard included:

- Reducing the minimum outdoor-air rates; introducing performance-based IAQP (1981 edition)
- Formalizing IAQP; introducing “sick building syndrome” terminology and the requirement for multizone recirculating systems; increasing the minimum outdoor-air rates, removing thermal comfort (1989 edition)

- Recognizing the harm of cigarette smoking; clarifying CO₂ as ventilation metric (1999 edition)
- Minor revision (2001 edition)
- Substantially modifying the IAQP and the ventilation rate procedure (VRP) (2004 edition)
- Adding Appendix H (2007 edition)
- Adding Section 6.4 for the natural ventilation procedure (NVP) and requirements for demand-control ventilation (2010 edition)
- Making changes to exhaust air requirements; clarifying the requirements for the quality of water used in humidification system and building level pressurization (2013 edition)
- Moving all residential spaces to Standard 62.2 (2016 edition)
- Significantly modifying the NVP; adding a new simplified version of VRP (2019 edition)

The outlines of the standards in different editions have had little changes over the years. The 2019 edition is divided into nine sections, including the purpose, scope, definitions, outdoor air quality, system and equipment, procedures, construction and system start-up, normative references, and 15 appendices. The definitions section provides definitions of terms used throughout the standard. The standards also serve as disciplines for terminology and concepts in building design and building code communities as well as for educators, public officials, and building owners. Additionally, ASHRAE also provides over 3700 searchable terms and definitions used in the fields of HVACs design, engineering, and commissioning as a free online resource (ASHRAE 2020c). The important feature of ASHRAE 62.1-2019 is its three procedures, the ventilation rate procedure (Fig. 1), the indoor air quality procedure (Fig. 2), and the natural ventilation procedure (Fig. 3) in Section 6. These procedures are methods for determining outdoor air intake flow through the HVAC system(s). In addition, the standard incorporates information relevant to a certain number of contaminants and their indoor sources. Other factors that contribute to IAQ, such as thermal comfort, noise, lighting, etc. are not within the scope of Standard 62.1. The mold growth and humidity tests of materials are referenced to the standardized test methods, UL 181 (UL 2013), ASTM C1338, and ASTM D3273. Thermal comfort is covered in ANSI/ASHRAE 55, Thermal Environmental Conditions for Human Occupancy.

The VRP is very often cited and widely used for compliance. It provides the prescriptive approaches for the ventilation calculations and tabulates the minimum ventilation rates in breathing zone, minimum exhaust rates, and zone air distribution effectiveness for a wide range of scenarios, such as different spaces and occupant density, etc. The acceptable air quality is achieved by specifying those parameters. In Standard 62.1-2019, the breathing zone outdoor airflow is given by Eq. 1 below (Copyright notice for ASHRAE Standards ©ASHRAE, <http://www.ashrae.org>. Used with permission from (2019) ASHRAE Standard-62.1 & ASHRAE Standard-62.2):

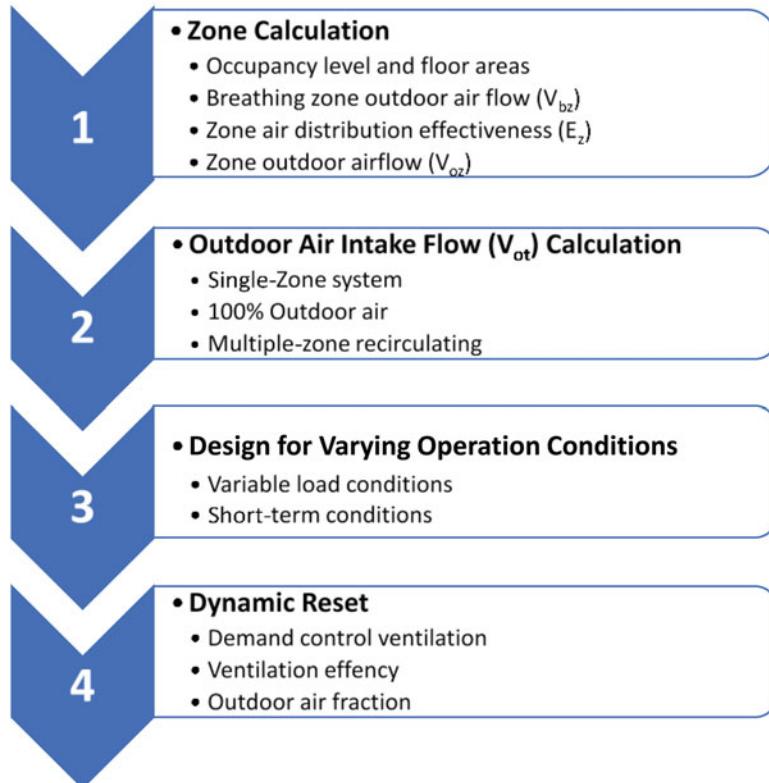

Fig. 1 ASHRAE Standard 62.1-2019, ventilation rate procedure (VRP)

$$V_{bz} = R_p \times P_z + R_a \times A_z \quad \text{ASHRAE 62.1} \quad (1)$$

where, V_{bz} is the breathing zone outdoor airflow, A_z is the zone floor area (ft^2, m^2), P_z is the zone population, R_p is outdoor airflow rate required per person, and R_a is the outdoor airflow rate required per unit area. The zone outdoor airflow (V_{oz}) is calculated by:

$$V_{oz} = V_{bz}/E_z \quad \text{ASHRAE 62.1} \quad (2)$$

where E_z is the zone air distribution effectiveness. For a single-zone system, the outdoor air intake flow (V_{ot}) is determined by:

$$V_{ot} = V_{oz} \quad \text{ASHRAE 62.1} \quad (3)$$

If the air handler supplies only outdoor air to the zones, the V_{ot} value shall be the sum of the zone outdoor airflows for all zones as:

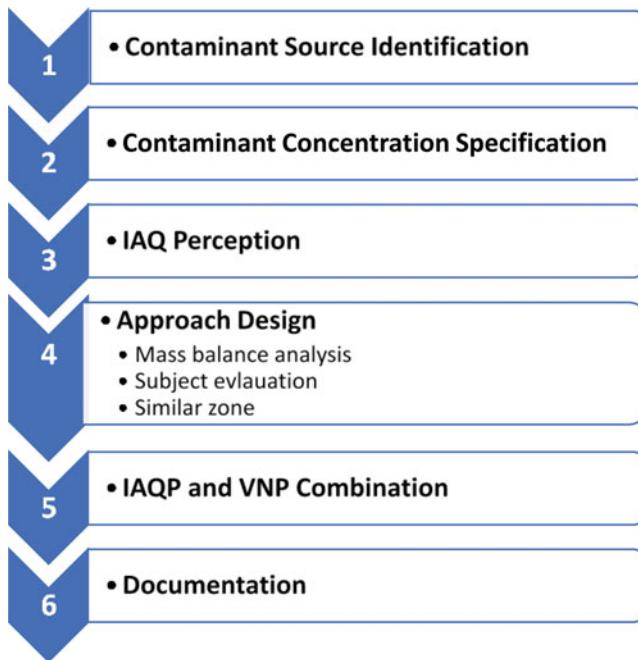

Fig. 2 ASHRAE Standard 62.1-2019, indoor air quality procedure (IAQP)

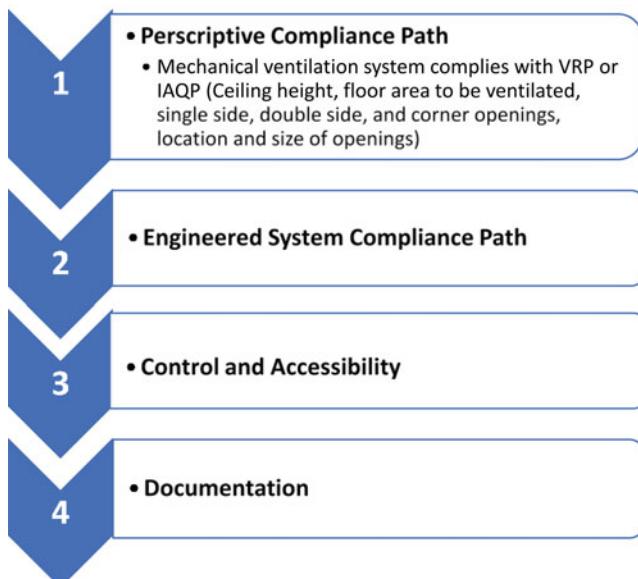

Fig. 3 ASHRAE Standard 62.1-2019, natural ventilation procedure (NVP)

$$V_{ot} = \sum_{\text{all zones}} V_{oz} \quad \text{ASHRAE 62.1} \quad (4)$$

For multiple-zone recirculating systems, the uncorrected outdoor air intake (V_{ou}) is calculated by:

$$V_{ou} = D \sum_{\text{all zones}} (R_p \times P_z) + \sum_{\text{all zones}} (R_a \times A_z) \quad \text{ASHRAE 62.1} \quad (5)$$

where the occupant diversity ratio (D) is determined by:

$$D = P_s / \sum_{\text{all zones}} P_z \quad \text{ASHRAE 62.1} \quad (6)$$

The VRP also offers calculations for a simplified procedure through Eqs. (6–7) to (6–10):

$$E_v = 0.88 \times D + 0.22 \text{ for } D < 0.60 \quad \text{ASHRAE 62.1} \quad (7)$$

$$E_v = 0.75 \text{ for } D \geq 0.60 \quad \text{ASHRAE 62.1} \quad (8)$$

$$E_{pz-\min} = V_{oz} \times 1.5 \quad \text{ASHRAE 62.1} \quad (9)$$

$$V_{ot} = \frac{V_{ou}}{E_v} \quad \text{ASHRAE 62.1} \quad (10)$$

where, E_v is the system ventilation efficiency and V_{pz-min} is the minimum primary airflow.

When the VRP is applied, it is important to evaluate and determine whether outdoor air treatment is necessary. For instance, particulate matter with a maximum diameter of 10 µm (PM10), particulate matter with a maximum diameter of 2.5 µm (PM2.5), ozone, and other outdoor contaminants are to be considered (Standard 62.1-2019 Section 6.1.4). Also note that ASHRAE provided an online Excel spreadsheet (62MZCalc.xls), and more recently, developed and updated a smart phone application for comprehensively calculating ventilation rates for simple and complicated ventilation systems of various buildings exclusively through Carmel Software Corporation (ASHRAE 2020d). The application is user friendly with features of being flexible with multiple projects, calculations in the field and the office, and full online help support. The latest application was developed based on Standard 62.1-2013. Trane Air Conditioning Economics (TRACE™) 700 commercial software developed by TRANE Technologies also integrated the VRP of Standard 62.1 in its design-and-analysis program (Trane 2020).

The IAQP is a performance specification based on acceptable concentrations of indoor air contaminants for protecting the health of the occupants in buildings. The factors to be considered include the contaminant sources, concentrations, and emission rates and IAQ acceptable limits. Mass balance equations for a single-zone system under the steady-state condition are provided in Appendix E of Standard 62.1-2019. It is worth mentioning that the criteria for acceptable IAQ may be different among IAQ experts and thus performing the IAQP is challenging.

The NVP includes mechanical ventilation systems in accordance with the VRP and/or IAQP. It defines the requirements for conditions such as ceiling height, floor space, opening locations, and size, etc.

ASHRAE 62.2

The ASHRAE Standard 62.2 Committee first approved and released the standard in 2004 as the only nationwide standard for low-rise residential buildings in the USA. Low-rise residential building refers to buildings with one to three stories. In the standard, the acceptable IAQ in residential buildings is achieved by controlling dwelling unit ventilation, local demand-controlled exhaust, and contaminant sources. The standard primarily applies to new construction but provides an alternative compliance path for existing buildings in its Appendix A. Standard 62.2 is reviewed and revised in 3-year cycles with interpretations and addenda being published between each edition. The contemporary version is ANSI/ASHRAE Standard 62.2-2019.

The 2019 edition has ten sections: purpose, scope, definitions, dwelling-unit ventilation, local exhaust, other requirements, air-moving equipment, climate data, references, and five appendices. The foreword and Appendix E of Standard 62.2-2019 detail the changes of the edition compared to its 2016 version. The updated scope and title of Standard 62.2-2019 is no longer limited to low-rise residential buildings. It applies to residential buildings in which occupants are nontransient. An important aspect of ASHRAE 62.2-2019 is the dwelling-unit ventilation in Section 4, which provides methods to calculate whole dwelling-unit ventilation rates and is summarized in Fig. 4. The local exhaust system with the option of demand-controlled mechanical exhaust or continuous mechanical exhaust discussed in Section 5 addresses kitchen and bathroom ventilation.

Other noteworthy facts about Standard 62.2 are that it does not address indoor activities that potentially cause high indoor contaminations such as painting, cleaning, smoking, etc., as well as concentration limits of contaminants. Standard 62.2 also does not address thermal comfort conditions and refers users to ANSI/ASHRAE 55.

In Section 4, the total ventilation rate is calculated using Eq. 11 or 12 with the parameters in different units:

$$Q_{\text{tot}} = 0.03A_{\text{floor}} + 7.5(N_{br} + 1) \quad \text{ASHRAE 62.2} \quad (11)$$

where Q_{tot} is the total required ventilation rate (cubic feet per minute, cfm), A_{floor} is the dwelling-unit floor area (ft^2), and N_{br} is the number of bedrooms (not to be less than 1).

$$Q_{\text{tot}} = 0.15A_{\text{floor}} + 3.5(N_{br} + 1) \quad \text{ASHRAE 62.2} \quad (12)$$

where Q_{tot} is expressed in units of L/s, and A_{floor} in units of m^2 .

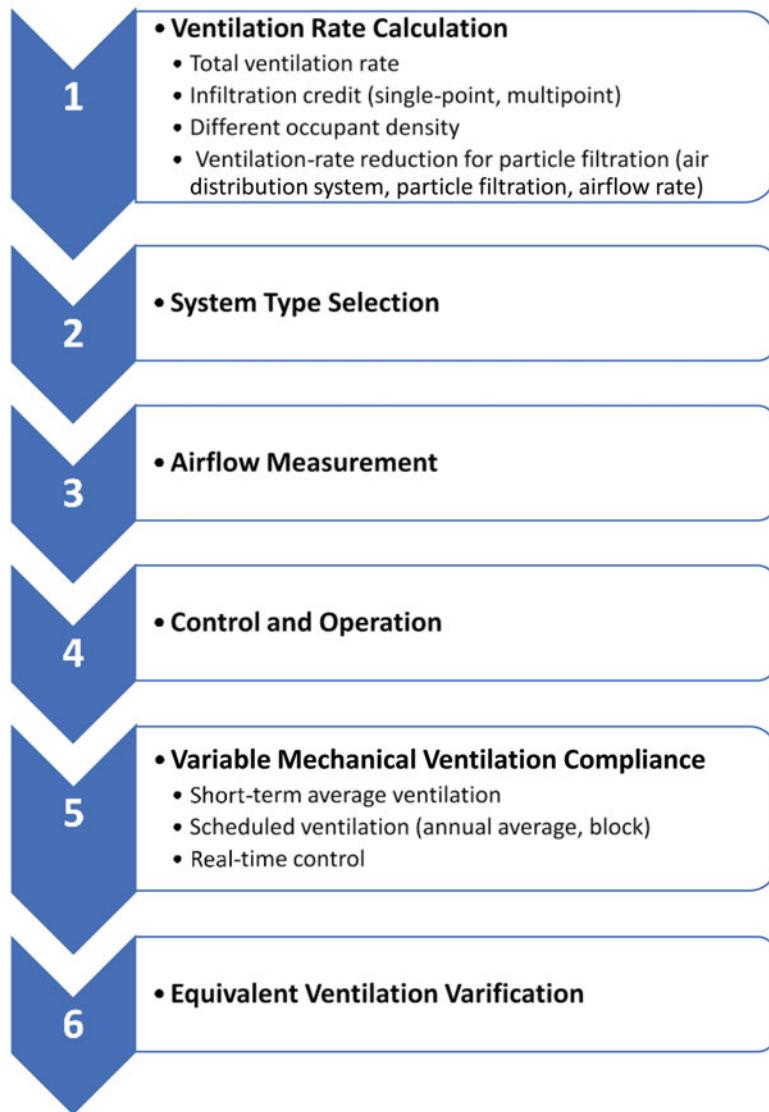

Fig. 4 ASHRAE Standard 62.2-2019, dwelling-unit ventilation process

The required mechanical ventilation rate (Q_{fan}) is calculated by:

$$Q_{fan} = Q_{tot} - \Phi(Q_{inf} \times A_{ext}) \quad ASHRAE\ 62.2 \quad (13)$$

where Q_{fan} is the required mechanical ventilation rate (cfm, L/s); Q_{inf} is the infiltration rate (cfm, L/s); $A_{ext} = 1$ for detached dwelling units, otherwise, for horizontally attached dwelling units, it is the ratio of exterior envelope surface area that is not

attached to garages or other dwelling units to total envelope surface area; $\phi = 1$ for balanced ventilation system, and $Q_{\text{inf}}/Q_{\text{tot}}$ otherwise.

The effective annual average infiltration rate, Q_{inf} , using a single-point envelope leakage test can be calculated via:

$$Q_{\text{inf}} = 0.052 \times Q_{50} \times wsf \times \left(\frac{H}{H_r} \right)^z \quad \text{ASHRAE 62.2} \quad (14)$$

where Q_{50} is the leakage rate at 50 Pa depressurization or pressurization (cfm, L/s), wsf is the weather and shielding factor, H is the vertical distance between the lowest and highest above-grade points within the pressure boundary (ft, m), H_r is the reference height, 8.2 ft. (2.5 m), and z is equal to 0.4 for the purpose of calculating the effective annual average infiltration rate.

For Q_{inf} using a multipoint envelope leakage test, the effective leakage area is used for the calculations. The effective leakage area can be calculated by the ASTM procedure:

$$ELA = \frac{L_{\text{press}} + L_{\text{dpress}}}{2} \quad \text{ASHRAE 62.2} \quad (15)$$

where ELA is the effective leakage area (ft^2 , m^2), L_{press} is the leakage area from pressurization (ft^2 , m^2), and L_{dpress} is the leakage area from depressurization (ft^2 , m^2). ELA can also be calculated by the Canadian General Standards Board (CGSB) procedure:

$$ELA = 0.61 \times (0.4)^{n-0.5} \times L_{\text{cgsb}} \quad \text{ASHRAE 62.2} \quad (16)$$

where n is the exponent measured from the CGSB 149.10 Standard, determination of the airtightness of building envelopes by the fan depressurization method, referenced in the Standard 62.2; and L_{cgsb} is the CGSB leakage area (ft^2 , m^2).

Then the normalized leakage is calculated using Equation:

$$NL = 1000 \times \frac{ELA}{A_{\text{floor}}} \times \left[\frac{H}{H_r} \right]^z \quad \text{ASHRAE 62.2} \quad (17)$$

where NL is the normalized leakage. Thus, the Q_{inf} is calculated using the following equations in different units:

$$Q_{\text{inf}}(\text{cfm}) = \frac{NL \times wsf \times A_{\text{floor}}}{7.3} \quad \text{ASHRAE 62.2} \quad (18)$$

where A_{floor} is ft^2 .

$$Q_{\text{inf}}(\text{L/s}) = \frac{NL \times wsf \times A_{\text{floor}}}{1.44} \quad \text{ASHRAE 62.2} \quad (19)$$

where A_{floor} is m^2 .

There are also available tools to make the calculations easier. For example, Robert Bean has developed the ASHRAE Standard 62.2 calculator, a free tool for Standard 62.2 calculations for home designers. It works for both 2011 and 2013 editions of the standard (Rossetti 2014). In addition, RED Calc software developed by Residential Energy Dynamics includes both free and “pro” versions of a calculation tool based on 2010 to 2019 editions (RED 2020a, b).

Applications

Standard 62.2 applying to residential buildings in which occupants are nontransient and Standard 62.1 applying to essentially all other buildings, largely commercial, have served as the most prominent standards to specify minimum ventilation rates for acceptable IAQ. These standards have provided a reference point for many building and energy codes and regulations as well as various green building certification schemes for US homes and buildings. Their major applications in the USA are summarized in Table 2. As we can see, different editions of the standards are adopted in different applications. One of the reasons behind this is that controversies exist among IAQ acceptable limits and ventilation requirements in different editions.

Standards 62.1-2016 and 62.2-2016 serve as the prescriptive compliance for the ventilation and IAQ requirements in California 2019 Building Energy Efficiency Standards, which took effect on January 1, 2020, for the zero net energy (ZNE) target (California Energy Commission 2018). Standard 62.2-2013 was adopted by Building Performance Institute, Inc (BPI) in their standard ANSI/BPI-1200-S-2017 (BPI 2017), which has been used for energy audits and related diagnostic tests by professionals nationwide. The approaches of Standards 62.1 and 62.2 have also been included in national model codes and well-known rating and labeling green building certification schemes as listed in Table 2. In the table, the year marked in parenthesis is the edition of the ASHRAE 62 standards referenced in the application when the information is available.

Priority Areas for Future Standardization Related to IAQ Testing
