Foreword

This book opens with editors Yiping Zhang, Philip Hopke, and Corinne Mandin explaining not only the purpose of this Handbook but also why it is so timely. In fact, indoor air quality (IAQ) has never been more important in terms of sustaining human health, well-being, and productivity. As we have seen so vividly with the COVID-19 outbreak, having buildings thoughtfully designed to appropriately protect their occupants and increase resilience is an essential public health requirement.

As the science of detection, simulation, analysis, and prediction has advanced, so has our understanding of the complex interactions among physical systems, human behavior, and the consequences of exposures. This Handbook will serve a new generation of investigators, designers, and practitioners as well as update those in the field since the first handbook was published in 2001.

So, how did the modern era of indoor air science begin? As the period of cheap energy ended, largely triggered by the oil embargo of 12 OPEC nations in October 1973, there were concerted efforts to conserve energy. Many decisions were made by individuals, professional organizations, and governments that compromised ventilation and degraded indoor air quality. To start to address these emerging issues, the US Department of Energy began to sponsor research on energy and IAQ at Lawrence Berkeley National Laboratory (LBNL). At LBNL, Greg Hollowell, David Grimsrud, John Girman, Tony Nero, and others were the first scientists and engineers in the USA to focus their efforts on indoor environments. Further afield, researchers in the UK, Europe, and the Nordic countries were engaged in research on radon, molds, thermal comfort, NO₂, odors, and optimizing ventilation.

At that time, I was on the faculty at Harvard working with Ben Ferris on the Six Cities Study. We were researching the long-term effects of ambient air pollution in adults and children across six US cities. We were characterizing ambient pollutants and tracking respiratory health. In our study, we saw a high prevalence of smoking among participants, many of whom lived in damp homes where gas-fired appliances were used. In industrialized Steubenville, Ohio (the city with the dirtiest outdoor air in our study), some 75% of the children lived in homes where one or more of their parents/caregivers smoked cigarettes. In the much cleaner city of Topeka, Kansas, over half the homes cooked with natural gas. These simple observations stimulated our curiosity to expand our research on the health effects of residential indoor pollution.

A seminal moment early in my academic career was co-chairing the National Research Council Committee on Indoor Pollutants with Michael Lebowitz. Our committee drew together what was known about the emerging field of indoor environments (National Research Council 1981). Collaborating with two committee members, Greg Hollowell and Demetrious Moschandreas, led to an *International Symposium on Indoor Air Pollution, Health and Energy Conservation* held on the campus of the University of Massachusetts Amherst (1981). Attracting over 500 participants from Europe, Asia, and North America, the Amherst symposium helped to establish indoor air science at the nexus of health, engineering, and design. What began as curiosity-driven research was now a research community open to ideas and to making a difference. Organizations led by Ole Fanger, Thomas Lindvall, Ib Andersen, Brigitte Berglund, and Tony Pickering encouraged many disciplines to convene around critical questions of IAQ. The interdisciplinary nature of IAQ science and practice persists and continues to draw in new disciplines, as reflected in the contributions to this new *Handbook of Indoor Air Quality*.

Twenty years on from these foundational gatherings, I collaborated with colleagues Jon Samet and John McCarthy to edit the first *IAQ Handbook*, published in 2001 by McGraw Hill (Spengler et al. 2001). By that time, many studies had been published on indoor contaminants in office buildings, homes, schools, and vehicles. The connection between the indoor environment and health was established with authoritative reports on passive exposures to tobacco smoke, radon, formaldehyde, asbestos, and molds (see the first chapter: History and Perspective on Indoor Air Quality Research). Universities and governmental agencies established research centers focused on ventilation, filtration, source mitigation, measurement and modeling, health, comfort, and productivity. Over time, indoor air science became more sophisticated as it incorporated the complex interactions among building systems and occupants. With the shift from a focus on air quality to total indoor environmental quality, the demand for professional consulting services grew as building managers, companies, and homeowners realized the potential impact of non-optimal indoor environmental quality.

In 2000, the US Green Building Council began what became an influential rating system for new buildings—the Leadership in Energy and Environmental Design, commonly known as LEED. This system has developed and now includes evidence-based credits on indoor environmental quality (IEQ) for occupants. Ventilation credits reference ASHRAE Standard 62.1 for non-residential buildings as a minimum prerequisite. Additional IEQ credits address contaminants emanating from cleaning practices, pest control, materials, and smoking, while others seek to improve the thermal, acoustic, and visual conditions. The World Green Building Council is now promoting more efficient and healthier buildings through 73 national green building organizations.

To scientists and engineers entering the field of IEQ today, I applaud your foresight in joining such a dynamic community. Indoor environments will continue to be important to the health, comfort, and productivity of people. There is much more to know and to do. Our COVID-19 pandemic experience may be the most widely publicized and broad-based event on our mind right now.

The pandemic has certainly advanced the importance of ventilation and filtration for keeping people well. Technologies such as *computational fluid dynamics*, advanced chemical analytical capability, human biomarkers, and genetic sequencing all have a part to play in unravelling IEQ and health. Devices built into our cell phones that track locations while measuring aspects of our physiological and cognitive performance, and emotional tone, or the use of virtual and augmented reality to indoor research is just beginning. Creating immersive experiences (visual, olfactory, auditory, and tactile) of indoor environments opens imaginative research avenues and new design opportunities.

Before the end of this century, the built environment is forecasted to double. Better buildings for our communities, both from an energy and materials standpoint can serve to sustain and improve the human condition and our natural world. To meet the challenges of rapid urbanization, depletion of natural resources, climate change, and the wide-scale threats posed by disparities, the United Nations Sustainable Development Goals (SDGs) present a path to a world that leaves no one behind. These goals call upon governments, the public and private sectors, and non-governmental organizations to work in partnership. To advance sustainable equitable with environmentally conscious development, our IEQ community needs to be included in these partnerships since many of the SDGs relate to the built environment (U.N. Sustainable Development Goals). The 2022 *Handbook of Indoor Air Quality* is a critical contribution to the journey ahead for humanity.

Preface

In 2001, McGraw-Hill published the *Indoor Air Quality Handbook* whose editors-in-chief were J.D. Spengler, J.M. Samet, and J.F. McCarthy. The handbook has contributed greatly to the development of indoor air quality research and has been a major contribution to providing the available knowledge regarding indoor air quality. Since then, new indoor air quality issues have been identified, and many achievements in the science and technologies of indoor air quality investigation and control have been accomplished, accompanied by the maturing of a new young generation of researchers. At the same time, the world has changed deeply: Internet, Wi-Fi, social media, Internet of Things, etc. are part of our lives and greatly influence research in every field. Climate change, increasing urbanization, energy-efficient buildings, low-carbon technologies, and social inequities also characterize what defines our world today. A handbook introducing the research advances in indoor air quality since 2001 was strongly needed as a new stepping stone to improved indoor environmental quality. Springer Nature invited us in 2016 to prepare such a handbook. We were very glad to accept this invitation, and we contacted three young researchers in the field of indoor air science to join the project as associate editors. A total of 136 authors from 19 countries have contributed to the handbook that you are now reading.

People live in indoor environments over 85% of their lifetime, and an adult inhales about 15 m^3 (17.5 kg) of air each day, which represents over 70% of the daily mass intake of the human body. Therefore, indoor air quality is very important to human health. The handbook presents our basic understanding of indoor air quality and the research achievements since 2001. It is divided into 12 sections: introduction to indoor air quality, indoor air chemicals, indoor air particles, measurement and evaluation, source/sink characteristics, indoor chemistry, human exposure to indoor pollutants, health effects and health risk assessment, indoor air quality and cognitive performance, standards and guidelines, indoor air quality control, and air quality in various indoor environments. It involves the fields of built environment, building energy, atmospheric environment, exposure science, public health, chemistry, fluid dynamics, etc., and highlights the diversity of disciplines engaged in indoor air science. Note that thermal comfort and biological contamination are not included because they represent fields of research too large to also be effectively addressed here. To have a handy reference on the current state of knowledge is

essential for researchers and practitioners working in indoor air and the related fields. It is also useful for the experts in other domains, policymakers, and general public to obtain basic knowledge on indoor air and be aware of recent advances, particularly in the context of the massive amount of information available online including unreliable reports.

This handbook was designed to be a dynamic resource. That is, in addition to the print version, the book is also published online and will be updated by the authors as needed to keep it aligned with updated knowledge. This salient feature can make the handbook current with research developments and various responses from the readers.

Last but not least, now that the handbook is ready for publication, we want to express our many thanks to all the contributors. To avoid duplication, those thanks are expressed in the “Acknowledgments” section.

Acknowledgments

The *Handbook of Indoor Air Quality* has been published with the assistance of many people. We would like to express our deep gratitude to those contributors who have provided their assistance over the past few years to make this Handbook possible. First, we are grateful to Dr. Yeung Siu (Stephen) Wai, editor of Major Reference Works, Springer Nature, who provided us the opportunity to launch the handbook. In making the production process effective, Haiqin Dong and Salmanul Faris Nedum Palli of Springer Nature have spent much time on monthly meetings and supporting services. Second, we are grateful to all the authors (over 130 from 19 countries) and all the reviewers (their names are in List of Reviewers on a separate page). Their knowledge, research experience, and achievement together with their great efforts guarantee the quality of the book. Third, we are grateful to Prof. C. Weschler, Rutgers University, USA, for the very helpful suggestions on the book framework, providing considerable detailed information and advice. We are also grateful to the following experts (arranged according to alphabet order of family names) for their helpful suggestions and information on Chap. 1.1, History and Perspective on Indoor Air Quality Research: W.P. Bahnfleth (USA), C. Chao (Hong Kong, China), Q.Y. Chen (USA), L. Fang (Denmark), X.B. Guo (China), F. Haghhighat (Canada), O. Hänninen (Finland), Y.G. Li (Hong Kong, China), J. Little (USA), L. Liu (China), L. Morawska (Australia), G. Morrison (USA), W.W. Nazaroff (USA), J.L. Niu (Hong Kong, China), A. Persily (USA), T. Salthammer (Germany), B. Singer (USA), S. Tanabe (Japan), K.W. Tham (Singapore), L. Wallace (USA), P. Wargocki (Denmark), P. Wolkoff (Denmark), X. Yang (China), J(ensen) Zhang (USA), and J(im) Zhang (USA). Last but not the least, we would like to express our heartfelt thanks to Prof. J. Spengler, Harvard University, USA, for writing the foreword of the current *Handbook of Indoor Air Quality*, both as a pioneer and leading scientist who has contributed greatly to indoor air science and as a Co-Editor-in-Chief of the *Handbook of Indoor Air Quality* 2001, 1st ed. New York: McGraw-Hill. Without their contributions, this handbook would not have attained its present status.

About the Editors

Yinping Zhang
Tsinghua University
Beijing, China

Yinping Zhang, Ph.D., is a professor in the Institute of Built Environment, Tsinghua University, Beijing, China. He is chairman of the Association of Indoor Environment and Health of China, director of the Beijing Key Laboratory of Indoor Air Quality (IAQ), head of the Building Environment Test Center, Tsinghua University, and president of the Academy of Fellows of the International Society of Indoor Air Quality and Climate (ISIAQ).

Zhang received his Bachelor (1985), Master (1988), and Ph.D. degrees (1991) from the University of Science and Technology of China (USTC). He has been a visiting scholar or professor in Stuttgart University, Germany (1994.5–95.5); Tokyo University, Japan (1996.10–12); and the Technical University of Denmark (DTU) (2004.10–12) and the Otto Mønsted visiting professor at DTU, Denmark (2007/2008, 3 months).

His principal research interests are indoor air quality and building energy efficiency. He has been the PI for over 40 research projects whose budgets were over 10 million \$US. He has published more than 10 books or book chapters, and more than 280 papers in international journals. His H index is 66 (Web of Science Core Collection). He is editor-in-chief or a key member of the editorial boards for over 20 Chinese IAQ-related standards. He has given over 20 plenary and keynote speeches in International Conferences including four International Conferences of Indoor Air (Copenhagen,

Denmark, 2008; Hong Kong, China, 2014; Ghent, Belgium, 2016; Seoul, Korea, 2020).

He serves as an associate editor of *Energy and Buildings* and *Carbon Neutrality* and is a member on the editorial boards of *Indoor Air*, *Environmental International*, *Sustainable Cities and Society*. He received the 1st Prize from the Natural Science Ministry of Education of China (2010), the 1st Prize from the Science and Technology Development Ministry of Beijing (2020), and the Inoue Uichi award (Japan, 2022).

Philip K. Hopke
Clarkson University
Potsdam, NY, USA

Dr. Philip K. Hopke is the Bayard D. Clarkson Distinguished Professor Emeritus at Clarkson University, former Director of the Center for Air Resources Engineering and Science (CARES), and former Director of the Institute for a Sustainable Environment (ISE). He is the head of the Aerosol Technologies Lab at Novosibirsk State Technical University and also holds an adjunct professorship in the Department of Public Health Sciences at the University of Rochester School of Medicine and Dentistry. Dr. Hopke is a past Chair of EPA's Clean Air Scientific Advisory Committee (CASAC) and has served on the EPA Science Advisory Board (SAB). Professor Hopke is a Past President of the American Association for Aerosol Research (AAAR) and was a member of more than a dozen National Research Council committees. He is a member of the NRC's Board of Environmental Studies and Toxicology. He is a fellow of the International Aerosol Research Assembly, the American Association for the Advancement of Science, and the American Association for Aerosol Research. He is an elected member of the International Statistics Institute and was the recipient of the Eastern Analytical Symposium Award in Chemometrics and the Chemometrics in Analytical Chemistry Conference Lifetime Achievement Award. He is also a recipient of the David Sinclair Award of the AAAR. He served as a Jefferson Science Fellow at the U.S. Department of State during the 2008–09 academic year.

Professor Hopke has extensive experience in indoor air quality issues including radon and radon decay product behavior, indoor atmospheric chemistry and secondary particle formation, in-room aerosol dynamics, and cooking and other sources of primary indoor particulate matter. He has been editor-in-chief of *Aerosol Science and Technology*, an editor of *Health Physics*, an editor of *Atmosphere, Air Quality, and Health*, and is currently an editor of *Aerosol and Air Quality Research* and *Chemometrics and Intelligent Systems*. He has written 1 book, edited 5, and published over 640 peer-reviewed journal papers.

Professor Hopke received his B.S. in Chemistry from Trinity College (Hartford) and his M.A. and Ph.D. degrees in Chemistry from Princeton University. After a postdoctoral appointment at M.I.T. and 4 years as an assistant professor at the State University College at Fredonia, NY, Dr. Hopke joined the University of Illinois at Urbana-Champaign, rising to the rank of professor of environmental chemistry, and he subsequently came to Clarkson in 1989 as the first Robert A. Plane Professor with a principal appointment in the Department of Chemistry. He moved his principal appointment to the Department of Chemical and Biomolecular Engineering in 2000. In 2002, he became the Clarkson Professor and Director of CARES. On July 1, 2010, he became Director of ISE that houses Clarkson's undergraduate and graduate environmental science degree programs as well as managing its sustainability initiatives. In May 2016, he moved to emeritus status.

**Corinne Mandin**

Scientific and Technical Center for Building (CSTB),
Marne-La-Vallée, France

Dr. Corinne Mandin earned her PhD in environmental chemistry from the University of Rennes, France. Previously she received an MSc in organic chemistry from the National School of Chemistry at the University of Montpellier and an MSc from Mines ParisTech in environmental engineering. She has been working on human exposure to chemicals in indoor environments, first at INERIS (French national institute for industrial environment and risks) for 8 years, and now at CSTB (French

scientific and technical center for building) that she joined in 2009.

She leads the French Indoor Air Quality Observatory, a research program created by the French government in 2001 to carry out nationwide surveys on indoor air quality in buildings. Her research interests include human exposure to volatile and semi-volatile organic compounds, particles, and fibers, especially in dwellings, schools, and office buildings.

She is a member of the “expert committee related to air” at the French Agency for Environmental Health and she previously chaired the “IAQ Guidelines Expert Committee” from 2009 to 2013. She collaborates with the World Health Organization and the European Joint Research Center. She was involved in several EU research projects (SINPHONIE, OFFICAIR, ALDREN). After having served as the Vice-President for Research (2016–2018), she currently serves as the President of the International Society for Indoor Air Quality and Climate (ISIAQ) (2020–2022).

About the Associate Editors

Cong Liu
School of Energy Engineering
Southeast University
Dhaka, Bangladesh

Dr. Cong Liu earned his Ph.D. in civil engineering from Tsinghua University, China. Before that, he received a Bachelor degree in thermal engineering from Southeast University, China. He was a visiting scholar in Missouri University of Science and Technology (2011–2012) and a postdoc in Georgia Institute of Technology (2014–2016). He is now an associate professor and vice dean in the Department of Refrigeration and Building Environment. His research covers transport and measurement of air pollutants, interaction of energy with environment and health, and heat and mass transfer. He is a member of the International Society of Indoor Air Quality and Climate.

Wenjuan Wei
Scientific and Technical Center for Building
Marne-la-Vallée, France

Dr. Wenjuan Wei is a research scientist in the Scientific and Technical Centre for Building (CSTB) since 2018. She received her B.S. in Energy and Power Engineering from Huazhong University of Science and Technology (HUST, 2005–2009) and her Ph.D. in Civil Engineering from Tsinghua University (2009–2014). She was a guest researcher at the National Institute of Science and Technology (NIST, 2011–2012) and a postdoctoral researcher at CSTB (2016–2018). During her

postdoctoral appointment, she was a Marie Skłodowska-Curie Fellow of the European Commission's Marie Skłodowska-Curie Actions and a PRESTIGE Fellow of Campus France. Dr. Wei is a specialist in indoor environmental quality (IEQ). Her research interests include emission and transport of (semi) volatile organic compounds (S)VOCs, indoor heat and pollutant exposures, and IEQ index. She has participated in several European and French research projects, such as ALDREN and PARC. She has published 37 peer-reviewed journal articles, and her h-index is 19. She got the Yaglou Award in 2022.

**Jianping Cao**

School of Environmental Science and Engineering
Sun Yat-sen University
Guangzhou, China

Dr. Jianping Cao got his Bachelor degree (2012) from the University of Science and Technology of China and his Ph.D. degree (2017) from Tsinghua University. After a 1-year postdoctoral experience at Virginia Tech., he jointed Sun Yat-sen University (Guangzhou, China) as an associate professor in 2018. He is now an associate professor in the School of Environmental Science and Engineering and the deputy director of the Department of Environmental Science in Sun Yat-sen University. His researches focus on the quantitative analysis, transport characteristics, exposure assessment, and mitigation of indoor air pollutants, especially focusing on semi-volatile organic compounds (SVOCs), one of the ubiquitous pollutants in indoor environments. He has published 32 research papers in international peer-reviewed journals since 2016. He currently serves as a Secretary in Youth Committee of Indoor Environment and Health Branch of the Chinese Society for Environmental Science, a Youth Editor of *Building Simulation: An International Journal*, and a Guest Editor of *Atmosphere* (Special Issue: Characterization and Mitigation of Indoor Air Pollution). Abstract

Modern indoor air science started in the 1970s. The reasons for separating the modern and old eras are: (1) building energy conservation became important due to the oil embargo in the Middle East in 1973 that had a great impact on building design and operation and in turn indoor air quality; (2) ambient air pollution became a topic of concern in many developed countries; (3) “modern diseases” were found to be associated with “modern exposure” during this period; (4) many new computational and measurement technologies such as computational fluid dynamics (CFD) and gas chromatography-mass spectrometry (GC-MS), respectively, occurred with the development of computer and the related technologies; and (5) a series of international societies and conferences related to indoor air science with worldwide impact were launched and recognized beginning in the 1970s. Modern indoor air science has been driven by two forces. One driver is the demands to fix important indoor air problems arising from a broad variety of pollutants: radon, asbestos, environmental tobacco smoke, particles (PM_{10} , $PM_{2.5}$, ultrafine particles), formaldehyde, volatile organic compounds, semi-volatile organic compounds, house dust mites, mold, bacteria, and associated health effects, e.g., sick building syndrome symptoms, asthma and allergies, Legionnaires’ disease, lung cancer, and airborne infections such as SARS and nowadays COVID-2019. The second driver is the new technologies such as CFD, big data analysis, advanced chemical analytical capability, sensing, control, and human biomarker analysis, which have contributed greatly to modern indoor air science. By understanding the influences of these two drivers on the development of indoor air science over the past decades, we can also perceive its future. In this first chapter, we summarize the history of indoor air science and outline some major challenges for the coming years.

Keywords

Indoor air quality · Health · VOCs · SVOCs · Particulate matter · History

Introduction

Although indoor air pollution has been a problem since people moved into caves and started fires for heat and cooking, it is only relatively recently that there has been extensive scientific study of indoor air quality (IAQ), its origins and potential mediation methods. The purpose of this chapter is to describe the development of the field of IAQ research and summarize our current state of efforts to address IAQ issues and improve human health.

Early Stage Development Before 1970s

Air, water, and food are necessary bodily intakes for human life. Their average intake (mass) for an adult per day for air, water and food are about 15 kg (ca. 13 kg inhaled indoors), 2 kg, and 2.3 kg for an 80 kg person, respectively (USEPA 2011). According to time-activity pattern investigations in 12 European countries, the USA, and China, people spend about 90% of their time indoors, including the enclosed environment of transportation, during their whole life (Szalai 1972; Klepeis et al. 2001; Duan et al. 2013). Therefore, indoor air quality (IAQ) can greatly influence human comfort, health, productivity, creativity, and well-being.

The history of our understanding on breathing is relatively short with respect to human history (Fitting 2015). Priestley (1733–1804), von Scheele (1742–1786), and Lavoisier (1743–1794) revealed the mystery of breathing. Priestley and van Scheele independently discovered oxygen (https://en.wikipedia.org/wiki/Carl_Wilhelm_Scheele). von Scheele and Lavoisier found air to be a mixture of gases. Lavoisier pointed out the role of oxygen in breathing, including the quantitative association between oxygen consumption and carbon dioxide (CO₂) release. As a result, the concentration of CO₂ was regarded as a measure of the freshness of air. Pettenkofer (1818–1901) noted that the unpleasant sensations of stale air were not due merely to warmth or humidity or to CO₂ or oxygen deficiency, but to the organic species emitted from the skin and exhaled from the lungs. He viewed CO₂ as not important itself, but an indicator of the concentration of other noxious or unpleasant substances emitted from people. In 1858, he published a book on ventilation in dwellings and stated that in order to keep people comfortable, the concentration of CO₂ should not be higher than 1000 ppm (the limit value was later referred to as the Pettenkofer number) (Sundell 1994, 2017). Billings (1889) published a book on the principles of ventilation and heating comfort. At that time, the study of ventilation mainly addressed comfort and not health. Odors, mainly body odors, and thermal comfort were regarded as the factors in setting guidelines for ventilation. A milestone study from this time was from Yaglou et al. (1936) about the perception of odor by building occupants, and the ventilation rate needed to make the air acceptable. Their research results have been used in numerous standards for ventilation (Sundell 1994; Janssen 1999; Persily 2015).

In Sweden in the 1950s and 1960s, “Light concrete” using alum shale with high radium content was a very common building material. Rolf Sievert investigated the risks of radium radiation exposure in the homes in Sweden from 1950. It was found that the ventilation rate influences indoor concentration of radon (Sundell 1994, 2017).

In 1952, the severe ambient air pollution in London, called the Great London Smog later, killed thousands of people in a few weeks (Bell et al. 2004). In 1962, the book “Silent Spring” about synthetic pesticides like DDT (dichlorodiphenyltrichloroethane) brought further attention to outdoor environments (Carson 1962). In addition,

pollutants emitted by many industries to ambient environments and pollutants in workplaces were also becoming of increasing interest. Therefore, in the 1960s and 1970s in many developed countries like the USA, organizations such as the US Environmental Protection Agency (EPA) and US Occupational Safety and Health Administration (OSHA) were established. Indoor environments were starting to be regarded as potentially protective against bad ambient air.

Subsequent attention turned to pollutants of indoor origin, including formaldehyde, radon, asbestos, tobacco smoke, and many volatile organic compounds. Wittmann (1962) published the first paper on the release of formaldehyde from particleboard. An early box model on passive (nonreactive) pollutants was developed (Turk 1963). Biersteker et al. (1965) simultaneously collected 800 paired indoor and outdoor air samples from 60 homes. They found that the I/O ratios of “smoke” and SO₂ were about 80% and 20%, respectively. Newer homes had lower SO₂ concentrations due to lower outdoor air change rates. The early focus on indoor particulate matter (PM) was generally on environmental tobacco smoke (ETS) and its related pollutants (Repace and Lowry 1980). Repace and Lowry defined a range of exposures to ETS and suggested that ventilation would not be the best solution given diminishing returns and the associated energy costs. Instead, they suggested smoking was incompatible with indoor spaces. The issues related to particulate matter in indoor air expanded with the increased interest in ETS (Repace and Lowry 1980), the role of particles in exposure and dose to radon decay products (Hopke et al. 1995), and the identification of indoor cooking (especially using solid fuel) as a major source of particles (Smith 1987).

Researchers from the Netherlands (Voorhorst et al. 1963, 1967; Pepys et al. 1968) found that house dust-mites were a major cause of allergies, which changed the research interest from “dust” to allergens in dust, and to pollen, pets, and most importantly house dust-mites.

In 1970, the Swedish Building Research Institute and the Swedish Radiation Protection Institute carried out a study of hundreds of homes in Gavle. They found that concentrations of radon were inversely correlated with the ventilation rate and possibly with the incidence of lung cancer. A key finding was that the lower the rate of ventilation, the higher risk of lung cancer (Sundell 2017).

With the development of additional analytical instruments and techniques, the number and types of compounds measured indoors increased. This provided the basis for indoor air quality research for “modern stage development.”

Modern Developments Since the 1970s

It can be considered that the modern indoor air science started in the 1970s, as suggested by Sundell (2017). According to our understanding, the main reasons for his statement are as follows: (1) building energy conservation became important due to the oil embargo in the Middle East in 1973, which had a great impact on building design and operation in turn indoor air quality; (2) ambient air pollution

became a topic of concern in many developed countries; (3) some diseases, later called “modern diseases,” were found to be associated with the exposure to newly man-made chemicals (Sundell 2017), later called “modern exposure”; (4) many new computational and measurement technologies such as computational fluid dynamics (CFD), gas chromatography-flame ionization detection (GC-FID), and gas chromatography-mass spectrometry (GC-MS), respectively, occurred with the development of desktop computers and the related technologies; and (5) a series of international societies and conferences related to indoor air science with worldwide impact were launched and recognized beginning in the 1970s (Appendix, Table A1).

Indoor Air Conferences

The first International Conference on Indoor Air was held at Copenhagen in 1978. About two hundred people took part in it. Quoting from the proceedings, “The purpose was to study the effect of the indoor air climate on man’s comfort, performance and health.” This conference was the inaugural event in what was to become the Indoor Air conference series (Nazaroff 2012). The first paper presented at this conference was by the Harvard group (Ferris, Speizer, Spengler, et al.) on the “six cities study.” As Sundell (2017) stated, “We recognized from the start that data from central station monitoring might not provide adequate detail of exposure, how is the exposure modified by indoor levels and what are the implications on health.” The “six cities study” had a great impact on subsequent indoor air quality studies. Starting in 1978 in Copenhagen, the Indoor Air conference series were held triennially through 2014, and biannually since then (Appendix, Table A1). A Healthy Buildings conference series was launched by the International Society of Indoor Air Quality and Climate (ISIAQ, see below) in 1988 to focus on the application of indoor air science in practice.

Sundell (2017) introduced the major research topics and the number of presentations for each of these major topics of every Indoor Air conference through 1978–2014. It’s interesting to follow the changes in research interests. It should be noted that much information cannot be found by searching the Web of Science because the conference proceedings for this early period are not readily available.

The Indoor Air conferences impacted IAQ studies and control strategies greatly. The second Indoor Air conference in Amherst, Massachusetts (USA) in 1981 was the first large indoor air conference open to all and had over 500 attendees. The third Indoor Air conference in Stockholm, Sweden, in 1984 had over 700 attendees from more than 40 nations and five volumes of conference proceedings.

Japan launched a sanitation law for buildings over 3,000 m² in the 1970s. Mandatory measurements of CO₂, carbon monoxide (CO), temperature, humidity, etc., every 2 months were required. However, for those new houses that had been insulated and air tightened to improve energy efficiency without mechanical ventilation systems, indoor concentrations of formaldehyde and some typical VOCs were very high and caused “Sick House Syndrome.” Indoor Air 1996 in Nagoya had

impact on changing the situation: the building code was changed in 2002. The tenth international conference was held in Beijing, China, in 2005. With over 1000 participants, Indoor Air 2005 was the first conference series held in a developing country, which greatly stimulated the development of indoor air-related research in China as can be seen in Fig. 3. A highlight of Indoor Air 2014 was the publication of a special topic issue of Indoor Air journal (2016, issue one) consisting of ten review papers written by the keynote speakers. Some of them have been highly cited. Due to COVID-2019, the Indoor Air 2020 (Seoul, Korea) conference was held online for the first time in the history of the Indoor Air Conference Series. The informal feedback has been very positive as the presentations remained available online for 6 months, which might be more impactful than usual conferences.

During this period, there were also many important conferences on indoor air quality, which were quite impactful: International Conference on Indoor Air Quality, Ventilation and Energy Conservation (IAQVEC) series (launched in 1992 in Montreal, Canada, initiated and organized by Profs. Francis Allard and Fariborz Haghishat), ROOMVENT series (launched in 1987 in Stockholm), International Symposium of Heating, Ventilating and Air-Conditioning (ISHVAC) series (launched in 1991 in Beijing by Tsinghua University), International Workshop on Energy and Environment of Residential Buildings (EERB) series, International Conference of Built Environment and Public Health (BEPH) series, American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE) IAQ conference series, symposia/workshops of American Society for Testing and Materials (ASTM) as well as the US EPA. In addition, joint conferences with other scientific societies were organized such as the ISSEE-ISES-ISIAQ joint conference held in Basel, Switzerland, 2013 and the ISES-ISIAQ joint conference held in Kaunas, Lithuania, 2019. The multidisciplinary academic exchange at these two joint conferences was very impressive.

The Academy of ISIAQ Fellows

The experience of the 1980s encouraged community leaders to create formal structures to replace informal processes. In 1991, leaders of the first five Indoor Air conferences (Appendix, Tables A1 and A2) founded the International Academy of Indoor Air Sciences (IAIAS). Its purpose was to “promote international scientific cooperation in the field of indoor air science.” IAIAS invited new members who by invention, research, or other activities had contributed significantly to indoor air science. In the late 1990s, the IAIAS established two major awards to recognize outstanding achievements in indoor air science: the Yaglou award honors Professor C.P. Yaglou’s pioneering work on thermal comfort, indoor air quality, and requirements for acceptable ventilation; the Pettenkofer award honors Professor M. Pettenkofer who is regarded as the founder of modern hygiene science and whose accomplishments included pioneering work on carbon dioxide and indoor air quality (Nazaroff 2012). In 2005, the IAIAS merged with ISIAQ (see below) and became the Academy of Fellows of ISIAQ (the Academy). Table A2 lists the

executive committee of the Academy of Fellows of ISIAQ (1991–2022). Currently, the Academy retains primary responsibilities to nominate and elect new Fellows and to promote and select awardees. Becoming a member of the Academy is a recognition of research, practice, and/or outstanding service in the field of indoor air science.

The academic awards were extended later and now include: Lifetime Achievement Award – bestowed as appropriate on occasion to scholars who have made seminal contributions to indoor air science through their career's work; Pettenkofer Gold Medal – awarded to an individual in recognition of outstanding work in advancing the indoor air science; Yaglou Award – acknowledge outstanding work of young promising researchers within the indoor air science and to encourage them to continue their career in this field; Best Paper Awards – granted to the top papers published in Indoor Air journal during the previous 3 years, as judged by the editors and editorial board; and Student Awards – established in 2008 and granted in two categories: Student Achievement Awards are given to students based on their commitment and dedication to the field for any combination of academic, professional, and research achievements; Student Paper Awards are given to students who have published an outstanding paper in the field of indoor air quality during the past year.

International Society of Indoor Air Quality and Climate (ISIAQ)

ISIAQ was founded in 1992 by 109 international scientists and practitioners following the 5th International Conference on Indoor Air Quality and Climate (Toronto, 1990). It is an international, independent, multidisciplinary, scientific, nonprofit organization whose purpose is to support the creation of healthy, comfortable, and productivity-encouraging indoor environments. As a Society, its major role is to facilitate international and interdisciplinary communication and information exchange by publishing and fostering publication on indoor air quality and climate. It organizes, sponsors, and supports initiatives such as meetings, conferences, and seminars on indoor air quality and climate. It also co-operates with government and other agencies and societies with interests in the indoor environment and climate (Nazaroff 2012). The presidents of ISIAQ since 1992 are listed in Appendix, Table A3.

Indoor Air journal, the Official Journal of ISIAQ

In the late 1980s, professors Fanger from Denmark and Thomas Lindvall from Sweden, leaders in the indoor environment field, proposed to publish a new journal titled Indoor Air. Professor David Grimsrud served as the first editor-in-chief (EIC). The inaugural issue of the journal was published in March, 1991 (Grimsrud 2011). With the great contributions of the EICs, David Grimsrud (1991–2000), Jan Sundell (2001–2010), William W Nazaroff (2010–2018), and Yuguo Li (2019–present) and with many members in the editorial board, the journal becomes more and more

impactful, which can be seen from its increasing published paper number and impact factor. The journal has enjoyed high visibility both within and beyond the indoor air science community.

Representative Events or Works on Indoor Air Quality Field in the Modern Stage Since the 1970s

Many research topics have been explored starting in the 1970s and many studies have advanced our understanding of indoor air science. Table 1 lists selected representative examples. The selection is based on: original works having impacted later studies as a paradigm or later important applications and standards; review papers with novel insights having driven later studies; important events having significant impact on later studies or practice. Some important events and excellent studies may have been omitted due to our limited historical memory and knowledge. We wish that the readers could suggest other seminal studies in the future. Considering this chapter is being published online, we have chances to periodically revise it.

Quantitative Analysis of the General Information in Web of Science

In Web of Science Core Collection (WoS-CC), we searched the indoor air quality paper information on August 23, 2021. Some major conclusions are presented here.

The Number of Indoor Air Quality–Related Papers has Increased Rapidly Since 1990

We searched the number of papers by using the topic keyword “indoor air quality” by publication year. Figure 1 shows that the number of papers has increased rapidly since 1990. Many indoor air quality–related papers can only be identified by searching the keywords such as “formaldehyde”, “benzene”, “ventilation”, etc., instead of by “indoor air quality” on WoS-CC. Thus, Fig. 1 may underestimate the number of published papers.

Number of Papers Related to Specific Indoor Air Pollutants Since 1990

From a search similar to the one mentioned above, the numbers of papers covering indoor air pollutants since 1990 are shown in Fig. 2. Although many indoor air quality–related papers may not be fully identified by searching on these topic words in WoS-CC, the trend shown in Fig. 2 should still be illustrative.

Table 1 Selected representative events or works on indoor air quality (1971–2021)

Year	Events or works	References
1971	Measurements showing the impact of indoor chemistry, driven by nitrate containing particles from outdoors, on indoor telephone switching equipment	Hermance et al. (1971)
1972	Earliest strong work on time-activity pattern investigations in 12 European countries	Szalai (1972)
1973	First rate constants for ozone removal by surfaces reported	Mueller et al. (1973) Sabersky et al. (1973) Thompson et al. (1973)
1973	First box model of indoor chemistry published	Sabersky et al. (1973)
1973	First version of ASHRAE Standard 62, Standards for Natural and Mechanical Ventilation, published	Persily (2015)
1974	First Computational Fluid Dynamics (CFD) book report and paper in indoor air field	Nielsen (1974a, b)
1974	It was observed that ozone reactions indoors occurred largely on surfaces, presented model for indoor-outdoor pollutant relationship, and called out the potential to remove ozone from indoor air	Shair and Heitner (1974)
1975	Article showing formaldehyde pollution due to chipboard used as building material in Danish homes	Andersen et al. (1975)
1978	First international indoor climate symposium launched, which led to the series of Indoor Air conferences	Fanger and Valbjørn (1978)
1978	First labeling system for indoor material and furniture, German “Blue Angel,” in the world. A series of labeling systems for indoor material and furniture occurred later, such as M1 and AgBB in Europe (Committee for Health-related Evaluation of Building Products 2018; The Building Information Foundation RTS 1996); BIFMA in the USA (BIFMA International 2011), and more recently in Asian countries, including Japan, Korea, and Singapore	Blue Angel (2002), Zhang et al. (2022)
1979	Early major work on indoor-outdoor relationships for airborne particulate matter of outdoor origin	Alzona et al. (1979)
1979–1985	US EPA TEAM Study measured personal exposures (800 people in 8 cities) to numerous toxic/carcinogenic chemicals and found that organic pollutants were much higher indoors than outdoors and that exposures occurred mostly indoors	Wallace et al. (1987)
1979	First WHO report on indoor air quality	WHO (1979)
1980	SVOCs (phthalates, organophosphates and adipates) reported in indoor airborne particles; their relative abundance in indoor PM larger than that typically reported for outdoor PM	Weschler (1980)

(continued)

Table 1 (continued)

Year	Events or works	References
1981	The US National Academy of Sciences produced a landmark report: “Indoor Pollutants.” The committee was chaired by Spengler JD and co-chaired by Lebowitz MD	NRC (1981)
1981	ASHRAE ventilation standard distinguishing between smoking and nonsmoking spaces published	Weschler (2009)
1981	A concept for evaluating the effect of fresh air distribution indoors on indoor air quality, air age, was put forward	Sandberg (1981) Sandberg and Sjöberg (1983)
1982	Consumer Product Safety Commission banned urea-formaldehyde foam insulation in homes/schools	Weschler (2009)
1982	First paper on health effects related to buildings	Kröling et al. (1982)
1984	WHO defined the term “Sick Building Syndrome”	Sick building syndrome-Wikipedia; Finnegan et al. (1984)
1984	US EPA restricted indoor use of pentachlorophenol (PCP) in paints and wood	Weschler (2009)
1984	Recognition that soil gas could penetrate into buildings carrying with high levels of radon generated naturally by radioactive decay of radium	Nero and Nazaroff (1984)
1985	US EPA established Office of Indoor Air Quality	Weschler (2009)
1986	Asbestos Hazard Emergency Response Act signed into law	Weschler (2009)
1986	US National Academy of Sciences published “The airliner cabin environment: air quality and safety”, which called for a ban on tobacco smoking in passenger cabins of commercial aircraft. This changed indoor smoking habits and likely contributed to the later series of indoor smoking bans	Weschler (2009)
1986	First comprehensive indoor chemistry model developed. Results from the model agreed with measurements of pollutants in a museum gallery	Nazaroff and Cass (1986)
1986	Early study of sensory reactions of 62 human subjects exposed to a low concentration mixture of 22 VOCs emitted by building materials and furnishings	Mølhave et al. (1986)
1987	First Air Quality Guidelines published	WHO (1987)
1987	Publication of seminal book “ <i>Biofuels, Air Pollution, and Health: A Global Review</i> ” establishing that household pollution from biofuels had a worldwide health impact comparable or larger than outdoor pollution	Smith (1987)
1987	Researchers from US EPA and China CDC showed that the coal combustion indoors was a major cause of lung cancer especially for women in Xuanwei county of Yunnan province in China	Mumford et al. (1987); He et al. (1991)

(continued)

Table 1 (continued)

Year	Events or works	References
1987	A large study published on SBS symptoms among office employees, called the Danish Town Hall Study	Skov and Valbjørn (1987)
1988	Indoor Radon Abatement Act directed US EPA to identify areas with potential for high indoor radon	Weschler (2009)
1988	First conference in the Healthy Buildings series held in Sweden	Berglund et al. (1988)
1988	Fanger proposed “Olf and decipol” units for perceived air quality	Fanger (1988a, b)
1989	WHO recommends “source control” as best means of reducing indoor air pollution due to VOCs	WHO (1989)
1989	ASHRAE standard eliminated distinction between smoking and nonsmoking spaces	Persily (2015)
1989	Publications of the European Directive for construction products, the so-called “Construction Product Directive”. This was later amended by a Council Directive in 1993, again in 2011 through Regulation (EU) No 305/ 2011	European Commission (EC) (1989, 1993, 2011)
1989	First published analysis indicating that indoor ozone exposure (concentration × time) is often comparable to or larger than outdoor exposure	Weschler et al. (1989)
1989	The International Society of Exposure Analysis (ISEA) (subsequently renamed the International Society of Exposure Science (ISES)) created in 1989	https://www.ises.org
1989	First report (No 1) from the “European Concerted Action on Indoor Air Quality and Its Impact on Man” program about Radon. There followed another 29 reports about various aspects of VOCs and emission testing, and labeling. Important reports for European research	1989–2013 European Commission, Luxembourg https://op.europa.eu/en/publication-detail/-/publication/34beabd5-f38b-4336-ac69-3eec614bbad4
1989	First international course on indoor air quality and health held in Copenhagen and organized by Nordic Advanced Training in Occupational Health	Later held in 1992, 1996, 1999, 2003, 2006, and 2018 (endorsed by ISIAQ and Int Comm on Occup Health (ICOH))
1990	US EPA bans mercury in interior latex paint	Weschler (2009)
1990	Sources of indoor air pollution begin to be evaluated	Tichenor et al. (1990)
1991	Indoor Air, official journal of ISIAQ, was launched	Grimsrud (2011)
1991	Exposure science occurs as an independent science branch	Lioy and Weisel (2014)
1991	Introduction of the Field and Laboratory Emission Cell (FLEC), to be used both on-site and in the laboratory for controlled emission testing. Later achieved international standardization, ISO, ASTM, NORDTEST, China, etc.	Wolkoff et al. (1991a)

(continued)

Table 1 (continued)

Year	Events or works	References
1991	The first human provocation studies in climate chambers with typical building materials	Johnsen et al. (1991) Wolkoff et al. (1991b)
1992	International Society of Indoor Air Quality and Climate (ISIAQ) was founded in 1992 by 109 international scientists and practitioners following the 5th International Conference on Indoor Air Quality and Climate, Indoor Air '90 (Toronto, 1990)	https://www.isiaq.org/about_us.php
1992	The reaction products of ozone reacting with an indoor surface (new carpets) were observed for the first time, which stimulated studies on indoor chemistry and building products. It's the first paper on indoor chemistry and building products	Weschler et al. (1992)
1992	First international workshop bringing together experts from different disciplines to address indoor air as a multidisciplinary field of applied science. A monograph based on the event: Morawska L, Bofinger ND and Maroni M (Editors). Indoor Air – An Integrated Approach, Elsevier Science Limited, 1995, was published	Morawska et al. (1995)
1993	“Six cities study” starting in 1974 was published in the top journal, New England J Med, which investigated in six communities the health effects of air pollutants. Although the study was not focused on indoor air per se, it had a great impact on later indoor air quality studies	Dockery et al. (1993)
1993	Recognition that indoor combustion of solid fuels for heating and cooking in developing countries produced PM concentrations that can be an order of magnitude or higher than observed in Europe and North America. Thus, two areas of research on indoor particles have evolved with one focused on built environments in higher income countries (WHO 2010) and the other on the use of solid fuel combustion for indoor heating and cooking (WHO 2014)	Smith (1993)
1993	NIOSH and BASE study, the first major studies of office buildings (>100) in the USA, started in 1993	Brightman et al. (2008)
1994	A mechanistic model for emissions of VOCs from indoor materials was presented and formed the basis of later developments in VOC emission mechanistic modeling studies	Little et al. (1994)
1994	The Danish Indoor Climate Labeling system was launched, which is the first system to introduce odor and health based on VOC emissions	Wolkoff and Nielsen (1996)
1994	First meeting of ISO/TC146/SC6 (Indoor Air) held in Berlin, Germany by Prof. Bernd Seifert. Since then, 44 standards including ISO-16000 Part.1-40 (indoor) and 122919 Part 1-10 (interior air of road vehicles) have been published and updated	Tanabe (2017) https://www.iso.org/committee/52822.html

(continued)

Table 1 (continued)

Year	Events or works	References
1995	Residential air exchange rates in the USA: Empirical and estimated parametric distributions by season and climatic region was published	Murray and Burmaster (1995)
1996	The German Committee on Indoor Air Guide Values publishes its first Indoor Air Guide Value for toluene. Since then, values for about 53 VOCs/SVOCs have been derived	https://www.umweltbundesamt.de/en/topics/health/commissions-working-groups/german-committee-on-indoor-air-guide-values#german-committee-on-indoor-air-guide-values-air Fromme et al. (2019)
1996	Finland launched labeling system on formaldehyde and TVOC for building materials, which was called “M1”	The Building Information Foundation RTS (1996)
1996	Prediction of elevated indoor hydroxyl radical concentrations ($\sim 2 \times 10^5$ molecules/cm ³ at 20 ppb O ₃) because of indoor ozone/terpene reactions. Confirmed with experiments a year later	Weschler and Shields (1996, 1997a)
1996	Publication of the results of the “European AUDIT project” of 56 offices	Bluyssen et al. (1996)
1996	Early comprehensive review on indoor particles, which has strongly impacted later studies	Wallace (1996)
1996	PTEAM Study of 189 Los Angeles residents’ personal and indoor exposures to PM _{2.5} and PM ₁₀ published	Özkaynak et al. (1996)
1997	Detailed examination of potential chemical reactions among indoor pollutants (indoor chemistry)	Weschler and Shields (1997b)
1997	First Japanese guideline value for formaldehyde. Since then, guidelines for 13 chemicals and TVOC (tentative) were published	Azuma et al. (2020)
1998	Publication of the LEED (Leadership in Energy and Environmental Design) Green Building Rating System for New Construction (LEED v1.0). The VOC emissions for paints and coatings, adhesives and sealants, flooring, wall panels, ceilings, insulation, composite wood, and furniture are evaluated. Besides VOC emissions, the VOC content for paints, coatings, adhesives, and sealants are also evaluated	USGBC (2021) Zhang et al. (2022)
1998	European EXPOLIS study: first (and still remaining the only one) random working age population sample-based study on personal exposures including indoor measurements at homes and workplaces in Europe (seven cities in total)	Jantunen et al. (1998), Hänninen et al. (2004)
1998	Impact of temperature and humidity on the perception of indoor air quality was published. Lower temperature and dryer air make air quality perceived better under test conditions. The finding has influenced some ventilation standards for the limiting criteria of low humidity exposure	Fang et al. (1998)

(continued)

Table 1 (continued)

Year	Events or works	References
1999	Indoor air quality shown to have an impact office work	Wargocki et al. (1999)
1999	Ozone/terpene reactions recognized as source of secondary organic aerosols (SOA)	Weschler and Shields (1999)
2000	WHO published the report on the right to healthy indoor air	WHO (2000), Mølhave and Krzyzanowski (2000)
2001	First Indoor Air Quality Handbook published by McGraw-Hill	Spengler et al. (2001)
2001	The first study on the US time-activity patterns named as The National Human Activity Pattern Survey (NHAPS) was published, which have subsequently been applied worldwide to exposure assessment	Klepeis et al. (2001)
2001	China launched a mandatory standard on indoor air pollution control of civil building engineering, GB 50325-2001	https://www.chinesestandard.net/ PDF/English.aspx/ GB50325-2001
2001	Dampness in building and health (DBH) study reported the association between the dampness and mite exposure in buildings and health effects, which led to studies in Bulgaria, Singapore, USA (Texas), South Korea, Denmark, and mainland of China	Bornehag et al. (2001)
2001	A long-term research program dedicated to indoor air is funded by the French Government with the objective to perform regular nationwide measurement surveys in buildings: the French IAQ Observatory	Kirchner et al. (2011)
2002	China launched Indoor Air Quality Standards (GB/T18883-2002), which is for indoor air quality of nonindustry buildings	China CDC (2002)
2003	Biomonitoring of phthalate esters as a routine method. An estimation of the daily intake of di (2-ethylhexyl)phthalate (DEHP) and other phthalates in the general population was reported	Koch et al. (2003)
2003	The first approach using dimensionless analysis to obtain the generalized VOC emission correlations for building materials	Xu and Zhang (2003)
2004	First thorough study to show DEHP emission from PVC flooring and uptake of DEHP in floor dust	Clausen et al. (2004)
2005-2007	Reports on Relationships of Indoor, Outdoor, and Personal Air (RIOPA) were published. 48-h integrated indoor, outdoor, and personal air samples were collected between summer 1999 and spring 2001 at three different locations in the USA. Samples were analyzed for VOCs and particles	Weisel et al. (2005), Turpin et al. (2007)
2006	The first field study of indoor surface chemistry was published	Wang and Morrison (2006)

(continued)

Table 1 (continued)

Year	Events or works	References
2006	The first mechanistic model for emissions of SVOCs from indoor material was presented, which formed the basis of later developments in SVOC emission modeling studies	Xu and Little (2006)
2006	EU adopted Registration, Evaluation, Authorization, and Restriction of Chemicals (REACH)	Weschler (2009)
2007	Textbook on Exposure Analysis published	Ott et al. (2007)
2008	The first assessment of acid/base chemistry on indoor surfaces was published	Ongwandee and Morrison (2008)
2009	WHO Guidelines for Indoor Air Quality: Dampness and Mould	WHO (2009)
2009	Publication of a review paper on the changes in indoor pollutants since the 1950s, which attracted interest from many related disciplines	Weschler (2009)
2009	Ultrafine particle emissions from printers were found, which was considered as a turning point for printer design worldwide	Morawska et al. (2009)
2010	Studies with human subjects identified the major gas-phase products resulting from reactions of ozone with human skin lipids	Wisthaler and Weschler (2010)
2010	WHO Guidelines for Indoor Air Quality: Selected Pollutants	WHO (2010)
2010	Publication of a review paper on formaldehyde in the indoor environment, which attracted much interest of many related disciplines on the topic	Salthammer et al. (2010)
2011	Burden of disease of indoor air pollutants reported with DALY (disability-adjusted life years put forward by Murray and Lopez (1996)), which can be compared with other damage or loss for the first time. Researchers in Lawrence Berkeley National Lab (LBNL), USA estimated the health risks of typical indoor air pollutants, which got close to the idea as a pioneer work	Hänninen and Knol (2011), Hänninen et al. (2013) Logue et al. (2011, 2012)
2011	First major report on “Climate Change, The Indoor Environment, and Health”. It shows that climate change will affect indoor air pollutant concentrations, which shifts human exposure and influences public health	The committee was chaired by Spengler JD. The Institute of Medicine of the US National Academies (2011), Nazaroff (2013)
2013	ECA Report No 29: Harmonization framework for health-based evaluation of indoor emissions from construction products in the European Union using the EU-LCI concept	Kephalopoulos et al. (2013)
2013	First study showing that e-cigarettes release nicotine, aromatic compounds and nanoparticles. The publication triggered many other scientific studies and serves as a basis for discussions on legal measures	Schripp et al. (2013)

(continued)

Table 1 (continued)

Year	Events or works	References
2013	Human reference limits for key terpene ozone-initiated reaction products are derived for the first time	Wolkoff (2013)
2014	WHO Guidelines for Indoor Air Quality: Household Fuel Combustion	WHO (2014)
2014	Formaldehyde was confirmed to be a human carcinogen by the National Research Council of the United States because there is sufficient evidence of carcinogenicity from studies in humans that indicates a causal relationship between exposure to formaldehyde and at least one type of human cancer	US-NRC (2014)
2014	The WELL Building Standard® Version 1.0 (WELL v1.0) was launched for the Commercial and Institutional Office building sector. It applies to office spaces, where well-being is related to worker health, performance, and motivation. Indoor air quality is an important part in it. Later, a series of addendum on residential buildings was published	International WELL Building institute (2014)
2015	The ratios of inhalation and dermal exposure to phthalates (and later other SVOCs) were experimentally determined via an intervention study in a room for the first time, which provided a starting point for combined indoor/biomonitoring studies of SVOCs	Weschler et al. (2015)
2015	First publications of research funded by Sloan Foundation's <i>Chemistry of Indoor Environments (CIE)</i> program occurred	https://sloan.org/programs/research/chemistry-of-indoor-environments
2016	Assessment standard for healthy building (T/ASC 02-2016) was launched in China. Indoor air quality score contributed to roughly 25% of the total score. Since 2017, buildings with 30 million square meters have been certificated	ASC (2016)
2017	First assessment of the socioeconomic costs of indoor air pollution at the national scale, i.e., in France. The six target pollutants were benzene, radon, particles ($PM_{2.5}$), trichloroethylene, CO, and environmental tobacco smoke (ETS). It was found that the annual cost due to indoor air pollution was €20 billion (particles accounted for 70%), which was about 1% French GDP	Boulanger et al. (2017)
2017	First results of the European OFFICAIR study: seasonal and spatial variability of indoor air quality in 37 newly built or recently retrofitted office buildings across Europe	Mandin et al. (2017)
2017	First book on the inverse design approach in indoor air field	Chen et al. (2017)

Table 1 (continued)

Year	Events or works	References
2018	On the development of health-based ventilation guidelines: principles and framework	Carrer et al. (2018)
2020	Use of a negative ion device can effectively reduce PM _{2.5} concentrations indoors. However, exposure to negative ions and/or ion-induced reaction products was significantly associated with increases in some biomarker levels indicative of increased cardiovascular health risks. Referring to this finding, Indoor Air Quality Standards of School Classrooms in China suggests to take caution in using negative ionization device to mitigate indoor PM _{2.5} exposure	Liu et al. (2020)
2021	WHO global air quality guidelines update: Particulate matter (PM _{2.5} and PM ₁₀), ozone, nitrogen dioxide, sulfur dioxide, and carbon monoxide. The WHO states that the same standard guidelines apply to both indoor and ambient air quality	WHO (2021)

International Journals That Have Published the Most Indoor Air-Related Papers

Indoor air quality-related papers are published in many international journals. Table 2 shows the number of papers of the top ten journals publishing the most papers since 1991. We searched on 15 August 2021 in WoS-CC by using the keyword “indoor air quality.”

Many excellent international journals such as Environmental Health Perspectives, The Lancet Public Health, Journal of Hazardous Materials, Environmental Science and Technology Letters also published indoor air quality-related research articles and review papers. Some indoor air quality-related papers are also published in top journals such as The New England Journal of Medicine, The Lancet, Science, Nature, Chemical Review, and Journal of American Medicine Association (JAMA).

Institutions That Published the Most Indoor Air-Related Papers

The top ten institutions in producing the most indoor air quality papers are shown in Fig. 3. Papers produced in all these institutions have increased rapidly since 2000 especially for Tsinghua U, U London, and Tianjin U.

Averaged Citations Per Paper of the Ten Institutions Publishing the Most Indoor Air Quality Papers

The average citations per paper of the top ten institutions in publishing the most indoor air quality papers are shown in Fig. 4. The ranks of the average

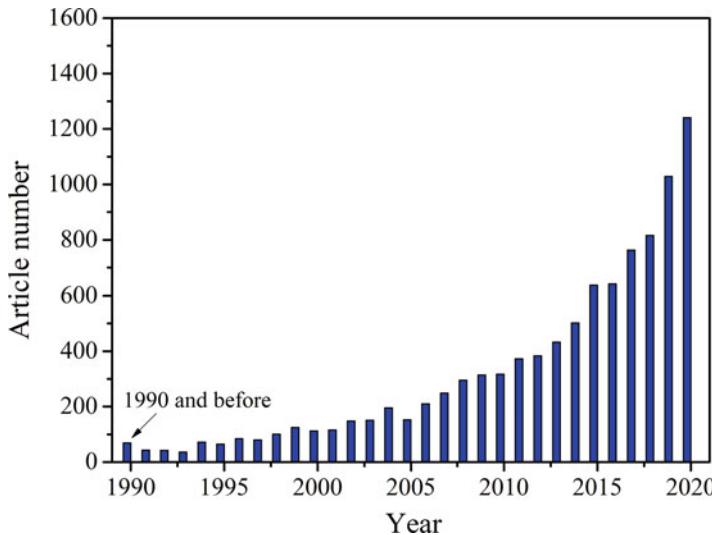

Fig. 1 Evolution of the annual number of peer-reviewed papers on indoor air quality since 1990. (Website: WoS-CC; Keyword: indoor air quality; Document type: articles; Date of analysis: Aug.23, 2021)

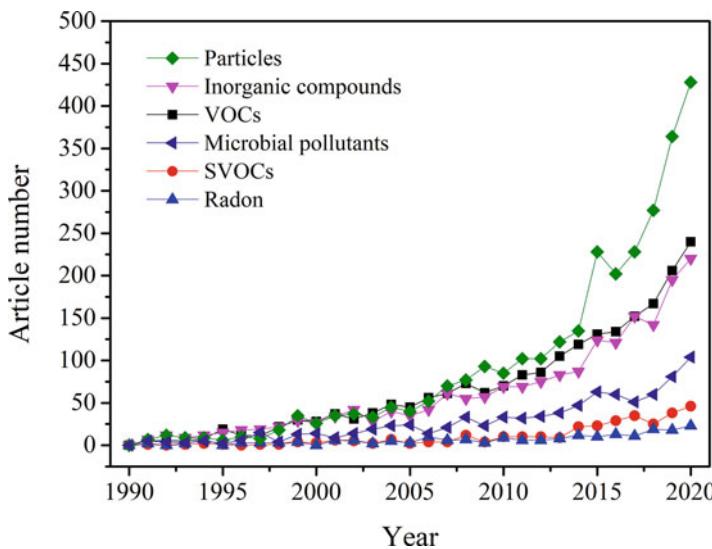

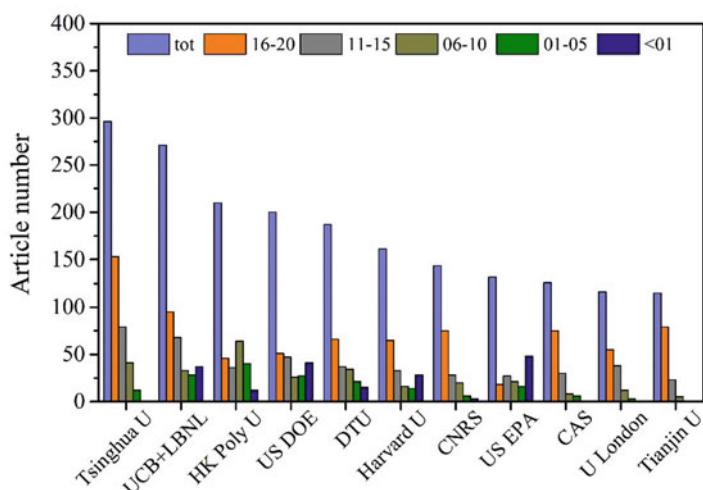

Fig. 2 Evolution of the annual number of peer-reviewed papers related to specific indoor air pollutants since 1990 (Website: WoS-CC; Keyword: “indoor air quality” AND pollutant name; Document type: articles; Date of analysis: Aug.23, 2021)

citations per paper for the total periods of these ten institutions are: DTU, USEPA, US DOE, UCB+LNBL, HK Poly U, Harvard U, U London, Tsinghua U, Tianjin U, CNRS. The average citation per paper of DTU before

Table 2 List of journals and their respective number of IAQ papers published during the period in WoS-CC (Totally 33120 papers were found in the searching)

Journals	Number of papers	Percentage (%)
Building and Environment	1103	3.33
Indoor Air	678	2.05

**Fig. 3** Number of indoor air science articles published by authors from different institutions. Ranked by total number of articles published. **Tsinghua** University, **UCB** (University of California, Berkeley)+**LBNL** (Lawrence Berkeley National Laboratory), **HK Poly U** (Hong Kong Polytechnic University), **US DOE** (United State Department of Energy DOE), **DTU** (Technical University of Denmark), **Harvard** University, **CNRS** (Centre National de la Recherche Scientifique, France), **US EPA** (United States Environmental Protection Agency), **University of London**, **Tianjin** University. Bars represent different publication year intervals: before 2001, during 2001–2005, during 2006–2010, during 2011–2015, during 2016–2020, and for all articles (tot, highest bar)

2001 is substantially higher than that of the other nine institutions. During 2011–2020, the difference of the average citations per paper of the ten institutions is not so large.

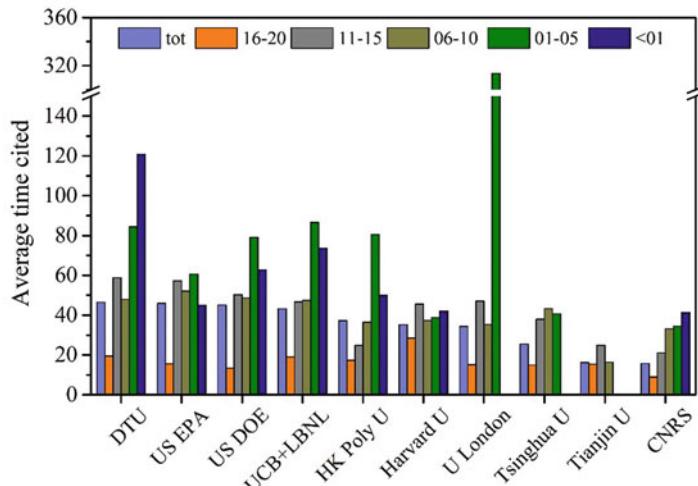

Fig. 4 Number of average citations per paper of the ten institutions in Fig. 3. Ranked by citations per paper for all articles (tot). Bars represent different publication year intervals: before 2001, during 2001–2005, during 2006–2010, during 2011–2015, during 2016–2020, and for all articles (tot)

On the Research Advances Since 2001

Spengler, Samet, and McCarthy as editors-in-chief published the *Indoor Air Quality Handbook* in 2001 (Spengler et al. 2001). To avoid overlaps, the present handbook focuses on those research advances that have occurred since 2001. Moreover, thermal comfort and indoor air quality studies related to biological aerosols are not included in the present handbook although they were included in the previous one.

In addition, by referring to the contents of the previous handbook and by considering the research advances in the past two decades, the contents of the present handbook are arranged by sections and chapters. The research advances are classified into the following sections: indoor air chemicals, indoor air particles, measurement and evaluation, source/sink characteristics, indoor chemistry, human exposure to indoor pollutants, health effects and health risk assessment, indoor air quality and cognitive performance, standards and guidelines, indoor air quality control, and air quality in various indoor environments.

By design, each handbook chapter is a review paper on the chapter's topic. The authors are experts on the chapter's topic. Therefore, we avoid repeating their reviews in this chapter. Our intent has been to provide a very brief introduction to the “broad view”, as well as isolated “snapshots” for selected representative work by using Figs. 1, 2, 3, and 4 and Tables 1 and 2. Although some important “milestones” in the history of indoor air research may have been omitted, we hope that the historical track can be clearly discerned from this chapter.

Multidisciplinary Co-operation. Compared with previous periods, more studies in this period are multidisciplinary. As Rawlings et al. (2005) stated, such multidisciplinary collaborations were often led by some “star” researchers. Additionally, there are many social networks of scholars that researchers can join to disseminate and find new studies, which are very helpful for such multidisciplinary studies (Li 2019).

Targeting Health Effects. For human-centered space, the purpose of indoor air quality study is to improve human health. Those research studies on indoor air quality without an association to health can be quite important. However, the whole “chain” is complete only if the health risk is included. To some extent, the risk can be regarded as the metrics of the problem importance. Certainly, it is not necessary for every researcher to do health risk analysis. Instead, the purpose should be accomplished with the co-operation of multiple disciplines. Therefore, more multidisciplinary co-operation studies should address IAQ and health issues.

Focus on Exposure. Both the concentrations of pollutants and people’s time-activity patterns govern exposure to pollutants (Morawska et al. 2013; Salthammer et al. 2018). Some major elements regarding human exposure and indoor air in the research studies carried out since 2001 are: (1) the development of human biomonitoring and the understanding of the contribution of indoor air compared to other sources such as diet; (2) the consideration of ingestion and dermal exposure in addition to inhalation only; all the exposure pathways are now addressed; (3) the development of the exposome concept (Wild 2012) in which indoor exposure throughout life is a major piece.

Financial Support. Compared to ambient air quality research studies, financial support of indoor air quality studies has been very limited. The reasons for these limitations include: (1) ambient air quality is regulated in many countries such as USA, EU, and China, while indoor air quality is not; (2) various indoor environments, especially homes are regarded as private spaces in which governments should not interfere; (3) ambient air pollution data measured in a few central locations can represent the likely exposures across a large area that can then be associated with public health within that area. In indoor research, it is necessary to measure air quality in a large number of indoor spaces with limited health data available for the specific people occupying those spaces; (4) controlling ambient air quality could be done on a large scale by governing bodies, while controlling indoor air quality involves the “entire” building environment, e.g., building materials, furniture, furnishings, consumer products, air cleaners and outdoor air, as well as the occupants themselves (Sundell 2017).

Perspectives on Indoor Air Quality Research Related to Chemicals

Find important problems to tackle in indoor air fields. Kirk Smith (1947–2020) made seminal contributions by studying the impact of indoor air pollution from household combustion on human health in developing countries such as India, China, Mongolia, Mexico, and Guatemala. He found that in India and China

alone, over one million premature deaths can be attributed to using biofuels indoors (Smith 2000). One reason for his substantial research success is that he always aimed at important problems to study. As he used to say, researchers should “follow the risk”. His career provides an excellent example of that way of choosing important problems.

Use burden of disease as a measure of the “importance” and “risk”. How to find those important or high-risk problems in indoor air fields to tackle? How to prioritize research, remediation initiatives, and public policies? In 1996, Murray and Lopez (1996) put forward the concept of the “burden of disease” to express diverging health loss, whose unit was the “disability-adjusted life year” (DALY). DALYs provide an estimation of the equivalent number of healthy life-years lost in a population due to premature mortality and morbidity (DALY). It can also be converted into economic loss by estimating the cost of a DALY to the society in which the analysis is being made. Smith and Mehta (2003) reported the seminal work on the burden of disease from indoor air pollution in developing countries. We suggest to use the burden of disease approach in the indoor air field to assess the “importance” or the “risk” for those pollutants for which the toxicity is known as illustrated by Hänninen et al. (2014, 2022). By using DALYs, indoor air pollutants can be targeted and suitable thresholds can be clearly defined as relevant standards for different countries, regions, and buildings. In addition, we define here a new concept, coefficient of investment (COI) (that is the ratio of reduction of the cost of the DALYs to the invested cost needed to mitigate the risk) to be a core parameter in evaluating the effectiveness of indoor air quality control system or approach. By using COI, suitable engineering control approaches can be assessed. Under this framework, many studies should be performed in the near future.

Apply machine learning system and big data analysis technology. Past studies used questionnaires and sampling methods that are difficult to implement on a large scale and obtain accurate information. Therefore, it is difficult to identify the associations between indoor environmental characteristics and human responses. In recent years, sensor systems and corollary machine learning approaches and big data analysis technology have rapidly developed. A revolutionary event is that “Alpha Go” developed by Google defeated the top human Go player (Fig. 5). With various online sensors that are also quickly improving, big data of extensive indoor environment information can be obtained conveniently. Temporal and spatial variabilities of indoor air pollution can be better characterized. Moreover, many techniques to obtain human biomarkers of exposure are also developing very rapidly. Big data on human responses in the indoor environment can also be obtained. With the help of powerful machine learning tools applied with big data analysis skill, associations between indoor environment information, and human responses can be isolated that would be impossible to obtain using the traditional approaches. However, data quality is always very important to get reliable results. Standardized measuring protocols with documented and validated methods will still be important problems to tackle in the future.

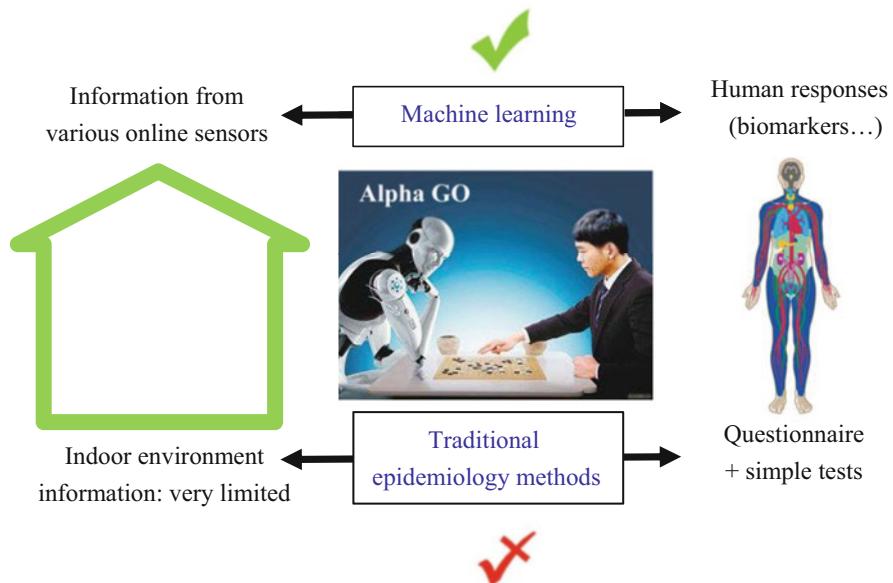

Fig. 5 Machine Learning System with Knowledge and Skill will be powerful in finding associations between indoor environment information and human responses

Understand and fix problems from the whole system (or integrated) view. A holistic view can reveal more links and associations than a partial view. For intercontinental travel, “flying” is much more efficient than surface transportation although it does not allow seeing the details of the surface. In the future, instead of detailed study of part of a well-defined problem, large questions related to the whole indoor environmental system can be solved using systematic approach. For example, the interplay between chemical exposure and both indoor and outdoor climatic conditions coupled with occupational exposures and personal risk factors such as host vulnerability that may enhance the impact of the chemicals needs to be integrated into the study design (Wolkoff 2020). Wild (2012) introduced the concept of exposome: the human exposome encompasses exposures to environmental factors throughout life, starting from conception and pregnancy. Indoor air science must be an integral part of exposome research to provide a comprehensive evaluation of human exposure to chemicals. Moreover, indoor air quality control should also receive attention as soon as energy efficiency or energy retrofits are addressed. Building or renovating buildings with a tighter envelope to remove air leakages and improve energy efficiency must absolutely involve considering the ventilation in the building.

Understand how to improve health via improved indoor air quality. Today, healthy buildings are not really “healthy” buildings but rather “not-sick” buildings. We know much about the effects of many targeted indoor air pollutants on human health. However, we know little about the effects related to improve indoor air

quality on improving health. For many developed countries, indoor air pollution problems can be neglected because they are not deemed important relative to development priorities. However, development should also include improved public health that comes from better indoor air quality. Study of this problem needs to be done in the near future given the size of the affected population. It would be the basis for developing truly “healthy” buildings. Moreover, vulnerable populations, i.e., pregnant women, unborn children, children, elderly, sick persons (in particular immune deficient individuals), are the ones for which healthy buildings are even more crucial.

Understand the serious indoor air problems in the rural or poor areas of developing countries and fix them. Identification and understanding the indoor air quality problems in rural or poor areas of developing countries such as in India, China, Mongolia, sub-Saharan Africa, and Central America remains very important. Research achievements can save millions of premature deaths in those countries. The problem of severe indoor pollution from solid fuel combustion in cooking/heating stoves has been known since the 1980s (Bonjour et al. 2013), but remains a significant issue for a large fraction of the world’s population. It produces more DALYs than any single biological agent (microbe or parasite). Both China and India have recently instituted programs to change to cleaner fuels, but much of the developing world still require cleaner cooking methods as discussed in ► Chap. 6, “[Appliances for Cooking, Heating, and Other Energy Services](#).“ It will take a concerted global effort to provide culturally appropriate solutions to the problem of clean cooking/heating appliances and the resulting improvement of indoor air quality.

Anticipate what will be the indoor environment in the context of global warming. There is now clear evidence that projected climate change will have major impacts on our lives, and particularly on our indoor environment (Vardoulakis et al. 2015). The risks are not yet fully described, but we can expect various outcomes, e.g., that higher temperatures will lead to higher building materials emissions and consequently higher indoor concentrations. Higher outdoor ozone concentrations may lead to more indoor chemistry and formation of secondary products. Mitigation and adaptation policies are needed, and, before that, a better understanding on how buildings will be impacted and used is needed. The indoor climate researchers have a key role to play.

Conclusions

Indoor air studies have become a well-defined component of scientific research. However, many challenges are yet to be met by the indoor air quality research community. Over the past decades, an innovative and dynamic research community has grown and proved its ability to develop understanding of indoor air quality

issues and provide solutions. In the future, using a multidisciplinary, holistic, and creative approach, multiple challenges related to indoor air quality will be addressed.

Abstract

High volatility organic compounds (or very volatile organic compounds, VVOCs) are an important category of indoor air pollutants, and the most-known VVOC is formaldehyde. Formaldehyde is ubiquitous in indoor

H. Wang · J. Xiong (✉)

School of Mechanical Engineering, Beijing Institute of Technology, Beijing, China
e-mail: xiongyj@bit.edu.cn

environment and mainly originates from the emissions of indoor materials and furniture. The existence of formaldehyde poses severe adverse health effect on people. This chapter introduces the formaldehyde properties and hazards, usages and pollution levels, determination methods, as well as the short-term and long-term emission models, the measurement of key emission parameters in the models, and the impact of environment factors on the key emission parameters and emission rate. This chapter attempts to provide a screen-level impression for the readers, to understand the formaldehyde, which should be helpful for the source characterization and control of formaldehyde in the indoor environment.

Keywords

VVOCs · Formaldehyde · Emission model · Key parameters · Impact factors

Introduction

High volatility organic compounds, or the so-called very volatile organic compounds (VVOCs), are an important subgroup of indoor pollutants and cover a wide spectrum of chemical substances (Salthammer 2016). Table 1 summarizes some typical VVOCs in the indoor environment. Among them, formaldehyde is by far the well-known VVOCs, which is also recognized as the most important compound in indoor environment. Therefore, this chapter just introduces formaldehyde as a typical representative of VVOCs. Formaldehyde is an important chemical for the global economy, widely used in construction, wood pressing, furniture, etc. Formaldehyde has been classified as a human carcinogen that causes nasopharyngeal cancer and probably leukemia, contributing significantly to global burden of disease.

This chapter will introduce the formaldehyde properties and hazards, usages and pollution levels, determination methods, emission models, key parameters measurement methods, and impact factors.

Properties and Hazards of Formaldehyde

Properties

Formaldehyde (CH_2O) is also known as methanal, methyl aldehyde, oxymethylene, oxomethane, methylene oxide, and formic aldehyde. The three-dimensional structure of formaldehyde is shown in Fig. 1. The molecular structure of formaldehyde (shown in Fig. 2) includes two carbon-hydrogen single bonds (C-H) and a carbon-oxygen double bond (C=O), where the angle between the C-H bond is 116.5° , and the angle between the C=O bond and the C-H bond is 121.8° . At normal temperature and pressure, formaldehyde is a colorless and highly toxic gas with a pungent, irritating odor. It is readily reactive, readily polymerizable, and highly flammable and can decompose into methanol and carbon monoxide at temperatures above

Table 1 List of very volatile organic compounds (Salthammer 2016)

Group	Compound	Formula	Group	Compound	Formula
C1	Methanol	CH ₃ OH	C4	n-Butane	C ₄ H ₁₀
	Formaldehyde	HCHO		2-Methylpropane	CH ₃ CH(CH ₃)CH ₃
	Formic acid	HCOOH		1,3-Butadiene	CH ₂ CHCHCH ₂
	Chloromethane	ClCH ₃		Butanal	C ₄ H ₈ O
	Dichloromethane	CH ₂ Cl ₂		2-Methylpropanal	CH ₃ CH(CH ₃)CHO
	Trichloromethane	CHCl ₃		2-Methyl-2-propanol	CH ₃ C(CH ₃)OHCH ₃
	Trichlorofluoromethane	CCl ₃ F		Methacrolein	CH ₂ C(CH ₃)CHO
	Dichlorodifluoromethane	CCl ₂ F ₂		2-Butanone	CH ₃ COCH ₂ CH ₃
	Dichlorofluoromethane	CHCl ₂ F		Methyl vinyl ketone	CH ₃ C(O)CHCH ₂
	Chlorodifluoromethane	CHClF ₂		2,3-Butanedione	CH ₃ C(O)C(O)CH ₃
	Methyl bromide	CH ₃ Br		Vinyl acetate	CH ₃ C(O)OCHCH ₂
	Phosgene	COCl ₂		Furan	C ₄ H ₆ O
C2	Ethane	C ₂ H ₆	C5	2-Chloro-1,3-butadiene	CH ₂ CHCClCH ₂
	Ethanol	C ₂ H ₅ OH		n-Pentane	C ₅ H ₁₂
	Acetadehyde	CH ₃ CHO		Cyclopentane	C ₅ H ₁₀
	Chloroethane	C ₂ H ₅ Cl		2-Methylbutane	CH ₃ CH(CH ₃)C ₂ H ₅
	1,1-Dichloroethene	Cl ₂ CCH ₂		Isoprene	CH ₂ C(CH ₃)CHCH ₂
	Vinyl chloride	C ₂ H ₃ Cl		2-Methylfuran	(C ₄ H ₃ O)CH ₃
	Glyoxal	CHOCHO	C6	2-Methylpentane	CH ₃ CH(CH ₃)C ₃ H ₇
	Ethylene oxide	C ₂ H ₄ O		3-Methylpentane	C ₂ H ₅ CH(CH ₃)C ₂ H ₅
C3	Propane	C ₃ H ₈	Other	Carbon disulfide	CS ₂
	1-Propanol	CH ₃ (CH ₂) ₂ OH		Methylsulfide	HSCH ₃

(continued)

Table 1 (continued)

Group	Compound	Formula	Group	Compound	Formula
	2-Propanol	CH ₃ CH(OH)CH ₃		Dimethylsulfide	S(CH ₃) ₂
	Propanal	C ₃ H ₆ O		Trimethylsilanol	Si(CH ₃) ₃ OH
	2-Propenal (Acrolein)	CH ₂ CHCHO		Acrylonitrile	CH ₂ CHCN
		CO(CH ₃) ₂		Acetonitrile	CH ₃ CN
	2-Propanone (Acetone)	CH ₂ (OCH ₃) ₂		Dimethylamine	HN(CH ₃) ₂
	Dimethoxymethane	CH ₃ COOCH ₃		Trimethylamine	N(CH ₃) ₃
	Methylacetate	CHOCOCH ₃		Diethylamine	HN(C ₂ H ₅) ₂
	Methylglyoxal				
	2-Chloropropane	CH ₃ CHClCH ₃			

Fig. 1 The three-dimensional structure of formaldehyde

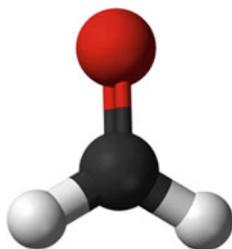

Fig. 2 The structure of formaldehyde

150 °C, but the uncatalyzed decomposition rate is very slow below 300 °C. The high chemical reactivity of formaldehyde makes it possible to carry out a variety of self-association reactions and forms a variety of chemical substances with water association (WHO 2002). Formaldehyde is highly soluble in polar solvents such as water and ethanol. In an aqueous solution, formaldehyde usually combines with water to form methylene glycol or self-polymerizes to form paraformaldehyde. Therefore, formaldehyde aqueous solution (commonly known as formalin) with a concentration of 37% is usually prepared and used for anticorrosion and sterilization. At room temperature, when the formaldehyde content is above 30%, the polymer will precipitate and make the solution turbid. Formaldehyde gas can form explosive mixtures with air under atmospheric pressure. The reported flammability is between 12.5% and 80% by volume, a 65–70% formaldehyde-air mixture being the most readily flammable (WHO 2002). The reported values for the physical and chemical properties of formaldehyde are shown in Table 2.

Hazards

Acute lethality. No reports of humans die from high levels of formaldehyde in the short term. Experiments using rats and mice with formaldehyde exposure have shown that the lowest dose usually produces a 0% mortality rate, and the highest dose usually produces a 100% mortality rate, but no clear limits have been reported (CAS 2008).

Nonlethal toxicity. Low-concentration formaldehyde exposure experiments on humans (≤ 20 ppm) and animals (≤ 31.7 ppm, nonhuman primates, rats, mice, and guinea pigs) showed nose/throat and eye irritation (CAS 2008). There were skin hypersensitivities in human experiments, and in animal experiments at 20 ppm and 30 ppm; it was observed that the hair around rats' genital area turned yellow

Table 2 Physical and chemical properties of formaldehyde (CAS 2008; Salthammer et al. 2010; WHO 2002)

Property	Range of reported values
Relating molecular mass	30.03
Melting point (°C)	-118 to -92
Boiling point (°C, at 101.3 kPa)	-21 to -19
Vapor pressure (calculated) (mm Hg, at 25 °C)	3883
Vapor density (air = 1)	1.067
Liquid density (g/mL, water = 1)	0.815
Water solubility (mg/L, at 25 °C)	Very soluble, up to 55% 980 L/L water
Henry's law constant (atm·m ³ /mol, at 20 °C)	3.27×10^{-7}
Autoignition temperature (°C)	300
Log octanol/water partition coefficient ($\log K_{ow}$)	0.35
Log organic carbon/water partition coefficient ($\log K_{oc}$)	0.70 to 1.57
Conversion factor	1 ppm = 1.23 mg/m ³ 1 mg/m ³ = 0.813 ppm

(Tobe et al. 1985). It should be noted that experiments on humans are short term, while experiments on animals are long term.

Neurotoxicity. Studies have tested the relationship between formaldehyde exposure and short-term memory, ability to concentrate, and changes in psychomotor functions, but no concentration-response relationship was found. However, the researchers did attribute the poor performance at 0.33 ppm exposure to irritation or central nervous system effects caused by the exposure. No report on neurotoxicity in animals (CAS 2008).

Developmental/reproductive toxicity. There is no evidence that formaldehyde exposure affects human development or reproduction. Inhalation, oral gavage, dietary, and drinking water studies have been used to investigate the effects of formaldehyde on animal reproduction and development, and it has been found that formaldehyde concentrations of 40 ppm are maternal toxicity, reflected in significant maternal weight loss; while concentrations of 20 ppm and 40 ppm are fetal toxicity, reflected in fetal weight loss (CAS 2008).

Genotoxicity. According to International Agency for Research on Cancer (IARC 2006), formaldehyde demonstrates positive effects in a large number of in vitro tests for genotoxicity, including bacterial mutation, DNA strand breaks, chromosomal aberrations, and sister chromatid exchange. Studies in humans showed inconsistent results with regard to cytogenetic changes (micronuclei, chromosomal aberrations, and sister chromatid exchange). The IARC reviewed some studies that showed increased DNA-protein cross-links in workers exposed to formaldehyde, which is consistent with the results of inhalation studies in mice and monkeys (IARC 2006; CAS 2008).

Carcinogenicity. According to the pollutant hazard list of IARC and WHO, formaldehyde is classified as a category A carcinogen. A study by the U. S. Environmental Protection Agency (U.S. EPA 2003) shows that there is a

significant statistical association between respiratory tumors in specific parts of the human body and formaldehyde exposure; formaldehyde exposure can induce cancer in rats and mice (nasal squamous cell carcinomas). The IARC (2006) stated that “sufficient epidemiological evidence that formaldehyde causes nasopharyngeal cancer in humans. There is strong but not sufficient evidence for a causal association between leukemia and occupational exposure to formaldehyde.”

Usages and Pollution Levels of Formaldehyde

Formaldehyde is an important economical chemical. The use of formaldehyde covers a wide range in people's lives. Urea formaldehyde resins, melamine formaldehyde resins, and phenol formaldehyde resins (UF, PF and MF resins) accounted for nearly 70% of global formaldehyde demand in 2017 (HIS Markit 2019). Particleboard, hardwood plywood, and medium-density fiberboard are the mostly manufactured wood-based boards with the use of urea formaldehyde resins; melamine formaldehyde resins, and phenol formaldehyde resins are largely used in composite wood products industry as glues. These resins are also molded to create different products, such as insulating layers, facial wipes, paper napkins, and paper product coatings.

Formaldehyde can completely negate or kill the activities of bacteria, fungi, yeast molds, viruses, and parasites, so that it is widely used in preservative and disinfectant. In the agricultural industry, formaldehyde is used as a fumigant to prevent mildew and rot in plants and vegetables. Formaldehyde has been also used in the medical fields. Some of the early medicinal applications of formaldehyde included its use in vasectomy, and as a disinfectant before hydatid cyst removal surgery. In the textile industry, in order to achieve anti-wrinkle, anti-shrink, and flame retardant effects, or to maintain the durability of printing and dyeing, it is necessary to add formaldehyde to the auxiliary agent in the production of clothing fabrics. Polyacetal made from formaldehyde can be used in thermoplastics in electrical and electronic applications, or in parts of motor vehicles and machines that are subjected to mechanical or thermal stress, and in household articles, such as light switches, sockets, lamps, plumbing parts, and motors.

According to report, worldwide annual production of formaldehyde is approximately 52 million tons in 2017 (Iabal et al. 2018). Products containing formaldehyde will gradually emit free formaldehyde in the process of use, and formaldehyde in the ambient air will damage human health through respiratory tract and skin contact. Formaldehyde levels between 0.1 and 0.5 ppm (about 0.12–0.6 mg/m³) can be detected by the human senses, 0.5–1.0 ppm (about 0.6–1.2 mg/m³) can cause eye irritation, and more than 1.0 ppm (about 1.23 mg/m³) can irritate the nose and throat (NICNAS 2006). A number of investigators have shown that formaldehyde exposure levels are generally higher indoors than outdoors. In the indoor environment, general sources of formaldehyde include: formaldehyde-containing resin products, cooking, various consumer products, such as furniture, carpets, glass fibers, permanent press cloth, paper products, cosmetic, perfumes, and some household cleaners.

Smoking is also an important source of indoor formaldehyde. Poor ventilation, high temperature, and residential renovation will increase the indoor formaldehyde concentration. In the outdoor environment, formaldehyde mainly comes from the exhaust gas produced by the combustion of diesel vehicle engines, the smoke produced by cigarettes and burning forests and wood products, as well as the formaldehyde emitted by indoor ventilation (Goldstein et al. 2021).

The indoor guideline values of formaldehyde regulated by different countries or organizations are summarized in Table 3, which can be categorized into two groups: short-term exposure (about 0.5–1 h) and long-term exposure (mostly 8 h). The short-term exposure limits are used to prevent acute health effects, such as sensory stimulation in a short period of time, while the long-term exposure limits are used to prevent chronic health effects. The short-term exposure limit recommended by the WHO (1987) is 0.08 ppm ($100 \mu\text{g m}^{-3}$).

Worldwide indoor and outdoor formaldehyde concentrations in air in several countries are summarized in Table 4. Indoor formaldehyde concentration levels in most countries are below or close to the limit ($100 \mu\text{g m}^{-3}$) recommended by the WHO (1987), but the levels reported in Cairo and Beijing are higher than this threshold, and the level reported in Beijing is more than two to three times the value. There is a uniform finding in different seasons and different cities: the concentration of formaldehyde in the indoor environment is higher than that in the outdoor environment. Previous studies have shown that the emission rate of formaldehyde increases with increasing temperature, so seasonal changes will lead to an increase in formaldehyde concentration in summer (Kinney et al. 2002; Ohura et al. 2006).

Table 3 International guideline values for formaldehyde in indoor air (Salthammer et al. 2010)

Country	Value		Comments
Australia	0.1 ppm	$120 \mu\text{g m}^{-3}$	Short duration
	0.08 ppm	$100 \mu\text{g m}^{-3}$	
Canada	0.1 ppm	$123 \mu\text{g m}^{-3}$	1 h
	0.04 ppm	$50 \mu\text{g m}^{-3}$	8 h
China	0.08 ppm	$100 \mu\text{g m}^{-3}$	1 h average
France		$50 \mu\text{g m}^{-3}$	2 h (proposed)
		$10 \mu\text{g m}^{-3}$	Long-term exposure (proposed)
Singapore	0.1 ppm	$120 \mu\text{g m}^{-3}$	8 h
Japan	0.08 ppm	$100 \mu\text{g m}^{-3}$	0.5 h
Korea	0.1 ppm	$120 \mu\text{g m}^{-3}$	8 h
Norway	0.05 ppm	$60 \mu\text{g m}^{-3}$	24 h average
	0.05 ppm	$100 \mu\text{g m}^{-3}$	30 min average
Poland	0.04 ppm	$50 \mu\text{g m}^{-3}$	24 h
	0.08 ppm	$100 \mu\text{g m}^{-3}$	8–10 h
UK		$100 \mu\text{g m}^{-3}$	0.5 h
USA (California)	0.027 ppm	$33 \mu\text{g m}^{-3}$	8 h
WHO	0.08 ppm	$100 \mu\text{g m}^{-3}$	0.5 h average

Table 4 Indoor and outdoor formaldehyde concentrations in various countries

	Indoor air	Outdoor air	
Uppsala	8.3 \pm 1.5 ^a	1.3 \pm 1.8	Sakai et al. 2004
Nagoya	17.6 \pm 1.8	5.8 \pm 1.5	Sakai et al. 2004
Shimizu (winter)	12.4 \pm 1.8	1.4 \pm 1.6	Ohura et al. 2006
Shimizu (summer)	18.7 \pm 2.6	2.5 \pm 1.4	Ohura et al. 2006
New York (winter)	11.5 \pm 4.9	2.1 \pm 0.9	Kinney et al. 2002
New York (summer)	28.5 \pm 13.8	5.3 \pm 2.3	Kinney et al. 2002
Los Angeles (winter)	21.0 \pm 11.0	3.9 \pm 1.3	Sax et al. 2004
Los Angeles (fall)	16.0 \pm 6.2	4.4 \pm 1.6	Sax et al. 2004
Mexico City	15.7 \pm 15.7	5.1 \pm 1.5	Serrano-Trespalacios et al. 2004
Paris	34.4 \pm 1.9		Clarissee et al. 2003
Quebec	29.5 \pm 1.6		Gilbert et al. 2006
Prince Edward	33.2 \pm 22.4		Gilbert et al. 2005
Cairo (spring)	117.5 \pm 49.6	38.9 \pm 9.5	Khoder et al. 2000
Cairo (summer)	141.6 \pm 63.0	49.6 \pm 12.7	Khoder et al. 2000
Beijing (winter)	228.0 \pm 160.9		Yao et al. 2005
Beijing (summer)	308.4 \pm 228.0		Yao et al. 2005

^ageometric mean \pm geometric standard deviation

The indoor and outdoor formaldehyde concentration levels in Shimizu, New York, Cairo, and Beijing in the summer season are higher than those in the winter season, which is consistent with the above pattern. Formaldehyde had a slightly higher concentration in the winter compared to that in the fall in Los Angeles, which could be interpreted as a lower exchange rate since people close windows in winter and less so during much of the rest of the year in Los Angeles.

As mentioned above, formaldehyde is widely used in a variety of industries in people's lives, including paint industry, the glue, dyes, rubber, metal, wood, leather, petroleum, pesticides, fertilizer, agricultural industries, medical, cleaning agents, preservatives, cosmetic, perfumes, vitamins, food, etc., which also leads to many people being exposed to formaldehyde in occupations. According to the pathological analysis data of humans and animals after exposure to formaldehyde for a certain period of time and some health hazard assessments, some safety and occupational health authorities have stipulated the formaldehyde occupational exposure limits (OELs, shown in Table 5): threshold value (TLV), time-weighted average (TWA), and short-term exposure limit (STEL). The indoor guideline value is lower than the occupational limit because people stay in the nonoccupational space for longer, and there are more vulnerable groups in the nonoccupational space, such as babies, the elderly, pregnant women, and children. The formaldehyde occupational exposure limit has had a downward trend over time as more information on its health risks has become available.

Table 5 Formaldehyde occupational exposure limits (OEL) of several countries (Zhang et al. 2009; Salthammer et al. 2010)

Country	OEL (ppm)		
	TWA ^a	STEL ^a	TLV ^a
Australia	1	2	
Canada			0.3
China			0.4
Germany	0.3		
Japan	0.1		
Sweden	0.5		1
South Africa	1	2	
UK	2	2	
USA			
The federal standard	0.75	2	
Recommended exposure limits ^b	0.016	0.1	0.3

^aTWA uses 8 h; STEL uses 30 min by most countries, except for the USA (15 min)

^bRecommended exposure limits (RELS as TWA and STEL) were recommended by NIOSH, and TLV by ACGIH

Methods for the Determination of Formaldehyde

Standard Test Methods

Perforator Method

The perforator method developed by the former European Particleboard Federation in the late 1960s has become the European standard EN 120 since 1984. EN 120 (1993) is used to determine the formaldehyde content of unlaminated and uncoated wood-based panels. Its extraction process is as follows: the formaldehyde is extracted from the test piece by boiling toluene, and then transferred to distilled water or desalinated water; and then the formaldehyde content in the aqueous solution is determined by the acetylacetone photometric method. EN 120 states that the correlation between the perforator value and the amount of formaldehyde emission depends on the density, porosity, and humidity of the test sample. The total running time of the perforator method is relatively short, so it is widely used in production quantification, classification, and control.

Flask Method

The flask method was standardized as EN 717-3 (1996). The main principle of the flask method is to hang a known amount of test panels above the water in a closed container kept at a constant temperature. The formaldehyde emitted from the test panels within a certain period time is absorbed by the water, and the formaldehyde content in the water is determined photometrically by the acetylacetone method.

Desiccator Method

The desiccator method is used to determine the amount of formaldehyde emitted by particleboard, fiberboard, plywood, oriented strand board (OSB), and wood laminate flooring. The main principle of the desiccator method is to put a certain exposed area of wood-based panels on the support of a clean dryer, and the bottom of the dryer contains a certain amount of distilled water. The wood-based panels are placed in a prescribed environment for a certain period time (about 24 h) and then analyzed by spectrophotometry to get the formaldehyde content.

Gas Analysis Method

The gas analysis method (EN 717-2 1994) can be used to determine the formaldehyde emitted from uncoated or coated wood-based panels, sidebands, floor coverings, foams, foils, laminated wood products, veneer wood products, and coated wood products. Formaldehyde emitted from test pieces of wood-based panels placed in the airtight chamber where the environmental conditions (temperature, humidity, airflow, pressure) are controlled, mixing with the air. This air is continually drawn off and passes through gas wash bottles containing water, which absorbs formaldehyde. The concentration of formaldehyde was determined by spectrophotometry or fluorescence method. The amount of formaldehyde released is calculated by the formaldehyde test concentration, sampling time, and sample exposure area of the test pieces. The procedure has been standardized in accordance with the EN ISO 12460-3:2015 standard.

Analysis of Formaldehyde

Spectrophotometric Method

Spectrophotometry is the most commonly used method in the determination of formaldehyde, and it has simple operation, low cost, strong selectivity, and high sensitivity (Hladova et al. 2019). According to different absorbers, the method can be divided into: acetylacetone method, MBTH method, AHMT method, chromotropic acid method, pararosaniline method, etc., and each spectrophotometric method has its advantages and disadvantages.

The acetylacetone (acac) method is a formaldehyde determination method based on Hantzsch reaction. The Hantzsch reaction refers to the cyclization of one kind of β -diketones with formaldehyde and ammonia in a slightly acidic solution to form dihydropyridine derivatives, which are generally colored and often fluorescent. Nash (1953) used 2,4-pentanedione (PD, acetylacetone) for the first time for formaldehyde determination based on Hantzsch reaction. Since then, this chemical reaction using PD has been used by many others and has been recommended in Europe and Japan for the determination of formaldehyde emissions from wood materials (Salthammer et al. 2010). The principle of acetylacetone method is that formaldehyde reacts with acetylacetone to form a yellow compound (dihydropyridine 3,5-diacetyl-1,4-dihydrolutidine (DDL)) under the action of ammonium salt and can be quantified

by ultraviolet/visible spectrophotometry under the wavelength of 412 nm. This method is simple in principle, easy to operate, stable in color, and not interfered by acetaldehyde, but its analysis process is relatively slow.

Since 1961, 3-methyl-2-benzothiazolone hydrazone hydrochloride (MBTH) has been introduced into the quantitative measurement of aldehyde compounds. Adding excessive amounts of MBTH to samples containing formaldehyde can trigger a variety of reactions. MBTH firstly reacts with formaldehyde to form an azine. Excess MBTH is oxidized with the addition of developer (Fe (III)). The oxidized MBTH reacts with the azine to form a strong blue color, and the resulting blue complex has the maximum characteristic absorption at 628 nm. The intensity of the blue color is proportional to the initial concentration of formaldehyde. The method is simple and easy to implement, with high sensitivity and low detection limit. However, MBTH is rarely used because of its high cost, interference with other lower aliphatic aldehydes, and instability of MBTH-formaldehyde intermediates.

The principle of AHMT method (Hladova et al. 2019) is that formaldehyde and 4-amino-3-hydrazino-5-mercaptop-4H-1,2,4-triazole (AHMT) are condensed under alkaline conditions, and then oxidized by potassium iodate to a purple red 6-mercaptop-5- triazolo [4,3-b]-s-tetrazine (MTT) compound. The depth of its color is proportional to the formaldehyde content. The concentration of formaldehyde is calculated by measuring the absorbance at 550 nm with a spectrophotometer. The AHMT method is more affected by aldehydes than the acetylacetone method.

The chromotropic acid method is that formaldehyde reacts with chromotropic acid in a concentrated sulfuric acid solution to form a red-violet hydroxydiphenylmethane derivative. The absorption maximum at 580 nm is used for UV/visible detection. This method has been standardized by the National Institute of Occupational Safety and Health (NIOSH) and is used to determine formaldehyde in large-scale chambers, in small-scale chambers, and in the desiccator method (Salthammer et al. 2010). Chromotropic acid method has the advantages of simple operation, rapid and sensitive, but it also has some shortcomings. It is not easy to handle in concentrated sulfuric acid, and the coexistence of phenols, aldehydes, alkenes, and NO₂ compounds has positive or negative interferences to the determination of formaldehyde (Hladova et al. 2019).

The pararosaniline method (Mikscha et al. 1981) is that formaldehyde and para-rosaniline form a magenta dye in the presence of sulfite ions, which is a unique reaction of formaldehyde. Its strong absorbance at 570 nm is used for UV/visible detection. In a strong acid medium, the pararosaniline method is a unique reaction of formaldehyde, and it is not interfered by other aldehydes and phenols during the measurement. However, this method also has some shortcomings: fast fading, susceptible to temperature, and the use of toxic mercury reagents.

Chromatographic Method

The chromatographic method (Li et al. 2007) for the determination of formaldehyde has a powerful separation function, simple operation, and good selectivity. It can be directly used for the determination of formaldehyde in indoors, textiles, and food. 2,4-Dinitrophenylhydrazine (DNPH) has been identified as a standard reagent for the determination of formaldehyde by many national and international standards bodies. DNPH reacts with formaldehyde in the presence of an acidic catalyst to form stable

and colored hydrazone derivatives. The hydrazone derivatives are separated by high-performance liquid chromatography (HPLC), and then the HCHO-DNPH derivative is detected by ultraviolet spectrum (UV) at 360 nm. The DNPH method has been used for different environmental samples, including automobile exhaust, waste and drinking water, and air pollution. In order to monitor air quality, a sampling tube based on DNPH coated solid adsorbent was developed. The DNPH method is described in EPA Method TO-11A, ASTM D 5197150 and has been accepted as an international standard by ISO (Salthammer et al. 2010).

Some interference should also be considered when using the DNPH method to monitor formaldehyde: ozone interference (Schulte-Ladbeck et al. 2001). Ozone easily reacts with DNPH and derived hydrazone compounds to interfere with the determination of formaldehyde. Therefore, an appropriate scrubber/descaler should be used to remove ozone. There are commercially available products, for example, ozone removal columns, which are used to remove ozone before DNPH sampling. The ozone removal column is filled with granular potassium iodide. When the ozone-containing air passes through the device, the iodine ions are oxidized to iodine, and the ozone in the air is consumed at the same time.

The analysis of aldehyde samples using HPLC follows these procedures (Wang et al. 2020a): (1) Extraction of aldehyde-DNPH derivatives: a quantitative acetonitrile solvent was accurately added to the DNPH sampling tube, which was then collected in a colorimetric tube, filtered with a membrane, and treated with an ultrasonic cleaner; subsequently, it was placed in a brown volumetric bottle and divided into a sample vial for use; (2) test and analysis: the prepared standard fluids and extractions of aldehyde-DNPH derivatives were analyzed by HPLC. The quantification is based on the retention time and peak area.

Sensors

Traditional formaldehyde measurement methods require well-trained operators to provide services and are expensive, and the system is large and difficult to carry, which promotes the application of sensor technology to formaldehyde measurement research (Chung et al. 2013). Descamps et al. (2012) proposed a colorimetric device based on the acetylacetone (acac) method to measure the concentration of gaseous formaldehyde in a nanoporous film doped with fluorine-P. Based on an ammonium sulfate derivatization reagent and a capillary electrophoresis-electrochemical detection (CEED) system, Deng et al. (2012) proposed a formaldehyde gas sensor with the minimum detection limit of 0.12 ppb and found that the detection signal strength was linearly correlated with the formaldehyde concentration in the concentration range of 0.4–770 ppb.

Emission Models of Formaldehyde

Short-Term Emission Models

Prediction of formaldehyde emissions in different indoor settings under various environmental conditions promote the development of modeling approach, which could be divided into short-term emission models and long-term emission models.

The short-term emission models mainly refer to the physical process of formaldehyde from indoor building materials and furniture, which include empirical models and physics-based models. The long-term emission models consider both the physical and chemical processes that occur inside the materials.

The empirical models are generally obtained through experimental observation and summarization of the test data and mainly include the power-law model, single-exponential (first-order) model, and double-exponential (second-order) model. Liu et al. (2015) applied the power-law model and single-exponential model to investigate formaldehyde emissions from composite wood and solid wood furniture and found that the power-law model worked better than the single-exponential model. The empirical models are simple and easy to use and are therefore frequently used in engineering applications, for example, in the BIFMA standard. However, these empirical models include empirical parameters, which do not have physical meanings and can just be obtained through nonlinear curve fitting of the model with test data. These empirical parameters are only applicable to the specific test conditions and cannot be extended to predict emissions in other scenarios. This limitation hinders wider use of empirical models, especially in real indoor environments where the environmental conditions change frequently. Therefore, Little et al. (1994) proposed the classic physics-based mass transfer model to characterize VOC emissions from single-layer building materials. This model considers two physical mass transfer processes for the VOC emissions: the internal diffusion process (characterized by D_m), and the interface partition process (characterized by K); while the external convective process is ignored. The key parameters (C_0 , D_m , K) in this model are the characteristic parameters, which reflect the essence of the emission process, and can be used in other emission scenarios (e.g., different ventilation rates or loading ratios). Some follow-up studies improved the application range of the Little's model and proposed various mass transfer models, for example, by considering the external convective process, by extending the model to multilayer materials, or by incorporating more general conditions. Here we will introduce some typical physics-based models.

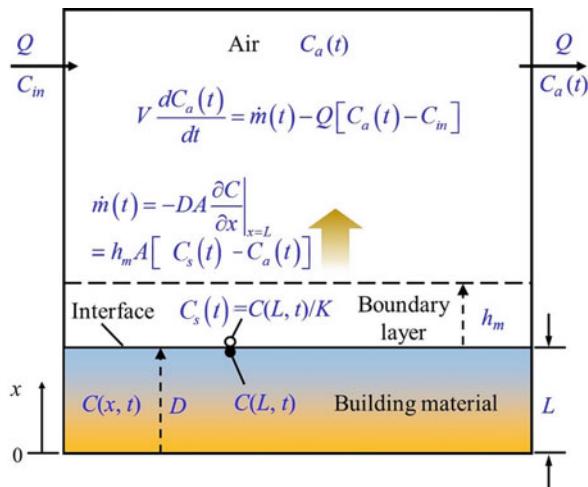

Formaldehyde emission from building material in a chamber or indoor environment is schematically shown in Fig. 3. The following assumptions are made: (1) the initial concentration of formaldehyde in the building material, C_0 , is uniformly distributed; (2) the inlet and initial formaldehyde concentrations of the chamber are zero; (3) mass transfer is one dimensional, vertical to the material surface; (4) the diffusion coefficient D_m and the partition coefficient K are constant; (5) the chamber air is well mixed; and (6) equilibrium always exists at the material/air interface.

Based on the above assumptions, the emission process of formaldehyde inside the material can be described by the one-dimensional diffusion equation:

$$\frac{\partial C_m}{\partial t} = D_m \frac{\partial^2 C_m}{\partial x^2} \quad (1)$$

where C_m is the VOC concentration inside the material, $\mu\text{g}/\text{m}^3$; t is the emission time, s ; D_m is the diffusion coefficient, m^2/s ; y is the coordinate, m .

Fig. 3 Schematic of formaldehyde emission from building material in a chamber

Since the material is placed on a stainless-steel chamber, no mass flux exists at the bottom of the material, or:

$$\frac{\partial C_m}{\partial x} = 0, \quad x = 0 \quad (2)$$

At the material/air interface, a third type of boundary condition can be used to describe the convective mass transfer process:

$$-D_m \frac{\partial C_m}{\partial x} = h_m (C_{as} - C_a), \quad x = L \quad (3)$$

where h_m is the convective mass transfer coefficient, m/s, which can be calculated using the empirical correlation; C_a is the formaldehyde concentration in the chamber and C_{as} is the formaldehyde concentration in the air at the interface, $\mu\text{g}/\text{m}^3$; L is the thickness of the material, m. Assume that an equilibrium exists at the material/air interface, that is:

$$C_m = K C_{as}, \quad x = L \quad (4)$$

where K is the material/air partition coefficient.

The initial condition for Eq. (1) is given as:

$$C_m(x, t) = C_0, \quad t = 0, \quad 0 \leq x \leq L \quad (5)$$

where C_0 is the initial VOC concentration inside the material, $\mu\text{g}/\text{m}^3$.

The above Eqs. (1)–(5) describe the emission process inside the material, together with the boundary conditions and the initial condition. These equations are not

closed because of the existence of C_a . An equation containing C_a is given as follows based on mass conservation of formaldehyde in the chamber:

$$V \frac{dC_a}{dt} = -AD_m \frac{\partial C_m}{\partial x} - QC_a, \quad x = L \quad (6)$$

where V is the volume of the chamber, m^3 ; A is the emission area of the material, m^2 ; Q is the ventilation rate, m^3/s .

Now the system of Eqs. (1)–(6) is closed. The formaldehyde concentrations in the material and the air phases can be solved simultaneously. In Little's model (Little et al. 1994), the external convection mass transfer resistance is neglected; that is, h_m is Eq. (3) is assumed to be infinity. Huang and Haghigat (2002) later developed an analytical model by neglecting the formaldehyde concentration in the air because of its low value relative to the concentration in the material by neglecting C_a in Eq. (3). After that, Xu and Zhang (2003) presented an improved mass transfer model by considering the full version of Eq. (3) and derived a semi-analytical model. The obtained solution is as follows:

$$C_m(x, t) = KC_a(t) + \sum_{m=1}^{\infty} \frac{\sin(\beta_m L)}{\beta_m} \cdot \frac{2(\beta_m^2 + H^2)}{L(\beta_m^2 + H^2) + H} \cdot \cos(\beta_m x) \cdot \left[(C_0 - KC_a(0))e^{-D\beta_m^2 t} + \int_0^t e^{-D_m \beta_m^2 (t-\tau)} \cdot K dC_a(\tau) \right] \quad (7)$$

where $H = h_m/D_m K$, β_m ($m = 1, 2, \dots$) are the positive roots of the following equation:

$$\beta_m \tan(\beta_m L) = H \quad (8)$$

Xu and Zhang's (2003) model is not a full analytical model since the solution of C_m in Eq. (7) is coupled with the air concentration C_a . By applying the Laplace transformation, Deng and Kim (2004) later derived a full analytical solution for the chamber formaldehyde concentration:

$$C_a(t) = 2C_0\beta \sum_{n=1}^{\infty} \frac{q_n \sin q_n}{G_n} e^{-D_m L^{-2} q_n^2 t} \quad (9)$$

with $G_n = [K\beta + (\alpha - q_n^2)KBi_m^{-1} + 2]q_n^2 \cos q_n + [K\beta + (\alpha - 3q_n^2)KBi_m^{-1} + \alpha - q_n^2]q_n \sin q_n$; $Bi_m = h_m L / D_m$; $\alpha = QL^2 / VD_m$; $\beta = AL / V$.

where Bi_m is the Biot number for mass transfer representing the ratio of the diffusion mass transfer resistance inside the material to the convective mass transfer resistance outside the material; α is the dimensionless air exchange rate; β is the ratio of the material volume to the chamber volume; q_n are the positive roots of the following equation:

$$q_n \tan q_n = \frac{\alpha - q_n^2}{K\beta + (\alpha - q_n^2)KBt_m^{-1}}, \quad n = 1, 2, \dots \quad (10)$$

In Deng and Kim's model, the initial VOC concentration in the chamber ($C_{a,0}$) and the inlet VOC concentration by ventilation (C_{in}) are zero. Later, Hu et al. (2007) developed a general analytical model for predicting emissions from arbitrary-layer building materials. It can estimate the formaldehyde emissions from arbitrary layered building materials whose mass transfer resistance through the gas-phase boundary layer on each side of it is not neglected and the initial distribution of material-phase formaldehyde concentration in each layer of building material is not necessarily uniform.

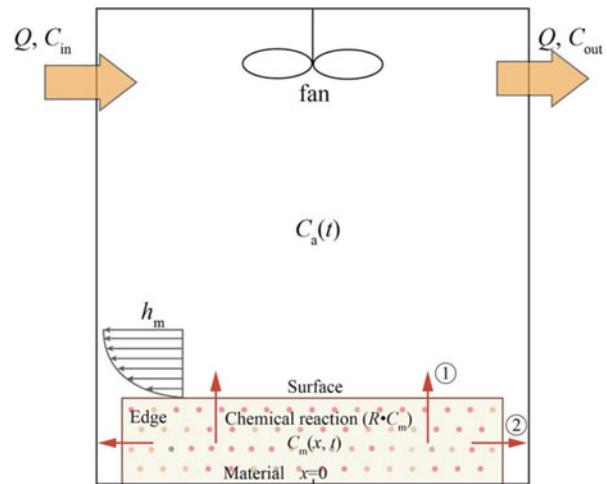

Long-Term Emission Model

The above physics-based models used short-term emission data to validate the effectiveness; whether these models can be extended to predict long-term emissions needs further investigation. In addition, these models generally consider the physical emission process only but neglect the chemical reaction process that is likely to occur in the long-term emissions especially for formaldehyde from composite wood panels (e.g., hydrolysis). Given this background, He et al. (2019) recently developed an improved mechanism-based model (long-term emission model) to predict the long-term behaviors of formaldehyde from composite wood materials with exposed edges and seams. One merit of the model lies in that it has a full analytical solution. Here we will briefly introduce this model.

A schematic of formaldehyde emissions from building material in a ventilated chamber or indoor environment is shown in Fig. 4. The formaldehyde emissions can originate from the top surface or the exposed edges. In most chamber tests, the edges are sealed. In these regions, emission occurs only from the top surface and can be treated as one-dimensional emission (the diffusion path perpendicular to the flat surface). By defining the diffusion path perpendicular to the edge surface, such one-dimensional emission can also describe the emission from the exposed edges and seams when they account for most of the emission quantity of the finished product. He et al.'s study mainly focuses on the latter emission scenario. Similar to other existing physical-based models, it is assumed that the formaldehyde distribution inside the material is uniform before testing, and the partition process at the material/air interface is governed by Henry's law. Further, it is assumed that the hydrolysis of UF resin inside the composite wood panel will continuously occur and produce new formaldehyde.

The chamber formaldehyde concentration for long-term emission can derive from both free formaldehyde initially in the material and hydrolysis of the UF resin. For the former, the emission rate of formaldehyde is described by physical mass transfer

Fig. 4 Schematic of formaldehyde emissions from building material in a ventilated chamber. (Scenario ① represents emission from top surface; scenario ② represents emission from exposed edges and seams)

process, and for the hydrolysis process, the reaction between UF resin and water vapor can be described by the following chemical reaction:

where P stands for the products except for formaldehyde. The formation rate of formaldehyde can then be written as

$$\frac{\partial C_m^F}{\partial t} = k \cdot C_{\text{UF}} \cdot C_{\text{water}} \quad (12)$$

where C_m^F is the concentration of formaldehyde in the building material originated from hydrolysis; k is the second-order rate constant; C_{UF} is the concentration of the UF resin in the building material; and C_{water} is the concentration of water vapor in the gas phase. Under the controllable chamber conditions (constant T and RH), the concentration of water vapor in the gas phase can be treated as a constant so that Eq. (12) is simplified to pseudo-first-order with regard to the concentration of UF resin:

$$\frac{\partial C_m^F}{\partial t} = k' \cdot C_{\text{UF}} \quad (13)$$

where k' is the pseudo-first-order rate constant.

As applied in previous studies based on experimental observation and theoretical analysis, the concentration of UF resin (C_{UF}) is assumed to be linearly correlated with the formaldehyde concentration in the material (C_m), that is:

$$C_{\text{UF}} = m \cdot C_m \quad (14)$$

where m is a constant and C_m is the concentration of formaldehyde in the building material including both physically free formaldehyde and chemically produced formaldehyde, $\mu\text{g}/\text{m}^3$.

By substituting Eq. (14) into Eq. (13):

$$\frac{\partial C_m^F}{\partial t} = R \cdot C_m \quad (15)$$

where $R = k' \cdot m$.

Based on the above analysis, the governing equation representing the physical diffusion and chemical reaction processes inside the material can be described by Eq. (16):

$$\frac{\partial C_m}{\partial t} = D_m \frac{\partial^2 C_m}{\partial x^2} + R \cdot C_m \quad (16)$$

The boundary conditions and initial condition, as well as the mass balance equation in the chamber, are the same to the above Eqs. (2)–(6). By virtue of the Laplace transform, an analytical solution is derived:

$$C_a(t) = 2C_0 \beta \sum_{n=1}^{\infty} \frac{q_n \sin q_n}{A_n} e^{(R - D_m \delta^{-2} q_n^2)t} \quad (17)$$

where

$A_n = [K\beta + (\alpha + G - q_n^2)KBi_m^{-1} + 2]q_n^2 \cos q_n + [K\beta + (\alpha + G - 3q_n^2)KBi_m^{-1} + \alpha + G - q_n^2]q_n \sin q_n$; $G = RL^2/D_m$; q_n are the positive roots of

$$q_n \tan q_n = \frac{\alpha + G - q_n^2}{K\beta + (\alpha + G - q_n^2)KBi_m^{-1}} \quad (n = 1, 2, \dots) \quad (18)$$

Equation (18) establishes the explicit relationship between the gas-phase formaldehyde concentration and four parameters, that is, C_0 , D_m , K , and R , which comprehensively considers the effect of physical and chemical processes.

In He et al. (2019)'s study, they compared empirical models and the long-term emission model. Two empirical models, a power-law model and a double-exponential model, are used. Both models have been widely used in previous studies. In addition, a pure physical model without chemical reactions is also included in the comparison. The values of coefficients in the empirical models are derived from least square regression by fitting the experimental data (gas-phase formaldehyde concentrations) for 3 months. For the physical model, the 3-month data are used to get the key parameters (C_0 , D_m , K). Figure 5 shows the comparisons of predicted gas-phase formaldehyde concentrations among the different models with experimental data. This figure indicates that the prediction from the

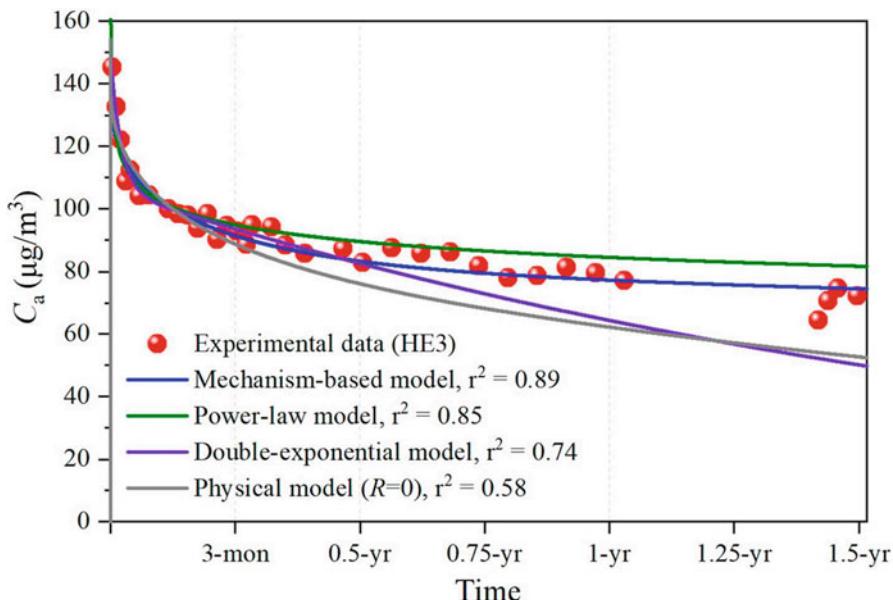

Fig. 5 Comparison of predicted gas-phase formaldehyde concentrations among different models with experimental data (He et al. 2019)

mechanism-based model or long-term emission model agrees well with the measured data over the whole period (1.5 year), while the prediction from the power-law model agrees well over about 1 year. The predictions of the double-exponential model and the physical model are a little lower than the measured data, especially for the long-term period (after 0.5 year). The square of the correlation coefficients (r^2) for the mechanism-based model, power-law model, double-exponential model, and physical model with experimental data are 0.89, 0.85, 0.74, and 0.58, respectively. These values are consistent with the above analysis. From this figure, we can further observe that the prediction of the mechanism-based model is between those of the double-exponential model and the power-law model. The power-law model agrees well with the data in the short- and mid-term emission periods, but for the relatively long-term emission period (i.e., after 1 year), the prediction of this model becomes close to equilibrium (decrease fairly slowly), which is not consistent with the pollutant emission behaviors. The double-exponential model represents exponential decay, and the trend of model is below the data observed in the long-term emission period. This trend is similar to that of the physical model. Therefore, for the long-term emissions from building materials and products, the existing empirical models and physical model are not able to accurately capture the formaldehyde emission characteristics. The good agreement for the short-, mid-, and long-term emissions between the model and experimental data demonstrates the effectiveness of the long-term emission model.

Measurement of Key Emission Parameters of Formaldehyde

Introduction of Measurement Methods for the Key Emission Parameters

The initial emittable concentration (C_0), the diffusion coefficient (D_m), and the material/air partition coefficient (K) are the three key emission parameters controlling the emission behaviors of formaldehyde from building materials or furniture. It is necessary to measure these parameters to understand the emission behaviors and how to control them. These key emission parameters are also the input of the above-mentioned short-term and long-term emission models. Many methods have been proposed to measure these three key emission parameters.

To measure the diffusion coefficients of VOCs in building materials, Kirchner et al. (1999) developed diffusion metric method, Bodalal et al. (2000) developed cup method, Meininghaus et al. (2000) proposed twin-compartment methods, Haghigat et al. (2002) proposed a dual-chamber method, and Blondeau et al. (2003) developed porosity methods. Generally speaking; all these methods produced large errors due to experimental disadvantages or took a long time. Cox et al. (2001b) measured K and D_m separately using a microbalance. However, the tests for K and D_m were based on a small sample of the material, which may not be different from the bulk material. Li and Niu (2005) used the inverse method to determine K and D_m for VOCs in building materials, but C_0 must first be known to use this method.

To measure C_0 of formaldehyde from dry building materials, traditional methods generally use solvent extraction or heat desorption methods (EN 120 1993). However, the methods only measured the total concentration instead of the emittable concentration of formaldehyde in the materials. Cox et al. (2001a) used free volume theory and a dual-mobility model to show that the total VOC concentration can be apportioned to mobile and partially immobilized fractions (C_0 in the aforementioned mass transfer models should be the concentration of the emittable compound or mobile fraction). They developed a fluidized-bed desorption (FBD) method to measure the C_0 of VOCs in vinyl flooring. The main merit of this method lies in that the application of cryogenic milling (CM) and FBD technique could accelerate the VOC emission greatly thus decreasing the experimental time. However, the apparatus of this method was relatively complicated, and the grinding process might change the physical or chemical properties of the material-VOC pairs, which might cause unpredictable measurement error of C_0 . The material was milled to powder at -140°C and the VOCs were then extracted from the powder at room temperature using FBD. The VOCs in the gas extracted from the fluidized-bed desorption and analyzed using GC/MS were assumed to be the mobile VOCs in the materials. Smith et al. (2009) applied the CM technique and developed an extraction method to determine C_0 . This method involved multiple equilibrium cycles and entailed flushing the chamber formaldehyde/VOCs multiple times once each emission process had reached equilibrium in a closed chamber. The tests often took a long experimental time (about 4 weeks). Furthermore, during the last few cycles of the extraction method, the uncertainty of measurement might increase due

to the very low formaldehyde/VOC concentrations in the chamber. The aforementioned methods target at extracting most of the formaldehyde/VOCs from the materials and then obtain the C_0 . In fact, it is not always necessary to extract most of the formaldehyde/VOCs. If it is enough to get the emission characteristic parameters just by extracting some of the formaldehyde/VOCs, it will undoubtedly reduce the test time. Later, Xiong et al. (2011a) developed a C-history method to rapidly, accurately, and simultaneously measure the three key emission parameters, which will be briefly introduced here. The summarization on some typical measurement methods is given in Table 6.

Introduction of the C-History Method

C-history method focuses on the emission process of formaldehyde from building material in a closed chamber (Xiong et al. 2011a), which can be used to

Table 6 Some measurement methods of the key emission parameters

Reference	Measurement method
Kirchner et al. (1999)	Cup method with measured parameter D_m Just one VOC can be tested at a time due to the use of purified VOC liquid Extraordinarily higher concentration inside the cup may overestimate D_m
Meininghaus et al. (2000)	Twin chamber method with measured parameters D_m and K Concentration level can be controlled at a required level Several VOCs can be tested in one experiment External convection is ignored, which will underestimate D_m when the airflow is slow
Yang et al. (2001)	Nonlinear regression method with measured parameters C_0 , D_m , and K K is predetermined by empirical correlations Maximum concentration in the chamber is difficult to detect, which may result in uncertainties for the measured C_0 and D_m
Cox et al. (2001a)	FBD method with measured parameters C_0 Short experimental time (within 7 h) Complicated experimental system Grinding process changes the physical properties of the material-VOC combination, which may cause unpredictable measurement errors
Cox et al. (2001b)	Microbalance method with measured parameters D_m and K Independent approach to measure the two parameters External convection is ignored
Li and Niu (2005)	Nonlinear regression method (inverse method) with measured parameters D_m and K There is a risk of multiple solutions due to the inter-dependence of the two parameters when they are estimated/fitted at the same time
Xu et al. (2009)	Twin chamber method with measured parameters D_m and K A similarity relationship between VOC and water vapor transport is established
Smith et al. (2009)	Extraction method with measured parameter C_0 Simple experimental system

Table 6 (continued)

Reference	Measurement method
	Long experimental time (about 4 weeks) Grinding process changes the physical properties of the material-VOC combination, which may cause unpredictable measurement error
Wang and Zhang (2009)	A method measuring the parameters C_0 , D , and K Experiments take about 7 days Peak concentration after injection is hard to detect, which will affect the measurement accuracy
Xiong et al. (2011a)	C-history method for a closed chamber with measured parameters C_0 , D_m , and K Short experimental time (1 ~ 3 days) High measurement accuracy (RSD < 10%) Multiple samplings in airtight conditions may result in VOC mass loss if the chamber volume is small, which may result in uncertainty (this is not the case for large chambers)
Xiong et al. (2011b)	VVL method with measured parameters C_0 and K Performing tests in parallel can decrease the experimental time (within 24 h) With some improvements this method can be used to measure D_m and h_m
Xu et al. (2012)	Determination of D and K of formaldehyde in selected building materials and the impact of relative humidity
Huang et al. (2013)	C-history method for a ventilated chamber with measured parameters C_0 , D_m , and K Experimental time is less than 12 h and R^2 ranges from 0.96 to 0.99 One test is performed in airtight conditions, while other tests are performed in ventilated conditions, thus some commonly measurement instruments (e.g., GC/MS, HPLC) can be used
Ye et al. (2014)	Simple method for estimating the ranges of D_m and C_0 using gas-phase VOC concentration data obtained from ventilated chamber tests Validated using the Monte Carlo method and the National Research Council of Canada's emissions database This simple method has more benefits when only a few data points are available K is not determined
Wang et al. (2020b)	A general regression method for measuring the C_0 , D_m , and K of VOCs from building materials/furniture

simultaneously determine the three key emission parameters, C_0 , D_m , and K . This method needs to measure the change tendency of formaldehyde concentration in the chamber ($C_a(t)$) and the equilibrium concentration (C_{equ}). When the emission process reaches equilibrium, by assuming the material/air partition process conforming Henry's law, C_{equ} can be derived as follows based on VOC mass conservation between the material phase and air phase:

$$C_{equ} = \frac{C_0}{K\beta + 1} \quad (19)$$

By virtue of mass transfer analysis for the emissions in closed chamber, the following equation yields:

$$\ln \left(\frac{C_{\text{equ}} - C_a(t)}{C_{\text{equ}}} \right) = \text{SL} \cdot t + \text{INT} \quad (20)$$

where SL and INT are the functions of D_m and K , described by the following two equations:

$$\text{SL} = -D_m L^{-2} q_1^2 \quad (21)$$

$$\text{INT} = \ln \left(-\frac{2(K\beta + 1) \sin q_1}{q_1 A_1} \right) \quad (22)$$

Therefore, if the chamber formaldehyde concentration is treated as the form of the logarithm of dimensionless excess concentration in Eq. (20), the SL and INT can be obtained by doing linear curve fitting. The two parameters D_m and K can be obtained directly because they are functions of SL and INT, and we have two equations with two unknown parameters. Combining Eq. (19) and the known value of K , C_0 can be calculated. Since the main characteristic of this method is to apply the concentration history of formaldehyde in a closed chamber, this method is called as the C-history method for a closed chamber.

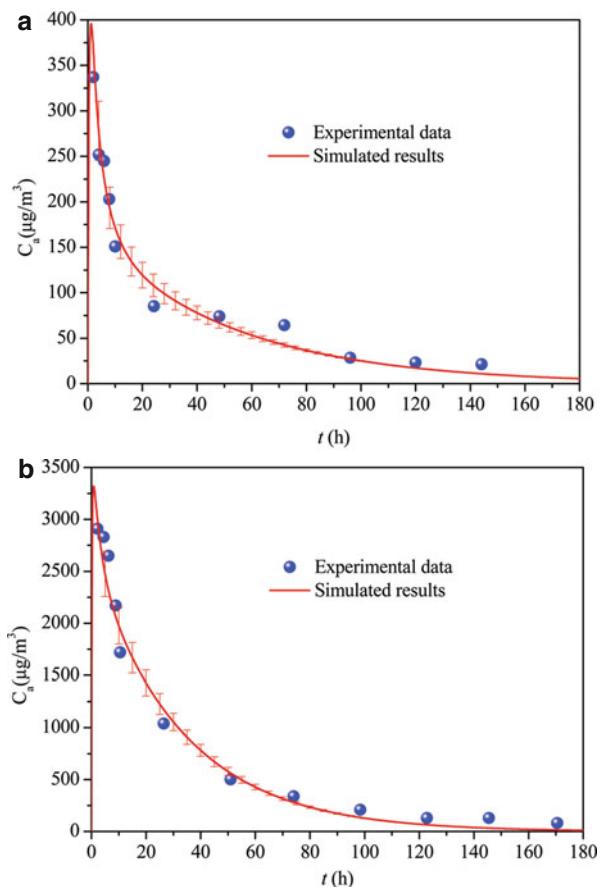

Independent experiments are performed to validate the measured key emission parameters. Based on the determined key emission parameters from the closed chamber and the analytical results for a ventilated chamber, the formaldehyde concentrations in the ventilated chamber were calculated and compared to the experimental data (Fig. 6). For the tested experimental time (within 180 h), the simulated results are in very good agreement with the observed data, suggesting that the measured parameters in the closed chamber are reliable and can be used to estimate formaldehyde emission in real ventilated conditions.

The C-history method just performs one emission process in closed chamber, making it very time-saving, with the experimental time generally less than 3 days, while the traditional methods tend to require 7 ~ 30 days. This is the main advantage of the C-history method. It is therefore a very convenient and effective method for rapid measurement of VOC emissions from building materials and for furniture labeling. In this method, the formaldehyde concentration in a closed chamber is sampled several times to determine the parameters. If the chamber volume is small, the multiple sampling may result in a change in the target formaldehyde concentration in the closed chamber, which may increase the measurement error. This drawback has been overcome by the C-history method for a ventilated chamber (Huang et al. 2013).

Impact of Environmental Factors on Formaldehyde Emissions

The three key emission parameters not only depend on the physical properties of the material-VOC combinations but also rely heavily on the experimental conditions especially the temperature and relative humidity. This combination is one of the most important features of these parameters. In general, indoor temperature varies within a

Fig. 6 Comparison of simulated results with the ventilated chamber experimental data for formaldehyde concentration of (a) medium-density fiberboard and (b) particle board (Xiong et al. 2011a)

temperature range, which is related to outdoor temperature, solar radiation, etc. Hunt and Gidman (1982) measured the temperature in 1000 buildings in the UK and observed an average temperature of 16 °C and a maximum temperature of 29 °C. McLaren et al. (2005) investigated the temperature in cars, and a maximum temperature of 67 °C was found in hot days. These temperature variances will cause a corresponding change to the three key emission parameters, which is one of the main reasons why formaldehyde and VOCs emit more rapidly in summer. The impact of temperature on the emission rate is a comprehensive effect of temperature impact on the key parameters since the emission rate is a function of the three parameters. The increase of emission rate with increasing temperature has been observed by many researchers. Myers (1985) reported that the emission rate of formaldehyde from particleboard increased by a factor of 5.2 between 23 °C and 40 °C. Lin et al. (2009) showed the emission rate and concentration increased 1.5–12.9 times when the temperature increased from 15 °C to 30 °C. Similar phenomena were also investigated by other researchers (Parthasarathy et al. 2011).

Impact of Temperature on C_0

It is found that the initial emittable concentration of formaldehyde (C_0) in a building material is much less than the concentration measured by the perforator method (C_{total}) under room temperature condition (Wang and Zhang 2009) and C_0 changes with the environmental conditions especially temperature. This phenomenon can be explained using statistical physics (Huang et al. 2015). From a microcosmic aspect, the formaldehyde molecules are bonded in the material surface by adsorption, and a molecule is emittable only when the kinetic energy of this molecule is high enough to overcome the bonding forces, that, to overcome an energy barrier. The sum of these molecules constitutes C_0 , which is obviously less than C_{total} . Considering that the average kinetic energy of the molecules increases with increasing temperature, it undisputedly leads to higher C_0 at higher temperatures. By using statistical physics theory, the correlations between the emittable ratio ($P = C_0/C_{\text{total}}$) and temperature, and between C_0 and temperature, are derived as follows:

$$\ln \left(P \sqrt{T} \right) = -\frac{A}{T} + B \quad (23)$$

$$C_0 = \frac{C}{\sqrt{T}} \exp \left(-\frac{A}{T} \right) \quad (24)$$

where A , B , and C are constants, which are not dependent on temperature but are only related with the physical properties of the material-formaldehyde combinations.

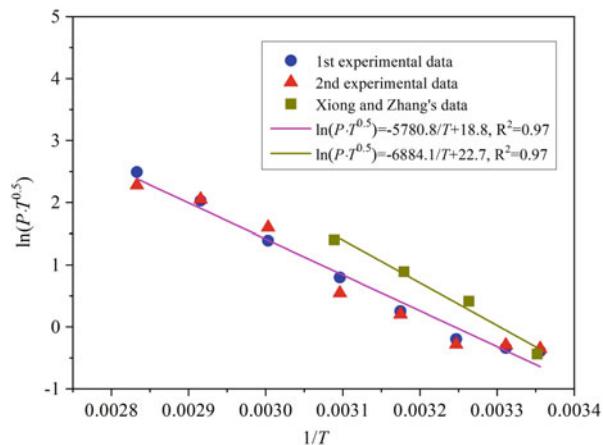

The two assumptions deriving these two equations are: (1) the energy barrier (ϵ_0) is a constant for a given material-formaldehyde combination; (2) chemical reactions are ignored and only physical interactions between formaldehyde and material molecules are considered. The derived correlations are thus applicable for emission scenarios meeting these conditions. When the parameters A , B , C in Eqs. (23) and (24) are obtained based on available results, the correlations can then be used to predict P and C_0 at other temperatures, which are very helpful and convenient for engineering applications.

Figure 7 shows the good agreement between the theoretical correlations and the experimental data (Huang et al. 2015), which demonstrates the effectiveness of the theoretical correlations. It should be noted that, up to now, the phenomenon of increased C_0 with increasing temperature is recently found in the formaldehyde emissions. Whether it is applicable for other VOCs is still not known or reported, and more experimental study is required.

Impact of Temperature on D_m

Diffusion of formaldehyde in building material is related with the heat motion of molecules, so the diffusion coefficient is significantly dependent on temperature. This effect is commonly assumed to follow with an Arrhenius-like behavior.

Fig. 7 Linear regression results by treating the experimental data with theoretical Eq. (23) and its comparison with the full relationship (Xiong and Zhang 2010; Huang et al. 2015)

However, the correlation lacks strong theoretical foundations. For VOC diffusion in porous materials, if the molecular diffusion is dominant, Deng et al. (2009) derived a theoretical correlation to characterize the influence of temperature on D_m :

$$D_m = B_1 T^{1.25} \exp\left(-\frac{B_2}{T}\right) \quad (25)$$

where B_1 and B_2 are positive constants for a given material-VOC combination.

This correlation indicates that D_m increases with increasing temperature. The calculations based on Eq. (25) agree well with the experimental data for four kinds of building materials (Deng et al. 2009). Once the parameters B_1 and B_2 are determined, the correlation can then be used to predict D_m at other conditions.

Impact of Temperature on K

Formaldehyde emission or adsorption in building materials is found to obey the Langmuir kinetic equation in many cases. By applying this equation, a theoretical correlation between the partition coefficient and temperature is deduced as (Zhang et al. 2007)

$$K = A_1 T^{1/2} \exp\left(\frac{A_2}{T}\right) \quad (26)$$

where A_1 and A_2 are positive constants for a given material-VOC combination.

Equation (26) indicates that K decreases with increasing temperature. Experimental tests of formaldehyde emissions from four kinds of building materials at temperatures 18–50 °C validates the reliability of the temperature correlation (Zhang et al. 2007).

Impact of Relative Humidity

Besides temperature, relative humidity (RH) also plays an important role in the emission behaviors. It should be noted that the influence of RH on the emissions of formaldehyde from composite wood products can be quite different from VOCs due to the hydrolysis of urea-formaldehyde adhesives. The impact of RH on the key emission parameters is a little more complicated. The increase of C_0 and K with increasing RH for formaldehyde from some building materials was reported (Xu and Zhang 2011). However, the impact of RH on K for VOCs indicates inconsistent outcomes, which is significantly related with the material-VOC combinations. Xu and Zhang (2011) investigated the sorption of toluene into calcium silicate and found that K decreased with the increase of RH . Deng (2010) examined the sorption of five VOCs into carpet and observed that K of ethylbenzene, undecane, and dodecane decreased with the increase of RH , while K of benzaldehyde and 1,2-dichlorobenzene firstly increased (in the RH range of 25–50%) and then decreased (in the RH range of 50–80%). In addition, the effect of RH on D_m for formaldehyde and VOCs is generally regarded as ignored (Farajollahi et al. 2009; Deng 2010; Xu and Zhang 2011).

The positive effect between the emission rate and RH for formaldehyde emissions has been observed in many experimental studies. Andersen et al. (1975) reported that the emission rate of formaldehyde from particleboard increased one fold in the RH range of 30–70%. For some VOCs, Lin et al. (2009) observed the similar phenomenon in the experiment that the emission rates of toluene, n-butyl acetate, ethylbenzene, and m,p-xylene increased 1.1–5.4 folds when RH increased from 50% to 80%.

Combined Effect of Temperature and Humidity on the Emission Rate

As mentioned above, the emission rate of formaldehyde from building materials are significantly influenced by the temperature and relative humidity. These two factors not singly but comprehensively affect the emission characteristics. The combined effect of temperature and relative humidity on the three key emission parameters C_0 , D_m , and K is the basis for obtaining the combined effect on the emission rate. According to the idea of variable separation method or the Berge equation, the combined effect of temperature and relative humidity can be regarded as the multiplication of effect of single variable. Based on this, the following correlation can be derived (Xiong et al. 2016):

$$E = E_1 T^{0.75} \exp \left(E_2 \cdot RH - \frac{E_3}{T} \right) \quad (27)$$

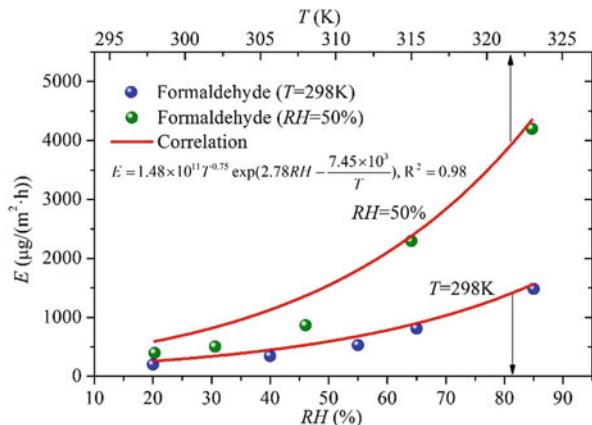

This equation explicitly characterizes the relationship between the steady-state emission rate and T , RH . Further analysis indicates that, with the increase of T or RH , the emission rate increases accordingly. Once the emission rate for a given material-pollutant combination is measured at three or more sets of environmental conditions, the three parameters E_1 , E_2 , and E_3 can be determined from nonlinear curve fitting

and the derived correlation (Eq. (27)) can then be applied to predict the emission rate at other T and RH different from the test conditions, which will be very helpful for engineering applications as well as for scientific researches. By combining ten sets of data for emission rates under varied temperature (25°C , 29°C , 35°C , 42°C , 50°C at $50\% RH$) and relative humidity (20% , 40% , 55% , 60% , 85% at 25°C) in prior studies, correlation (27) is applied to perform nonlinear regression. Fitting results between the emission rate and T , RH for formaldehyde from medium density fiberboard are shown in Fig. 8 (Xiong et al. 2016). The bottom x axis + y axis and the top x axis + y axis in Fig. 8 represent the results at a certain temperature ($T = 298 \text{ K}$) and a certain relative humidity ($RH = 50\%$), respectively. The time point for the emission rate at steady state in this figure is 40 h. Good regression accuracy is also obtained ($R^2 = 0.98$). The correlation between E and T , RH for formaldehyde from medium density fiberboard is represented as

$$E = 1.48 \times 10^{11} T^{0.75} \exp \left(2.78RH - \frac{7.45 \times 10^3}{T} \right) \quad (28)$$

With this quantitative correlation, the E of formaldehyde emissions from medium density fiberboard at different T and RH can be predicted. Take Beijing in China as an example. The indoor temperature and relative humidity of Beijing in summer and winter (with HVAC system) can be approximately taken as 24°C , 50% , and 20°C , 45% , respectively. Based on these data, the ratio of E in summer to that in winter is about 1.63, and this ratio can be regarded as the ratio of formaldehyde concentration in indoor environment in the two seasons. Yao et al. (2005) surveyed the indoor formaldehyde concentration levels in Beijing in 2003 and found that the formaldehyde concentration in summer is about 1.32 times to that in winter. This value is approximately consistent with the results based on prediction with Eq. (28), thus demonstrating the effectiveness of the correlation.

Fig. 8 The correlation between emission rate and T , RH for formaldehyde from medium density fiberboard (Xiong et al. 2016)

Conclusions

This chapter briefly introduces the formaldehyde properties and hazards, usages and pollution levels, determination methods, emission models, key parameter measurement methods, and impact factors. On the whole, the behavior of formaldehyde is now well understood. Nevertheless, so far, other very volatile organic compounds are seldom considered, and there are two main reasons for this: (1) the lack of a clear and internationally recognized definition of VVOCs; (2) the lack of a unified analysis method to identify and quantify VVOCs. In the past few years, VVOCs have increasingly become the focus of regulatory and health-related construction product emission assessments, which shows the importance of these substances. It is likely that the other VVOCs can be treated in a similar way to formaldehyde both experimentally and theoretically. However, work is still needed to obtain the necessary information on their presence in indoor air and their emission characteristics so that they are no longer “understudied.”

Abstract

Volatile organic compounds (e.g., benzene, toluene, xylene) are important indoor pollutants. Indoor VOCs mainly originate from furniture and building materials. VOCs can produce adverse health effects and therefore have drawn the attention of researchers of indoor environments and public health. This chapter introduces

VOCs · Emission character · Characteristic parameters · Emission models · Influencing factors

Introduction

Volatile organic compounds (VOCs) are organic chemical compounds whose composition makes it possible for them to evaporate under normal indoor atmospheric conditions of temperature and pressure. Different organizations have different definitions of VOCs. According to a World Health Organization (WHO) classification system, VOCs are defined by a boiling point range with a lower limit between 50 and 100 °C and an upper limit between 240 and 260 °C (WHO 1989). According to the ASTM International standard D3960-05, VOCs refer to any organic compound that can participate in atmospheric photochemical reactions (ASTM D3960-05 2018). The US Environmental Protection Agency (U.S. EPA) defines it as: volatile organic compounds are any carbon compound that participates in atmospheric photochemical reactions except for CO, CO₂, H₂CO₃, metal carbides, metal carbonates, and ammonium carbonate (U.S. EPA 1992). In China, VOCs refer to organic compounds with saturated vapor pressure greater than 70.91 Pa at room temperature, boiling point below 50–260 °C at standard atmospheric pressure of 101.3 kPa, and initial boiling point equal to 250 °C, or any organic solid or liquid that can volatilize at room temperature (GB 18582-2008 2008).

In the indoor environment, VOCs are introduced into the air mostly through the emissions from building materials, including flooring, paints, adhesives, wood protection agents, wall and roof coverings, sealants, wall plasters, bricks and concrete, etc. In addition, the use of detergents, deodorants, pesticides, cosmetics, the burning of household fuels in the kitchen (such as natural gas stoves), cooking fume, smoking, the use of printers, photocopiers, human breathing, and metabolism will also produce VOCs. VOCs not only pollute the environment but also affect human health (Soni et al. 2018).

The chapter will introduce properties and hazards of VOCs, measurement methods, emission characteristic parameters, emission models, and influencing factors.

Properties and Hazards of VOCs

Classes of VOCs

VOCs can be classified according to molecular structure or functional groups. These include aliphatic hydrocarbons (including those which are chlorinated–halocarbons), aromatic hydrocarbons, alcohols, ethers, esters, aldehydes, etc. (Anand et al. 2014).

At present, more than 300 types have been identified, and many of them are primarily found in indoor air. Table 1 presents the types and compositions of common VOCs. Common indoor VOCs include benzene, toluene, xylene, styrene, trichloroethylene, chloroform, trichloroethane, diisocyanate (TDI), diisocyanotoluene, etc. Table 2 lists typical indoor VOCs and their boiling points and vapor pressures.

Properties of VOCs

VOCs are a group of compounds that have some common physical-chemical properties (Cicolella 2008): (1) VOCs contain carbon, and most VOCs also contain nonmetallic elements such as H, O, N, P, S, and halogens; (2) their relative vapor density is heavier than air; (3) there are millions of species, most of which are

Table 1 Types and compositions of common VOCs

Type	Compositions
Aliphatic hydrocarbon	Methane, ethane, propane, cyclohexane, methylcyclopentane, hexane, 2-methylpentane, 2-methylhexane
Aromatic hydrocarbons	Benzene, toluene, ethylbenzene, xylene, n-propylbenzene, styrene, 1,2,4-trimethylbenzene
Halogenated compounds	Trichlorofluoromethane, dichloromethane, chloroform, carbon tetrachloride, 1,1,1-trichloroethane, trichloroethylene, tetrachloroethane, chlorobenzene, 1,4-dichlorobenzene
Phenol, ether, epoxy compounds	Cresol, phenol, ether, ethylene oxide, propylene oxide
Ketones, aldehydes, alcohols, polyols	Acetone, butanone, cyclohexanone, formaldehyde, acetaldehyde, methanol, isobutanol
Nitrile, amine compounds	Acrylonitrile, dimethylformamide
Acid, ester compounds	Acetic acid, ethyl acetate, butyl acetate
Polycyclic aromatic hydrocarbons	Naphthalene, phenanthrene, benzopyrene
Others	Methyl bromide, chlorofluorocarbons

Table 2 Typical indoor VOCs and their boiling point and vapor pressure

Name	Boiling point (°C)	Vapor pressure (below 20 °C, Pa)
1,1,1-trichloroethane	74.0	1.31×10^4
1,1,2-trichloroethane	114	2.35×10^3
Benzene	80.1	9.95×10^3
Chloroform	61.1	1.94×10^4
o-xylene	144	6.47×10^2
p-xylenes	138	8.75×10^2
Styrene	145	5.92×10^2
Toluene	111	2.89×10^2
Trichloroethylene	87.2	7.69×10^3
Toluene-2,4-diisocyanate	115–120	1.08

flammable and explosive, and some are toxic or even highly toxic; (4) most of them are insoluble or sparingly soluble in water, but easily soluble in organic solvents; (5) most of them are colorless with many having pungent or special odors; (6) low melting point, easy to decompose, and volatile, can participate in atmospheric photochemical reaction and thereby produce photochemical smog under irradiation with sunlight.

Hazards

The harm to human health and living environment is mainly reflected in the following aspects:

1. Most VOCs are malodorous gases, with pungent odors or odors, which can cause people's sensory discomfort and seriously reduce people's quality of life. Malodorous gas refers to all gas substances that stimulate the olfactory organs and cause people's dissatisfaction.
2. The special smell and the characteristics of penetration, volatilization, and fat solubility can cause many uncomfortable symptoms in the human body. It also has toxic, irritating, teratogenic, and carcinogenic effects, especially benzene, toluene, xylene, and formaldehyde are the most harmful to human health. Long-term exposure to VOCs can cause people to suffer from anemia and leukemia. In addition, VOCs can also cause diseases of the respiratory tract, kidneys, lungs, liver, nervous system, digestive system, and hematopoietic system. As the concentration of VOCs increases, the human body will experience symptoms such as nausea, headache, convulsions, and coma. Existing guidance for Environment Agency Inspectors is given in a series of Process Guidance Notes which divide VOCs into three categories (Marlowe et al. 1995): extremely hazardous to health, such as benzene, vinyl chloride, and 1,2-dichloroethane; class A compounds: those organic compounds that may cause significant harm to the environment including acetaldehyde, aniline, benzyl chloride, carbon tetrachloride, CFCs, ethyl acrylate, halons, maleic anhydride, 1,1,1-trichloroethane, trichloroethylene, trichlorotoluene; and class B compounds: organic compounds of lower environmental impact than class A compounds.
3. Most VOCs are flammable at fairly low concentrations, such as benzene, toluene, acetone, dimethylamine, and thiohydrocarbons. When the emission concentration of these substances is high and they encounter static sparks or other sources of ignition, they may easily cause fires. In recent years, fires and explosions caused by VOCs have occurred from time to time, especially in petrochemical companies.
4. Some VOCs can destroy the ozone layer, such as hydrochlorofluorocarbons (HCFC) (Solomon et al. 1992). When it is exposed to ultraviolet radiation from the sun, it can undergo a photochemical reaction to produce chlorine atoms that catalytically destroy ozone in the ozone layer. The decrease in the amount of

ozone and the destruction of the ozone layer increase the amount of ultraviolet radiation reaching the ground. Ultraviolet rays are harmful to human skin, eyes, and immune system.

5. Most VOCs are photochemically reactive (Yuan et al. 2012). Under sunlight, VOCs will chemically react with NO_x in the atmosphere to form secondary pollutants (such as ozone, etc.) or strong chemically active intermediate products (such as free radicals, etc.). Increasing the surface concentration of smog and ozone will endanger people's lives. It will also endanger the growth of crops and even cause the plant death. The haze caused by photochemical reaction (Song et al. 2019), in addition to reducing visibility, the generated ozone, peroxyacetyl nitrate (PAN), peroxybenzoyl nitrate (PBN), aldehydes, and other substances can irritate people's eyes and respiratory system, endangering people's health. The first photochemical smog episode was recorded in Los Angeles in 1943. Tokyo from 1970 to 1974 (Fukuoka 1975) and other cities have seen major photochemical smog pollution incidents.

Typical Indoor VOCs

Benzene

General Description

Benzene (CAS Registry Number 71-43-2; C₆H₆; molecular weight 78.1 g/mol) is an aromatic compound with a single six-member unsaturated carbon ring. It is a clear, colorless, volatile, highly flammable liquid with a characteristic odor and a density of 874 kg/m³ at 25 °C (HEI 2007).

At 1 atmosphere of pressure, benzene has a melting point of 5.5 °C, a relatively low boiling point of 80.1 °C and a high vapor pressure (12.7 kPa at 25 °C), causing it to evaporate rapidly at room temperature. It is slightly soluble in water (1.78 g/l at 25 °C) and is miscible with most organic solvents (WHO 2000). Benzene is soluble in lipids, has a log K octanol-water partition coefficient of 2.14 (HEI 2007) and a log K soil organic carbon-water partition coefficient of 1.85 at 25 °C. Its Henry's Law constant is 550 Pa.m³/mol at 25 °C, implying that it will have a tendency to volatilize into the atmosphere from surface water (IEH 1999).

Benzene in air exists predominantly in the vapor phase, with residence times varying between 1 day and 2 weeks, depending on the environment, the climate, and the concentration of other pollutants. Reaction with hydroxyl radicals is the most important means of degradation, with a rate constant of 1.2×10^{-12} cm³ molecule⁻¹ s⁻¹ at 298 K (IUPAC 2008a).

Other oxidants such as ozone and nitrate radicals can also contribute to a lesser extent to the degradation of benzene indoors, with rate constants of 2.7×10^{-17} cm³ molecule⁻¹ s⁻¹ at 298 K for nitrate radicals (IUPAC 2008b) and 1.7×10^{-22} cm³ molecule⁻¹ s⁻¹ at 298 K for ozone (WHO 2000, 2010; HEI 1999, 2007; IUPAC 2008c; NIST 2005).

Indoor Sources

Benzene in the family home mainly comes from the large amount of chemical raw materials used in building decoration, such as coatings, fillers, and various organic solvents. It can also infiltrate from attached garages where it has evaporated from stored vehicles such as cars or power lawn equipment. They all contain a large amount of organic compounds, which volatilize indoors after decoration. It is mainly contained in the following decorative materials: (1) Paint. Benzene which is an indispensable solvent in paint can volatilize from paint. Some low-grade and counterfeit paints are an important cause of excessive benzene content in indoor air; (2) Additives in various paints and coatings. The main components of additives are benzene, toluene, and xylene; (3) Various adhesives. In particular, solvent-based adhesives still have a certain market in the decoration industry, and most of the solvents used are toluene, which contains more than 30% benzene, but because of price, solubility, adhesiveness, and other reasons, it is still used by some companies. The sofas purchased by some households releases a large amount of benzene, mainly due to the use of adhesives with high benzene content in the production; (4) Waterproof materials. Waterproof materials contain a large amount of adhesives, and formaldehyde, benzene, etc. are the major components of adhesives (WHO 2010). Another major source of benzene is attached garages and vaporization from cars and household equipment like lawn mowers.

Hazards

It is generally believed that the origin of benzene's toxicity is caused by its metabolites, which means that benzene must be metabolized before it can cause harm to life (McHale et al. 2012). Benzene can be metabolized in the liver and bone marrow. The bone marrow is the formation site of red blood cells, white blood cells, and platelets. Therefore, benzene entering the body can form blood-toxic metabolites in the hematopoietic tissue itself. Long-term exposure to benzene can cause bone marrow and genetic damage. The blood test can find leukopenia, thrombocytopenia, pancytopenia, and aplastic anemia, and even leukemia. Someone investigated the health status of workers exposed to low-concentration benzene. The results showed that although the number of white blood cells in peripheral blood was within the normal range, it was significantly lower than that of the control group. In the benzene exposure group, the lymphocyte micronucleus rate of the observation population in the benzene production workshop was significantly different from that of the control group; with the increase of the benzene concentration in the work environment, the number of white blood cells decreased, and the lymphocyte micronucleus rate increased (EPA 2002). All these indicate that low concentrations of benzene are harmful to the health of the working population, and special attention should be paid to the damage to human genetic material. Inhalation of more than 4000 ppm of benzene for a short period of time not only has mucosal and lung irritation but also has inhibitory effects on the central nervous system. At the same time, it will be accompanied by headache, vomiting, gait instability, coma, cramps, and arrhythmia. Inhalation of more than 14,000 ppm of benzene will cause immediate death (WHO 2010; IARC 2012).

Guidelines

Guidelines on exposure levels are needed for indoor air, because indoor air is a significant source of benzene exposure and inhalation is the main pathway of human exposure to benzene. Benzene is present in both outdoor and indoor air. However, indoor concentrations are generally higher than concentrations in outdoor air owing to the infiltration of benzene present in outdoor air and to the existence of many other indoor sources. Typically, indoor concentrations are below the lowest levels showing evidence of adverse health effects. Considering benzene is present indoors and taking into account personal exposure patterns, which are predominantly indoors, indoor guidelines for exposure are needed.

Benzene is a genotoxic carcinogen in humans and no safe level of exposure can be recommended. The risk of toxicity from inhaled benzene would be the same whether the exposure was indoors or outdoors. Thus, there is no reason that the guidelines for indoor air should differ from ambient air guidelines (WHO 2010).

Previous WHO benzene guidelines for ambient air were calculated using the Plioform cohort studies (Crump 1994). Since these studies, new data have become available, such as those on the large Chinese workers cohort (Hayes et al. 1997). However, the unit risks and risk assessment analysis based on these data are still not available. Hence, we recommend continuing to use the same unit risk factors calculated from the Plioform cohort studies. The geometric mean of the range of the estimates of the excess lifetime risk of leukemia at an air concentration of 1 µg/m³ is 6×10^{-6} . The concentrations of airborne benzene associated with an excess lifetime risk of 1/10,000, 1/100,000, and 1/1000,000 are 17, 1.7, and 0.17 µg/m³, respectively.

As noted above, there is no known exposure threshold for the risks of benzene exposure. Therefore, from a practical standpoint, it is expedient to reduce indoor exposure levels to as low as possible. This approach will require reducing or eliminating human activities that release benzene, such as smoking tobacco, using solvents for hobbies or cleaning, or using building materials that off-gas benzene. Adequate ventilation methods will depend on the building location. In modern buildings located near heavy traffic or other major outdoor sources of benzene, inlets for fresh air should be located at the least polluted side of the building (WHO 2010).

Toluene

General Description

Toluene (CAS Registry Number 108–88–3; C₇H₈; molecular weight 92.1 g/mol) is a substituted aromatic hydrocarbon. It is a colorless, water-insoluble liquid with the smell associated with paint thinners. It is a monosubstituted benzene derivative, consisting of a methyl group (CH₃) attached to the phenyl group. As such, its systematic IUPAC name is methylbenzene. Toluene is predominantly used as an industrial feedstock and a solvent. It is also a common component of gasoline.

As the solvent in some types of paint thinner, permanent markers, contact cement, and certain types of glue, toluene is sometimes used as a recreational inhalant and has the potential of causing severe neurological harm (Streicher et al. 1981).

Indoor Sources

Exposure to toluene is generally via indoor air (Héroux et al. 2008). Indoor sources of toluene include building materials (e.g., solvent- and water-based adhesives, floor coverings, paint, chipboard), consumer and automotive products (e.g., cleaners, polishes, adhesive products, oils, greases, lubricants). The amount of toluene produced by smoking in the indoor environment is also considerable. According to statistics from the US EPA, the toluene content in mainstream cigarettes of unfiltered cigarettes is about ~100–200 µg, and the ratio of toluene concentration inside/mainstream cigarettes is 1.3 (EPA 1992). In attached garages, toluene generated by running engines or by product storage may also infiltrate into the indoor environment.

Hazards

Exposure to toluene has been shown to cause eye, nose, and throat irritation as well as headaches, dizziness, and feelings of intoxication. It has also been linked to neurological effects including poorer performances in tests of short-term memory, attention and concentration, visual scanning, perceptual motor speeds, and finger dexterity in the completion of physical tasks as well as negative effects on color vision and auditory capacity (Health Canada 2011).

In controlled exposure studies, healthy adults exposed to toluene for 4.5–7 h reported increased eye, nose, and throat irritation as well as headaches, dizziness, or feelings of intoxication at concentrations ranging from 189 to 566 mg/m³ (Andersen et al. 1983; Baelum et al. 1990), but not at 38 or 151 mg/m³ (Andersen et al. 1983).

Several occupational studies have reported effects of toluene on neurobehavioral endpoints (tests of manual dexterity, visual competency, and attention span) at concentrations ranging from 264 to 441 mg/m³ (Foo et al. 1988, 1990; Boey et al. 1997; Eller et al. 1999; Kang et al. 2005). No effects were seen at concentrations ranging from 75 to 113 mg/m³ (Kang et al. 2005), nor was any difference seen between exposed workers (98 mg/m³) and a reference group (11 mg/m³) (Seeber et al. 2004, 2005).

After toluene enters the body, about 48% is metabolized in the body and finally excreted from the body through the liver, brain, lungs, and kidneys. In this process, it will harm the nervous system. Volunteer experiments have shown that when the concentration of toluene in the blood reaches 1250 mg/m³, the short-term memory ability, attention span, and sensorimotor speed of the contacts are significantly reduced.

Guidelines

The lowest-observed-adverse-effect level for effects on the central nervous system from occupational studies is approximately 332 mg/m³ (88 ppm). A guideline value of 0.26 mg/m³ is established from these data adjusting for continuous exposure

(dividing by a factor of 4.2) and dividing by an uncertainty factor of 300 (10 for interindividual variation, 10 for use of a lowest-observed-adverse-effect level rather than a no-observed-adverse-effect level, and an additional factor of 3, given the potential effects on the developing CNS). This guideline value should be applied as a weekly average. This guideline value should also be protective for reproductive effects (spontaneous abortions). The air quality guideline could also be based on the odor threshold. In this case, the peak concentrations of toluene in air should be kept below the odor detection threshold level of 1 mg/m³ as a 30 min average (WHO 2000).

Xylene

General Description

Xylene (CAS Registry Number: 1330-20-7; C₈H₁₀; molecular weight: 106.16 g/mol) is any one of three isomers of dimethylbenzene, or a combination thereof. They are all colorless, flammable, slightly greasy liquids. They are of great industrial value (Fabri et al. 2000). The mixture is referred to as both xylene and, more precisely, xylenes. Mixed xylenes refers to a mixture of the xylenes plus ethylbenzene. Mixed xylenes are used widely as gasoline additives; as solvents in manufacturing and laboratory processes; in glues, adhesives, printing inks, paint thinners, and sealants; and as carrier solvents for delivery of some pesticides. The four compounds have identical empirical formulas C₈H₁₀. Typically, the four compounds are produced together by various catalytic reforming and pyrolysis methods (Cannella 2000).

The physical properties of the isomers of xylene differ slightly. The melting point ranges from –47.87 °C (m-xylene) to 13.26 °C (p-xylene). The para isomer's melting point is much higher because it packs more readily in its crystal structure. The boiling point for each isomer is around 140 °C. The density of each isomer is around 0.87 g/mL and thus is less dense than water. The odor of xylene is detectable at concentrations as low as 0.08–3.7 ppm and can be tasted in water at 0.53–1.8 ppm (Kandyala et al. 2010).

Indoor Sources

Indoor air sources of xylene include building and consumer products, such as adhesives and paints, and also tobacco smoke (ATSDR 2007). It can also infiltrate from attached garages.

Hazards

Xylene can be absorbed through the respiratory tract, skin, and digestive tract. Its vapor enters the human body through the respiratory tract, and part of it is discharged through the respiratory tract. The absorbed xylene is distributed in the body mostly in adipose tissue and adrenal glands, followed by bone marrow, brain, blood, kidneys, and liver. The toxicity of the three isomers of industrial xylene is slightly different, and all of them belong in the low-toxicity category. According to reports, three workers inhaled xylene with a concentration of 1000 ppm. One died 18.5 h

later. Autopsy showed pulmonary congestion and cerebral hemorrhage. The other two workers lost consciousness for 19–24 h, accompanied by memory loss and kidney functional changes (NIOSH 1978). In addition, inhalation of high concentrations of xylene can cause loss of appetite, nausea, vomiting, and abdominal pain, and sometimes can cause reversible liver and kidney damage. At the same time, xylene is also an anesthetic, and long-term exposure can cause nervous system dysfunction (CDC 2017).

Guidelines

According to OSHA, the permissible airborne exposure limit (PEL) is 100 ppm averaged over an 8-hour work shift. According to NIOSH, the recommended airborne exposure limit (REL) is 100 ppm averaged over a 10-hour work shift and 150 ppm, not to be exceeded during any 15-minute work period (EPA 2012).

Measurement Methods

VOCs measurement methods mainly include real-time monitoring and integrated sampling/analysis. These methods usually include sampling, pre-concentration, separation, and detection of several processes. The sampling methods of VOCs in the air can be divided into direct sampling, powered sampling, and passive sampling. Sample pretreatment methods include solvent analysis method, solid phase micro-extraction method, low temperature pre-concentration-thermal analysis method, etc.

Several real-time monitors for VOCs have been developed, and these utilize continuous detectors such as a photo-ionization detector (PID) or semiconductor sensor. These monitors can determine the total VOC (TVOC) concentration within approximately several seconds. However, their response depends on the nature of the organic constituents. Furthermore, proton transfer reaction-mass spectrometry (PTR/MS) has drawn great deal of attention for near real-time monitoring. These techniques allow immediate and continuous monitoring of the variation in TVOC concentration with time. PTR/MS can determine individual compound if the compounds have different masses and can produce ions via proton transfer reactions.

In integrated analysis, VOCs are collected into a sorbent tube with an air pump and analyzed using methods such as gas chromatography/mass spectrometry (GC/MS), gas chromatography/flame ionization detection (GC/FID), or high-performance liquid chromatography (HPLC). This method provides qualitative and quantitative information for each VOC in the collected air sample. Integrated analysis is recommended by some organizations for official VOC measurements. However, air samples have to be taken over at least half an hour and up to a few hours. Therefore, only time-averaged information can be obtained. Although integrated analysis is more accurate in qualitative and quantitative, and has high sensitivity in analysis and testing, the monitoring frequency and timeliness of monitoring results are obviously insufficient, and they cannot reflect the changes in gas concentration in time. The transport of the sample to the analytical lab may

result in sample loss and cross-contamination. The test process is tedious and time-consuming, the number of test samples is limited, and the test cost is high. Common methods for integrated analysis include gas chromatography and high-performance liquid chromatography.

Gas Chromatography

The most common technique used to detect, identify, and quantitate VOC is gas chromatography with flame ionization (FID), electron capture (ECD), or mass spectrometry (GC-MS) detection. Selection of a detection method requires consideration of various analytical parameters and regulatory requirements. Common stand-alone GC detectors used in VOC analysis include flame ionization detectors (FIDs), thermal conductivity detectors (TCDs), thermionic detectors (TIDs), electron capture detectors (ECDs), and atomic emission detectors (AEDs). The details of the detector including detectable compound and detection limit are listed in Table 3 (Dewulf et al. 2002).

High-Performance Liquid Chromatography

High-performance liquid chromatography (HPLC) is also widely used for separation, identification, and quantification of each component in a mixture. This technique is based on the logic of advancing a pressurized liquid solvent as well as a solid adsorbent at stationary phase at high pressure. Off-line VOCs are sampled using active air sampling through a 2,4-dinitrophenylhydrazine (DNPH)-coated solid sorbent cartridge for carbonyls, and XAD-2 (naphthyl isocyanate) sorbent tube, Tenax, or activated charcoal for a broader suite of polar VOCs. After that, the VOCs are analyzed by high-performance liquid chromatography (HPLC) (Salameh et al. 2018).

Emission Models for VOCs

Characteristic Emission Parameters

Three characteristic emission parameters are used to predict material emissions by virtue of physical models (Little et al. 1994). They are: the initial emittable concentration (C_0), the diffusion coefficient of the target VOC in material (D_m), and the material/air partition coefficient (K). These three key parameters are the physical property parameters, which are dependent on the species of pollutants and the test materials, as well as external environmental factors, such as temperature and relative humidity (Xiong et al. 2016).

Table 3 The details of detectors

Detector	Detectable compound	Detection limit
General-purpose detectors		
Flame ionization detector (FID)	Organic compounds (other than formaldehyde and formic acid)	0.1 ppm (0.1 ng)
Thermal conductivity detector (TCD)	All compounds other than the carrier gas	10 ppm (10 ng)
Barrier discharge ionization detector (BID)	All compounds other than He and Ne	0.05 ppm (0.05 ng)
Selective, high-sensitivity detectors		
Electron capture detector (ECD)	Organic halogen compounds Organic metal compounds	0.1 ppb (0.1 pg)
Flame thermionic detector (FTD)	Organic nitrogen compounds Inorganic and organic phosphorus compounds	1 ppb (1 pg) 0.1 ppb (0.1 pg)
Flame photometric detector (FPD)	Inorganic and organic sulfur compounds Inorganic and organic phosphorus compounds Organic tin compounds	10 ppb (10 pg)
Sulfur chemiluminescence detector (SCD)	Inorganic and organic sulfur compounds	1 ppb(0.1 pg)

The detection limits are approximations. Actual values will vary depending on the compound structure and analytical conditions

To illustrate the influence of these parameters, Guo et al. (2020) performed three sets of simulations to determine the influence of these parameters on the VOCs concentrations from multiple dry building materials. In each experiment, both size and emission surface area were kept constant for the two types of building materials under investigation, but with varying key parameters. Figure 1 shows the results from the simulations for single and multiple building materials. According to Fig. 1, higher C_0 and D_m lead to increased VOCs concentrations in the air, and higher K gives lowered VOCs concentrations. When there were more than one type of dry building materials existing, the change of VOCs concentrations in the air would be closer to that of the dry building material with higher C_0 , higher D_m , and lower K , especially at later stages.

In addition, convective mass-transfer coefficient (h) and air exchange rate (N) also affect the VOCs emissions. It was found that h only had significant influences at the start of the VOCs emission process, but at later stages, the influence of this parameter can be neglected. Lower h is associated with shorter time to reach steady state. When the magnitude of h was less than 10^{-4} , the VOCs emission would reach steady state quickly as shown in Fig. 2. Different values of N affect the whole VOCs emission from building materials (Fig. 3). At the later stages of VOCs emission process, it was observed that the VOCs concentration in the air was linearly correlated with N .

Model for Prediction of Indoor VOC Concentration

Emission source models conventionally express the emission rate or emission factor as a function of time. The emission rate of the entire source, $R(t)$ (mg/h), is defined as the total amount of VOC or TVOC emitted per unit of time from the entire source. The emission factor (emission rate per unit), $E(t)$, is defined as follows (Zhang et al. 1997):

1. For a surface source with a defined area, $E(t)$, is the amount of VOC or TVOC emitted per unit time and per unit surface area of the source. Therefore,

$$R(t) = A \times E(t) \quad (1)$$

where A is area of the emitting surfaces, m^2 .

2. For a non-surface source or a source whose surface area cannot be easily measured or calculated (e.g., when an office workstation module is tested in a full-scale chamber), $E(t)$ is the amount of emissions per unit time and per unit source. In this case,

$$R(t) = n \times E(t) \quad (2)$$

where n is number of units of the source.

Emission source models for building materials may be divided into two categories: statistical models and mass transfer models. The following subsections will

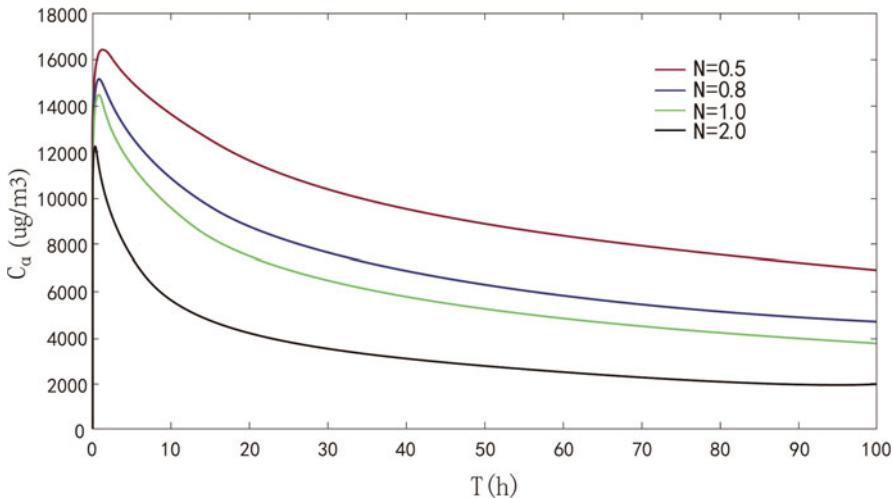

Fig. 3 Comparison of VOC concentrations with varying air exchange rate (N). (Figure taken from Guo et al. (2020))

introduce some common statistical and mass transfer models. In the following part, what we call emission rate is the emission factor (emission rate per unit), $E(t)$ ($\text{mg}/(\text{m}^2 \text{ h})$).

Statistical Models

These models are proposed/derived based on the observation and statistical analysis of emission data obtained from environmental chamber testing. The coefficients (or parameters) of these models are determined entirely by regression analysis of emission data obtained from chamber tests.

Constant Emission Factor Model

$$E(t) = \text{constant} \quad (3)$$

Chang and Krebs (1992) showed that this model described the emission of *p*-dichlorobenzene from moth cakes. In practice, it may also be used to approximate the emission rates from building materials that have nearly constant emission rates for a given period of time. For example, emission tests are often conducted by taking a single air sample after the test specimen is placed in a dynamic (i.e., ventilated) chamber for a fixed period of time (e.g., 24 h or a week) for the purpose of comparing emission strength of different products (Levin and Hodgson 1996). These test data may be used for evaluating the exposure of occupants to VOCs in a worst case scenario, assuming that the emission rates of these products are approximately constant.

First-Order Decay Model

$$E(t) = E(0) \exp(-k t) \quad (4)$$

where $E(0)$ is the initial emission rate, $\text{mg}/(\text{m}^2 \text{ h})$; k is first-order decay constant (or exponential decay constant), l/h ; and t is the emission time, h .

It is called a first-order decay model, because it can be derived from $d[E(t)]/dt = -k E(t)$ with the initial conditions: $E(t) = E(0)$, at $t = 0$. Both $E(0)$ and k are determined from the concentration data, $C(t)$, obtained in a dynamic chamber test. Several different calculation procedures are available for determining the model coefficients (ASTM 1990; Zhang et al. 1997).

A single first-order decay model is generally adequate for analyzing (representing) the VOC emission data from chamber test for a given time period. This time period is longer for a dry material or a “wet” material that is sufficiently dried than a “wet” material (e.g., from a week to 1 month for dry materials vs. 12 h for the initial emission period of “wet” materials). The validity of the model to predict the emission rate beyond the testing period has to be justified by some longer-term emission testing data for the same type of materials considered.

Double Exponential Model

$$E(t) = E_{01} \exp(-k_1 t) + E_{02} \exp(-k_2 t) \quad (5)$$

where E_{01} is the initial emission factor for the first (fast) decaying period, $\text{mg}/(\text{m}^2 \text{ h})$; and E_{02} is the initial emission factor for the second (slow) decaying period, $\text{mg}/(\text{m}^2 \text{ h})$.

With this model, the total initial emission factor is $E_{01} + E_{02}$, and the total emittable mass can be calculated by $E_{01}/k_1 + E_{02}/k_2$.

This model is adequate for representing chamber test data for both “wet” and dry individual materials. The coefficients of the model are determined by nonlinear regression analysis, but several procedures have been used by different researchers (Colombo et al. 1991; Chang and Guo 1992).

Second-Order Decay Model

$$E(t) = E(0)/[1 + k_2 E(0)t] \quad (6)$$

where k_2 is second-order decay constant, m^2/mg .

It is called a second-order decay model, because it is derived from $d[E(t)]/dt = k_2 E^2$ with the initial condition: $E(t) = E(0)$ at $t = 0$. It gives a very high initial emission rate followed by low and long-lasting emissions. Tichenor and Guo (1991) showed that this model well described the emissions from wood finishing materials. Clausen et al. (1993) represented k_2 as k_{21}/L to account for the effect of the thickness of a vinyl flooring (k_{21} is the second-order decay constant for unit thickness, L is the thickness of the source) and showed a good fit between the model and the test data. However, the model coefficients were not reproducible based on the results of three replicate

tests for the same material. The authors suggested that further validation of the model with better characterized data was necessary.

The *n*th-Order Decay Model

$$E(t) = E(0) / \left[1 + (n - 1) k_n E(0)^{(n-1)} t \right]^{1/(n-1)}, n > 1 \quad (7)$$

where k_n is the *n*th-order decay constant.

The *n*th-order decay model is a generalization of the second-order decay model. The additional parameter, *n*, provides a slight improvement in fitting the emission data (Tichenor et al. 1991).

Mass Transfer Models

These models are derived partially or entirely by applying the mass transfer theory to the emission processes. The coefficients (or parameters) in these models have more distinct physical meanings than those of statistical models. The model coefficients may be determined by regression analysis of data from the dynamic emission testing and/or experiments that are independent of the environmental chamber tests.

Interfacial Mass Transfer Models

The interfacial mass transfer across the boundary layer was described by Kays and Crawford (1981):

$$r(t) = K[C_s(t) - C(t)] \quad (8)$$

where r is rate of interfacial mass transfer, mg/(m²h); C_s air-phase concentrations at the interface of the surface, mg/m³; C is air-phase concentrations in the “free stream” over the surface, mg/m³; K is mass transfer coefficient, m/h; and t is the emission time, h.

Equation (8) states that the interfacial mass transfer rate (i.e., the emission factor in this case) is proportional to the concentration differential between the emitting surface and the ambient air. This principle has been applied successfully to model the initial period of the VOC emissions from “wet” materials, which are mainly controlled by the evaporative process.

Different assumptions about $C_s(t)$ have led to different interfacial mass transfer models as described below.

1. Constant Vapor Pressure Model:

$$E(t) = K[C_v - C(t)] \quad (9)$$

where C_v is VOC concentration in air corresponding to the saturated vapor pressure at the temperature of testing, mg/m³.

In this model, the concentration on the material surface is assumed to be constant and equal to the saturated vapor concentration in air. Chang and Krebs (1992) used this model to describe the emission of para-dichlorobenzene from a solid moth

repellent. They assumed that C_v was equal to the measured headspace concentration, while K was determined by regression analysis on the VOC concentration data from dynamic chamber testing. The model is only applicable to evaporative sources with a constant vapor pressure.

2. VB (Vapor Pressure and Boundary Layer) Model:

$$E(t) = K[C_v M(t)/Mo - C(t)] \quad (10)$$

where $M(t)$ is amount of VOC mass in the source, mg/m²; and total emittable VOC mass in the source, mg/m².

This model assumes that $C(t)$ is proportional to the VOC amount remained in the source (Guo and Tichenor 1992). When the VB model is applied to a well-mixed chamber space that has a constant air change rate and zero concentration at time zero, this model results in the following equation for the concentrations in the chamber:

$$C(t) = [L C_v K/(r_1 - r_2)][\exp(r_1 t) - \exp(r_2 t)] \quad (11)$$

where L is the loading ratio, m²/m³; N is air exchange rate, h⁻¹; and $r_{1,2} = \{[-(N + L K + C_v K/Mo) + [(N + L K + C_v K/Mo)^2 - 4 N C_v K/Mo]^{1/2}\}/2$.

The concentration of the most abundant VOC measured in the headspace analysis was used as C_v . Mo was the total amount of VOC emitted during the dynamic chamber testing. K was determined by fitting the model to the concentration data from the dynamic chamber testing (K was expressed as D_f/δ , where D_f is average diffusivity based on the most abundant compound, and δ is apparent laminar boundary layer thickness). The model was found to predict well the initial period (up to first 20 hours) of TVOC emissions from wood stains, polyurethane varnish, and wax.

3. VBX Model: VB Model for the Emissions of Individual VOCs

To quantify emission rate of individual VOCs from paints, Guo et al. (1998) developed the VB model to predict the emission rates of each individual compound:

$$E_i(t) = K_i(Cp_i - C_i) \quad (12)$$

where $E_i(t)$ is the emission factor of VOC_i, mg/m²; K_i is the mass transfer coefficient for VOC_i, m/h; Cp_i is the partial pressure for VOC_i expressed in mass concentration unit, mg/m³, $Cp_i = Cv_i x_i$, x_i is the molar fraction of VOC_i remaining in the solvent, dimensionless; $x_i = \Pi_i/\Pi$, and $\Pi = \sum \Pi_i$; Cv_i is the vapor pressure for pure VOC_i expressed in mass concentration unit, mg/m³; C_i is the vapor pressure for VOC_i expressed in concentration in the air, mg/m³; Π_i is the molar amount for VOC_i remaining in the source, moles/m²; and Π is the molar amount for TVOC remaining in the source, moles/m².

To simplify the implementation of the model, Guo et al. (1996) also proposed to use the original VB model instead of the summation for calculating the molar amount for TVOC and that the average molecular weight of TVOC was approximated by that of the compound with the highest vapor pressure in the mixture. The method was evaluated by experimental data from a small chamber and test houses

for “wet” materials including wood stain, polyurethane wood finish, and floor wax, and was found to be suitable for predicting the emissions from these materials during the initial period (up to first 20 h of testing).

4. A Semiempirical Model for Evaporative Sources

$$E(t) = K[C_s(0) \exp(-k_s t) - C(t)] \quad (13)$$

where $C_s(0)$ is the initial VOC concentration on the emitting surface, mg/m²; and k_s is the first-order constant for the VOC concentration on the surface, l/h.

This model assumes that $C_s(t)$ decreases exponentially with time. When applied to a well-mixed chamber space that has a constant air change rate, this model results in the following equation for the concentrations in the chamber:

$$C(t) = a[\exp(-b t) - \exp(-c t)] \quad (14)$$

where $a = L K C_s(0)/(L K + N - k_s)$; $b = k_s$; and $c = L K + N$.

Zhang et al. (1996) used this model to describe the initial period (first 12 h) of VOC emissions from wood stains applied on oak wood substrates. Nonlinear regression analysis was used to determine a , b , and c , and then solve the algebraic equations for K , $C_s(0)$, and k_s . The value of $C_s(0)$ was found to be significantly less than the saturation (equilibrium) concentration measured in the headspace analysis. This difference was attributed to the time delay (about 10–15 min) between applying the material onto the substrate and placing the specimen in the dynamic testing chamber.

The above interfacial mass transfer models are only applicable to evaporative sources such as during the initial period of emissions from “wet” building materials. In practice, the initial emission period is always followed by a second period during which the internal diffusion becomes the controlling process. A transition period is also expected between the two periods. Therefore, the surface concentration $C_s(t)$, in general, needs to be solved in conjunction with equation for the internal diffusion process within materials. This area needs further studies.

Internal Diffusion Mass Transfer Models

Considering that most interior building materials have a much larger surface area than their thickness, we limited our discussion to 1-D models:

For nonporous solid materials, Fick’s law may be used:

$$\rho_s A_s \frac{\partial C}{\partial t} = \rho_s A_s D_m \frac{\partial^2 C}{\partial x^2} + \rho_s A_s r_s \quad (15)$$

where A_s is the area of the surface, m²; C is the concentration in the solid, mg-species/mg-solid; D_m is the diffusion coefficient in the solid, m²/h; r_s is the local generation rate, mg-species/mg-solid; and ρ_s density of the bulk solid, mg/m³.

Assuming a zero local generation rate and a uniform initial VOC concentration within the material, Little et al. (1994) used the above model to describe the VOC emissions from carpets. The diffusion coefficients were estimated to be of the order

of 10^{-14} to $10^{-11} \text{ m}^2/\text{s}$, and the model was found to reasonably well fit the emission data over a period of about 150 h.

Christiansson et al. (1993) derived the following simplified model based on the above Fick's law:

$$E(t) = C_0(D_m/\pi t)^{0.5}, \text{ when } M(t)/M_0 \geq 50\% \quad (16)$$

$$E(t) = 2 C_0 D_m/z \exp(D_m \pi t/4z^2), \text{ when } M(t)/M_0 < 50\% \quad (17)$$

where C_0 is the initial pollutant concentration in the source, mg/m^3 ; D_m is the diffusivity of the pollutant in the source, m^2/h ; $\pi = 3.14159$; $M(t)$ is the amount of pollutant remaining in the source, mg/m^2 ; M_0 is the initial amount of pollutant remaining in the source, mg/m^2 ; and z is the thickness of the source.

Their results show that the above model described successfully the VOC emissions from PVC flooring materials tested.

For porous solid materials, diffusion within the solid can be attributed to three types: (1) diffusion in the air-phase, which can be characterized by an effective diffusion coefficient, D_e , in analogous to the Fick's law; (2) diffusion along the surfaces of the solid phase (surface diffusion), in which the diffusion coefficient is usually dependent on the concentration of the sorbed phase on the surfaces; and (3) diffusion through the solid. The partial differential equation for describing the diffusion within porous materials is much more complicated. For example, for sheet-like porous solids, assuming (a) the sorbed-phase concentration remains in equilibrium with the porous air-phase concentration, and (b) the surface and solid-phase diffusions are negligible, we have (Axley 1995):

$$\rho A_s e \frac{\partial C}{\partial t} + \rho_s A_s \frac{\partial C}{\partial t} = \rho_s A_s D_e \frac{\partial^2 C}{\partial x^2} + \rho_s A_s r_s \quad (18)$$

where D_e is the effective diffusion coefficient in the porous gas-phase, m^2/s ; ρ is the gas-phase density, $\text{g-air}/\text{m}^3$; ρ_s is the density of the bulk porous solid, g/m^3 ; C is the gas-phase concentration, g-species/g-air ; and C_s is the sorbed-phase concentration, $\text{g-species/g-bulk solid}$.

The above equation simply states that the total accumulation of the compounds (gas-phase plus the sorbed-phase) in a control volume is equal to that transferred by porous gas-phase diffusion and that by the distributed generation.

While the mass transfer equations are readily available, their applications to building materials are hindered by the lack of data on the diffusion coefficients for various materials. Methods for experimentally determining the diffusion coefficients are therefore necessary.

Other Mass Transfer Related Models

1. A Model for VOCs Emissions from Manufactured Wood Products:

$$E(t) = E(0) - K C \quad (19)$$

where K is the proportionality coefficient.

This model assumes that the source has a maximum (constant) emission factor when the ambient concentration is zero and decreases linearly with the increase of the concentration in air (Hoetjer and Koerts 1986; Mathews et al. 1987). This model is essentially equivalent to the constant vapor pressure model if one assumes that the surface concentration is constant and equal to $E(0)/K$.

2. A Model for Pollutant Emissions from Treated Wood Products:

$$E(t) = E(0)[1 - C(t)/C_v][M(t)/M_0] \quad (20)$$

where C_v is the saturated vapor concentration of the pollutant in air, mg/m³; $M(t)$ is the amount of pollutant remaining in the source at time t , mg/m²; and M_0 is the total emittable amount of pollutant in the source, mg/m².

This model assumes that the emission factor at any given time is proportional to the amount of pollutant remaining in the source and the difference between the pollutant concentration in air and the saturation vapor concentration. Jaycock et al. (1995) showed that this model could describe the emissions of biocides from isothiazolone-treated wood products.

In summary, statistical models are available for analyzing and reporting emission test results. Since these models are derived from relatively short-term test data (mostly up to 1-week period), their validity for predicting the emissions beyond the test period has yet to be evaluated with some long-term emission test data.

The trend in predicting the rates of VOC emissions from building materials/furnishings is to use mechanistic models that are based on fundamental mass transfer theory (i.e., the so-called mass transfer models). For “wet” coating materials applied on a realistic substrate (such as wood stains on an oak wood, paints on a gypsum board, etc.), the existing interfacial mass transfer model for evaporative sources appears to be adequate only for the initial emission period that is dominated by evaporation (about first 12 h). A more complete model that describes both the evaporative mass transfer and the internal diffusion (that becomes the controlling factor for the emission process after the initial emission period) is needed for “wet” coating materials. For “wet” installation materials (such as adhesives, caulk, and sealants), effective mass transfer models are yet to be developed. For dry materials (such as carpets, vinyl floorings, wood-based panels, gypsum wallboards, etc.), the 1-D internal diffusion mass transfer models have shown promising results, but comprehensive evaluations are necessary. The applications of mass transfer models are also hindered by the lack of data on the model parameters such as the in-material diffusion coefficients of VOCs for various building materials.

Therefore, there is a need to develop mass transfer models that can better describe the emission process and thus for predicting the emission rates beyond the standard testing period and testing conditions. Models for material systems (assemblies) and data for validating such models are especially needed.

Influential Factors of VOCs Emission

As the emission mechanism of VOCs is the same as formaldehyde (a high volatility organic compound, VVOC), the impact of influencing factors (temperature and relative humidity) on VOCs emission is similar with the impact on formaldehyde as described in the previous chapter. The emission characteristic parameters C_0 and D_m are functions of temperature (T) and relative humidity (RH). The equations are as follows (Xiong et al. 2016):

$$C_0 = \frac{C_1}{\sqrt{T}} \exp \left(C_2 \cdot RH - \frac{C_3}{T} \right) \quad (21)$$

where C_1 , C_2 , and C_3 are only related to the physical and chemical properties of the material-pollutant combinations.

$$D_m = D_1 T^{1.25} \exp \left(-\frac{D_2}{T} \right) \quad (22)$$

where D_1 and D_2 are only related to the physical and chemical properties of the material-pollutant combinations.

For formaldehyde and VOC emissions from building materials, Qian (2007) obtained a series of correlations between the emission rate and dimensionless emission time, or the mass transfer Fourier number (Fo_m , defined as $D_m t / \delta^2$). When the emission process reaches steady state (it means the conditions for which the emission rate change slowly), the Fo_m is no less than 0.2 (Qian 2007; Yao 2011), and the emission rate can be expressed as (Xiong et al. 2013):

$$E(t) = 2.1 \frac{D_m C_0}{\delta} \exp(-2.36 Fo_m) \quad (23)$$

The emission rate (E) is a function of emission characteristic parameters, C_0 , D_m and K . Therefore, E is a function of T and RH .

Substituting Eqs. (21) and (22) into Eq. (23), it yields:

$$E(t) = E_1 T^{0.75} \exp \left(E_2 \cdot RH - \frac{E_3}{T} - 2.36 Fo_m \right) \quad (24)$$

where E_1 , E_2 , and E_3 are only related with the physical and chemical properties of the material-pollutant combinations, $E_1 = 2.1 C_1 D_1 / \delta$, $E_2 = C_2$, $E_3 = C_3 + D_2$.

The parameter $E_3 (= C_3 + D_2)$ in Eq. (24) is generally of the order of 10^4 for commonly used building materials (Huang et al. 2015; Deng et al. 2009). Considering that Fo_m is approximately equal to or larger than 0.2 when the emission reaches steady state, the term($-2.36 Fo_m$) is relatively small compared with other terms in Eq. (24) (e.g., E_3/T is about 30 at room temperature) and can thus be ignored. Therefore, Eq. (24) can be simplified into the following:

$$E(t) = E_1 T^{0.75} \exp\left(E_2 \cdot RH - \frac{E_3}{T}\right) \quad (25)$$

This equation explicitly characterizes the relationship between the steady-state emission rate with T and RH . Further analysis indicates that, with the increase of T or RH , E increases accordingly. Once E for a given material-pollutant combination is

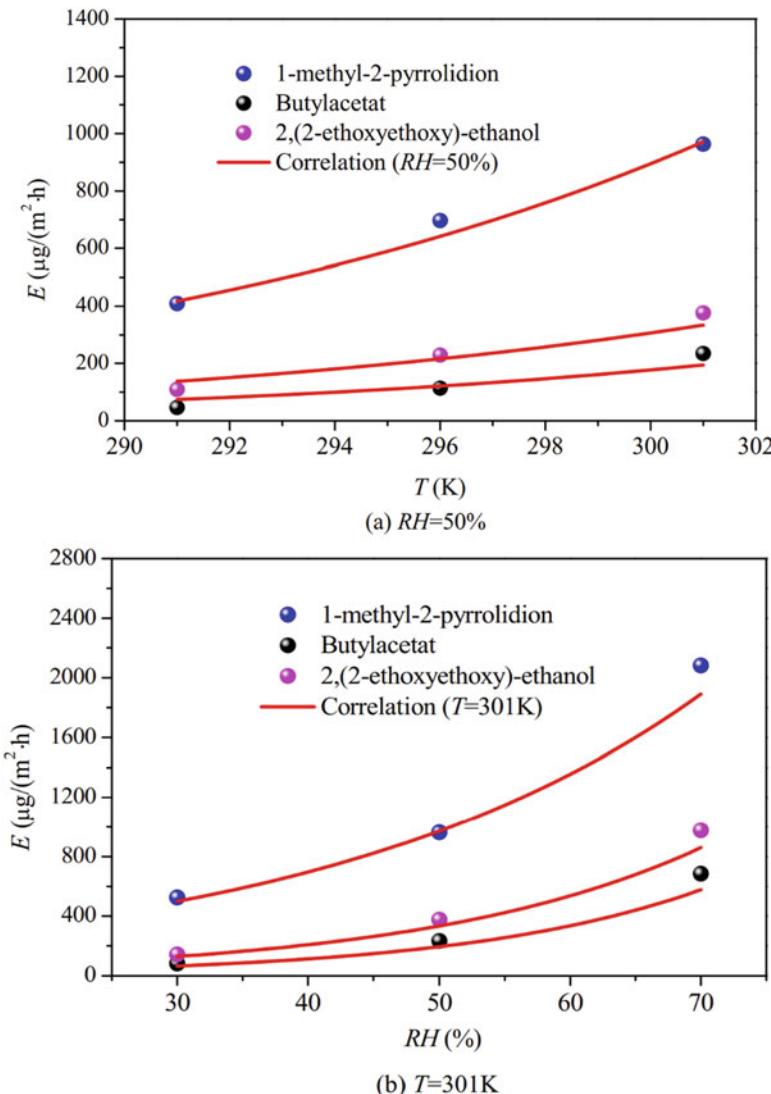

Fig. 4 The regression results by virtue of correlation (25) for three VOCs (1-methyl-2-pyrrolidinone, butyl acetate, and 2,(2-ethoxyethoxy)-ethanol). (Figure taken from Xiong et al. (2016))

measured at three or more sets of environmental conditions, the three parameters E_1 , E_2 , and E_3 can be determined from nonlinear curve fitting, the derived correlation (Eq. (25)) can then be applied to predict E at T and RH values different from the test conditions, which will be very helpful for engineering applications as well as for scientific studies.

The steady-state emission rate will change very slowly with Fo_m or emission time according to Eq. (24). Therefore, when using correlation (25) to predict E at different T and RH , the emission time corresponding to E should not differ substantially.

The regression results by virtue of correlation (25) for three VOCs (1-methyl-2-pyrrolidion, butyl acetate, and 2,(2-ethoxyethoxy)-ethanol) are shown in Fig. 4. Figure 4a presents the relationship of emission rate and temperature at a given relative humidity ($RH = 50\%$), and Fig. 4b shows the relationship of emission rate and relative humidity at a certain temperature ($T = 298$ K). The time point for the emission rate at steady state in this figure is 1 week. The R^2 for the three VOCs are all over 0.90, implying correlation (25) is also applicable for these pollutants. Further analysis based on the correlation indicates that the ratios of E in summer (with air conditioner, $T = 24$ °C, $RH = 50\%$) to that in winter (with air conditioner, $T = 20$ °C, $RH = 45\%$) in Beijing for 1-methyl-2-pyrrolidion, butyl acetate, and 2,(2-ethoxyethoxy)-ethanol from floor vanish are 1.66, 2.07, and 1.79, respectively (Xiong et al. 2016).

Conclusions

Reducing the concentration of VOCs indoors is an important indoor environment and health goal. The indoor building materials are the main indoor sources of VOCs pollutants. In order to control the indoor emissions, it is important to understand the VOCs emission characteristics of indoor building materials. Most studies about VOCs emission focused on dry materials and found that the three emission characteristic parameters, i.e., initial emission concentration (C_0), diffusion coefficient (D_m), and partition coefficient (K), are related to the building material, temperature, and relative humidity. More attention to the mechanism of VOCs emission, especially for wet materials, is needed in the future.

Abstract

In modern buildings, abundant synthetic materials and products are used to meet various demands of occupants. A vast of semi-volatile organic compounds (SVOCs) are added as additives or solvents to facilitate the production of, or enhance the performance of, these materials and products, leading to the ubiquity of SVOCs in indoor environments. SVOCs can be slowly emitted from these sources and then be partitioned among gas phase and various indoor surfaces. Due to their strong partitioning between air and surfaces, SVOCs have long indoor persistence (days to years, or even more). Human exposure to some SVOCs have been proved to be associated with diverse health risks, which have led to product reformulations in some cases. However, few knowledges about the indoor fate, human exposure, and the associated health risks are currently available for many other widely used SVOCs as well as the increasing number of emerging SVOCs. This chapter provides an overview on the usage, basic physicochemical properties, and adverse health effects of four classes of

SVOCs that have been frequently/newly investigated in the past 20 years, including (1) phthalate esters (PAEs) and their alternatives, (2) brominated flame retardants (BFRs), (3) organophosphate flame retardants (OPFRs), and (4) per- and polyfluoroalkyl substances (PFAS). Overall, this chapter aims to emphasize the importance of investigating SVOC pollution in indoor environments.

Indoor air quality (IAQ) · Phthalate esters · Brominated flame retardants · Organophosphate flame retardants · Per- and polyfluoroalkyl substances

Introduction

At present, plastic products, composite wood, synthetic carpets, foam cushioning, scented detergent, and electronic equipment (e.g., computers, televisions, and washer/dryers) have become ubiquitous indoors (Weschler 2009). Lots of chemical substances are added as additives or solvents to facilitate the production of, or enhance the performance of, these materials and products. Many of these chemicals (such as formaldehyde, benzene series, phthalates, and flame retardants) that are potentially harmful to human body will be emitted into the indoor air, resulting in the deterioration of indoor air quality (IAQ) (Destaillets et al. 2008; Weschler 2009; Xu and Little 2006; Zhang et al. 2013). Among these indoor air pollutants, volatile organic compounds (VOCs) have been widely concerned and studied in the past decades (Ohura et al. 2009; Wang et al. 2010; Zhang et al. 2016). Taking China as the example, substantial projects of related research have been launched and a series of standards related to the control of indoor VOC pollution have been promulgated since 2000 (Wang et al. 2010). Due to the changes in materials/products, building ventilation, occupant behaviors, public awareness, and government actions, levels of many indoor pollutants (including formaldehyde, aromatic and chlorinated solvents, and chlorinated pesticides) were found to increase and then decrease since 1950s (Weschler 2009). However, levels of other indoor pollutants were found to increase and remain high (e.g., phthalate esters, brominated flame retardants, bisphenol A, and nonylphenol). As shown in Table 2 of Weschler (2009), most of indoor pollutants with increasing levels belonged to semi-volatile organic compounds (SVOCs).

SVOCs are generally defined as organic compounds with vapor pressures between 10^{-14} and 10^{-4} atm (10^{-9} to 10 Pa) at environmental temperature (Weschler and Nazaroff 2008) or with boiling points between 240/260 °C and 380/400 °C at ambient pressure (WHO 1989). Due to their low vapor pressures, it is thermodynamically favorable for SVOCs to partition from gas phase into condensed phases. Especially for some SVOCs with high molecular weight, over 90% of their total mass indoors may be sorbed on indoor surfaces. Consequently, organic compounds that have meaningful abundances in both the gas phase and condensed phases can also be referred to as SVOCs (Weschler and Nazaroff 2008). Different from volatile organic compounds (VOCs, boiling point between 50/100 °C and

240/260 °C) and very volatile organic compounds (VVOCs, boiling point between <0 °C and 50/100 °C), SVOCs are more stable, are difficult to degrade, and tend to persist for years in indoor environments (Van Loy et al. 1997; Wang et al. 2010). Figure 1 illustrates the fate and transport of SVOCs in indoor environments.

As shown in Fig. 1, the indoor fate and transport of SVOCs mainly comprise of three processes: (1) emission: SVOCs are emitted into the indoor air from products or materials containing SVOCs (designated as SVOC source) that enter the indoor environments; (2) sorption: SVOCs in the air are easily sorbed by interior surfaces (including airborne particles, settled dust, exposed inanimate surfaces, and skin surfaces); and (3) exposure: SVOC in multiphases enter the human body via three pathways (inhalation of air and airborne particles, nondietary ingestion of dust, and dermal absorption from air, deposited particles, or contacted surfaces) (Eichler et al. 2021; Little et al. 2012; Xu et al. 2010). If the SVOC source is removed or fresh air (free of SVOCs) is introduced, the SVOC concentrations in indoor air will decrease. Meanwhile, the condensed-phase SVOCs may be released from the interior surfaces to the indoor air (i.e., desorption process shown in Fig. 1), impeding the decrease of gas-phase SVOC concentrations (Weschler and Nazaroff 2008). The frequent sorption-desorption transition is the key reason that makes the indoor fate and transport of SVOCs, as well as the control of indoor SVOCs, much more complex than those of VVOCs and VOCs. Taking the USA as an example, the US EPA suggests several guidelines to preserve the indoor air quality, however a specific indoor air quality index for SVOCs does not exist (Lucattini et al. 2018). The occurrence, fate and transport, health effects, and/or toxicity of SVOCs in indoor environments have become hot research topics in the past decades (Xu and Zhang 2011). Mechanistic models for describing the indoor fate and transport of SVOCs can be found in other chapters of this handbook, including Chap. ▶ 23, “Source/Sink Characteristics of SVOCs,” ▶ 25, “Predicting VOC and SVOC Concentrations in

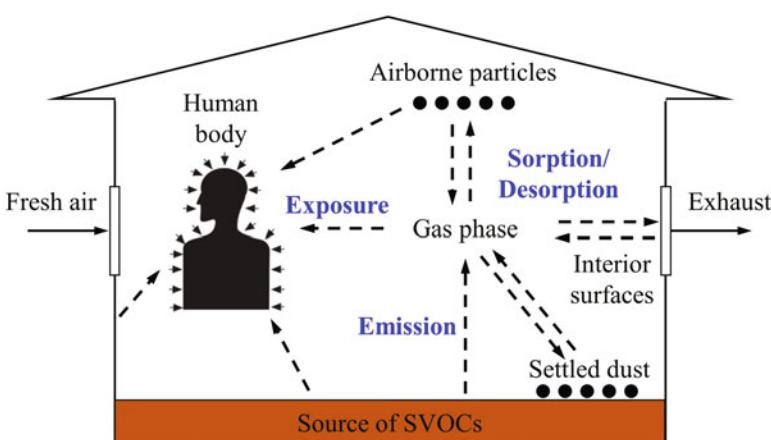

Fig. 1 Schematic of the fate and transport of SVOCs in indoor environments

Complex Indoor Environments,” and ► 38, “A Modular Mechanistic Framework for Assessing Human Exposure to Indoor Chemicals.”

Abundant studies have been attempted to measure the concentrations (or contents) of SVOCs in indoor air, dust, materials, and products (Bu et al. 2016; Lucattini et al. 2018; Melymuk et al. 2016; Raffy et al. 2017; Rudel and Perovich 2009; Shi et al. 2018; Wang et al. 2014; Wei et al. 2021). Lucattini et al. (2018) gave a relatively comprehensive review for the reported data of SVOCs in multiple indoor media (air, dust, and consumer products). The following classes of compounds were included: polychlorinated biphenyls (PCBs), polycyclic aromatic hydrocarbons (PAHs), polyfluorinated alkyl substances, polybrominated diphenyl ethers (PBDEs), brominated flame retardants (BFRs), emerging brominated flame retardants (EBFRs), organophosphate flame retardants (OPFRs), phthalate esters (PAEs), musks/fragrances, organochlorine pesticides, and pyrethroids. Based on this, the general information of the following classes of SVOCs are introduced in this chapter: (1) PAEs and their alternatives, (2) BFRs, (3) OPFRs, and (4) per- and polyfluoroalkyl substances (PFAS). They are the classes of SVOCs that are mainly released from indoor materials/products to the indoor air and have been frequently/ newly investigated in the field of IAQ, to the author’s best knowledge, since 2000.

Phthalate Esters (PAEs) and Their Alternatives

Phthalate esters (or phthalates, PAEs) are esters of phthalic acid (1,2-benzenedicarboxylic acid) with different alcohols. The general structure of PAEs is a diester of 1,2-dicarboxy-benzene, as shown in Fig. 2.

PAEs are hydrophobic compounds with low vapor pressures and viscous liquids with high boiling points and low melting points (like oil). The physicochemical properties of some commonly used PAEs are listed in Table 1.

PAEs can be divided into two groups according to their carbon chain length (i.e., R and R' in Fig. 2): high molecular weight (HMW) phthalates (7–13 carbon atoms) and low molecular weight (LMW) phthalates (3–6 carbon atoms) (Kashyap and Agarwal 2018). They are mainly used as plasticizers in the production of plastics, primarily polyvinyl chloride (PVC), to improve the product performance (e.g., flexibility and durability). Plastics are widely used in numerous indoor products, such as flooring, carpets, wall papers, synthetic leather, packaging, and toys. Di (2-ethylhexyl) phthalate (DEHP), followed by diisononyl phthalate (DINP), are the most commonly used PAEs. Additionally, PAEs with <3 carbon atoms (such as dimethyl phthalate [DMP] and diethyl phthalate [DEP]) are not used as plasticizers.

Fig. 2 General chemical structure of phthalate esters

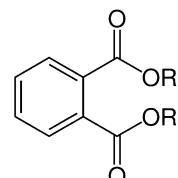

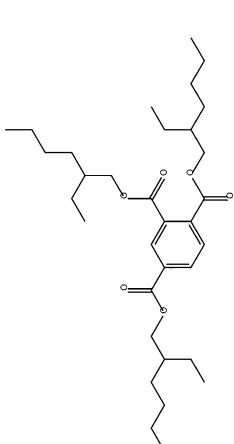

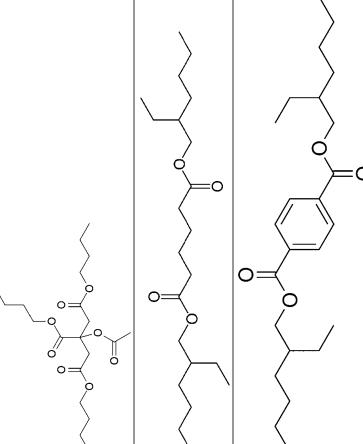

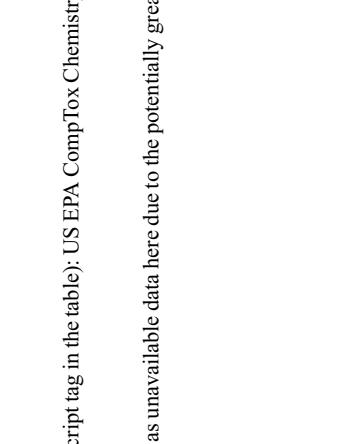

Table 1 Physicochemical properties of selected phthalate esters (PAEs) and their alternatives

PAEs and their alternatives	Formula	CAS	MW	Chain length	Vapor pressure ^a	Log K_{ow} ^b	Log K_{ow} ^c	Structure

and not classified in any group. These PAEs are used as solvents and fixatives in fragrances, additives in cosmetics, medical devices, and personal care and cleaning products (Kashyap and Agarwal 2018). Some LMW phthalates (such as di-*n*-butyl phthalate [DnBP] and di-iso-butyl phthalate [DiBP]) also have applications similar to PAEs with <3 carbon atoms, i.e., used as solvents (Ait Bamai 2020). Overall, PAEs are widely used in indoor materials and products. For example, PAEs are presented in all classes of indoor products investigated by Lucattini et al. (2018): electronics, building materials, textiles, furniture, health care/personal/cleaning products, and cosmetics. Because PAEs are not chemically bound to PVC and other materials, they may migrate out to the surrounding environments, e.g., emission to the indoor air, during their usage (Clausen et al. 2004), and subsequently lead to the deterioration of indoor air quality.

Compared to the long duration of usage in the plasticizer industry (since 1930s), concerns over the possible adverse health risks of PAEs are relatively recent (since 1970s) (Mayer et al. 1972). Currently, PAEs are known to be reproductive and developmental toxicants (Kashyap and Agarwal 2018). Based on human biomonitoring studies, human exposure to PAEs may cause several adverse health outcomes, such as fertility problems, respiratory diseases, childhood obesity, and neuropsychological disorders (Katsikantami et al. 2016). Consequently, authoritative regulations on PAE use have been implemented in some countries and regions. Six PAEs, including DMP, DEP, DnBP, BBzP, DEHP, and DnOP (all included in Table 1), have been identified as priority pollutants by the US EPA and the European Union (EU) (Kashyap and Agarwal 2018). Mass fractions of DnBP, BBzP, DEHP, and DnOP have been limited to $\leq 0.1\%$ in toys and childcare articles by EU (Directive 2005/84/EC), the USA (Consumer Product Safety Improvement Act of 2008 (CPSIA, 2008), China (China National Standard GB 6675, 2014), and Japan (Japan Toy Safety Standard ST-2002 Part 3, 2011) (Kashyap and Agarwal 2018). Furthermore, since 2015, DnBP, BBzP, and DEHP have been classified as reproductive toxicant category 1B and completely banned for any application without a specific authorization from EU (Eichler et al. 2019). The chemical risk management regulations and activities of PAEs in EU, the USA, Canada, and Australia were comprehensively summarized in Eichler et al. (2019).

Because of the strict regulations on the use of PAEs, there has been a reduction in their production. Higher molecular weight phthalates are being manufactured and employed by the plastic industry. Taking the most commonly used PAE, namely DEHP, as an example, the market share of DEHP in EU decreased from 42% in 1999 to 10% in 2014 (Nagorka and Koschorreck 2020). It was replaced mainly by DINP and DIDP. However, the EU also sets a restriction of 0.1% by weight for DINP and DIDP for toys and childcare products that might be placed in the mouth (Eichler et al. 2019), due to the increasing concerns on the potentially adverse health effects of these higher molecular weight PAEs. Except for higher molecular weight PAEs, manufacturers of PAE plasticizers have switched to non-PAE plasticizers such as adipates or citrates, which accounted for 40% of the EU plasticizer market until 2019 (Nagorka and Koschorreck 2020). Terephthalates and cyclohexane dicarboxylic acid esters were firstly introduced to the alternative plasticizer market, with di-

(2-ethylhexyl) terephthalate (DEHTP) and di-isobutyl cyclohexane-1,2-dicarboxylate (DINCH) as the most widely used phthalate alternatives (Deng et al. 2021). Subsequently, trimellitates, citrates, and adipates, including tris(2-ethylhexyl) trimellitate (TOTM), tributyl-O-acetyl citrate (ATBC), and di(2-ethylhexyl) adipate (DEHA), were applied as phthalate alternatives in electronics, apparels, and building materials. Furthermore, isophthalate esters, cyclohexene dicarboxylic acid esters, and new cyclohexane dicarboxylic acid esters were developed as the newest phthalate alternatives, including di(2-ethylhexyl) isophthalate (DEHIP), di(2-ethylhexyl) tetrahydrophthalate (DEHTH), di(2-ethylhexyl) cyclohexane-1,4-dicarboxylate (1,4-DEHCH), and di(2-ethylhexyl) cyclohexane-1,2-dicarboxylate (1,2-DEHCH). The physicochemical properties of some commonly used phthalate alternatives are also listed in Table 1. Although most manufacturers declare that these non-PAE plasticizers have no adverse health and environmental effects, mounting evidence implies that they may exhibit various toxic effects, e.g., endocrine-disrupting activity, reproductive and developmental toxicity, and carcinogenicity (Deng et al. 2021).

Due to their ubiquity in indoor environments and high concerns to their health risks, comprehensive data on levels of traditional PAEs (such as DMP, DEP, DnBP, BBzP, DEHP, and DnOP) in indoor air and dust are available in the literature (Ait Bamai 2020; Kashyap and Agarwal 2018; Lucattini et al. 2018). Abundant studies have focused on the emissions of PAEs from PVC floorings since 2003 (Afshari et al. 2004; Benning et al. 2013; Cao et al. 2017; Clausen et al. 2004; Eichler et al. 2018; Ekelund et al. 2010; Fujii et al. 2003; Hsu et al. 2017; Jeon et al. 2016; Liang and Xu 2014; Liu and Zhang 2016; Noguchi and Yamasaki 2016; Pei et al. 2017; Shi et al. 2018; Wu et al. 2016b; Xu and Little 2006; Xu et al. 2012). However, much less data have been reported for higher molecular weight PAEs and phthalate alternatives. More concerns are required for the pollution problems related to the emerging PAEs and non-PAE plasticizers in indoor environments.

Brominated Flame Retardants (BFRs)

Flame retardants (FRs) are substances used in plastics, textiles, electrical equipment, and other materials (or products) to make them less flammable. The FRs that have been/are in use can generally divided into six main categories: halogenated FRs (brominated and/or chlorinated), phosphorous FRs, nitrogen, intumescence systems (e.g., expanded foam), mineral (containing aluminum or magnesium), and others, e.g., antimony trioxide and nanocomposites (Rauert 2014). The brominated flame retardants (BFRs) are one of the most widely used flame retardants in consumer products since the 1970s. BFRs inhibit or slow down the growth of fire by releasing free radical bromine atoms into the air, before the material can reach its ignition temperature, which reduces heat generation, slows the burning process, and prevents the fire cycle from establishing and sustaining itself. BFRs are added to the material/product either through additive or reactive processes. The mass fraction of BFRs in products can be up to 30%. Similar to PAEs, BFRs can migrate from source materials

to indoor air through volatilization or transfer to indoor dust via abrasion of the source material and direct source-dust contact (Rauert and Harrad 2015).

There are around 75 different commercial BFRs used in electrical equipment (e.g., TV casings and computer monitors), accounting for more than 50% of their usage. Polybrominated diphenyl ethers (PBDEs) and hexabromocyclododecanes (HBCDs) are the two most commonly used BFRs. The general chemical structures of PBDEs and HBCDs are shown in Fig. 3. Products containing PBDEs and HBCDs are ubiquitous in indoor environments with considerable concentrations in indoor air and dust (Harrad et al. 2010).

Polybrominated Diphenyl Ethers (PBDEs)

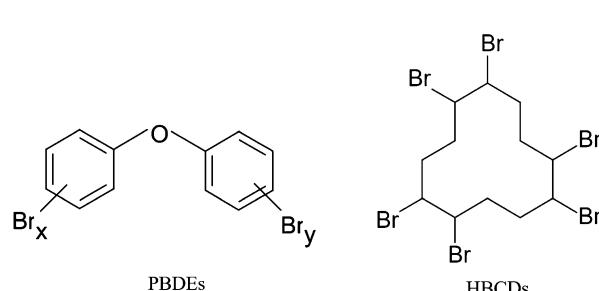

Penta-BDE, octa-BDE, and deca-BDE are the three PBDE formulations that are commonly produced and used. All formulations are comprised of congeners of different bromination levels and used as additives in products (Harrad et al. 2008; La Guardia et al. 2006):

1. Penta-BDE: mixture of BDE-47 (tetra-BDE), BDE-99 (penta-BDE), and some other tri- to hepta-BDEs; widely used in polyurethane foam (PUF) of carpets, furniture, and bedding, as well as in printed circuit boards and microprocessor packaging of computers
2. Octa-BDE: mixture of hexa- to deca-BDEs; used in thermoplastics, such as high impact polystyrene and acrylonitrile-butadiene-styrene copolymers
3. Deca-BDE: mixture of BDE-209 (deca-BDE) and low levels of nona- and octa-BDEs; used in thermoplastics applied in plastic housings for electrical good and textiles

Generally, the primary constituents of the three formulations are: tetra-BDE (BDE-47), penta-BDEs (BDEs –85, –99, –100), hexa-BDEs (BDE-153 and BDE-154), hepta-BDE (BDE-183), and deca-BDE (BDE-209). Therefore, these congeners are the predominant PBDEs found in indoor environments (La Guardia et al. 2006). Table 2 lists the selected physicochemical properties of these congeners.

Numerous evidences have indicated that PBDEs exert extensive toxicity and pose a great threat to human health. Human exposure to PBDEs has been found to be

Fig. 3 The general chemical structures of polybrominated diphenyl ethers (PBDEs) and hexabromocyclododecanes (HBCDs)

associated with endocrine dysfunction, developmental neurotoxicity, reproductive disorders, endocrine disruption, metabolism disruption, neurotoxicity, and carcinogenicity (Wu et al. 2020). Due to the concerns about potential human health effects of PBDEs, measures have been implemented to reduce or even stop their manufacture. For example, penta- and octa-BDEs were phased out in the EU and the USA in 2004. Deca-BDE was phased out in the USA in 2009 and eventually added to the Stockholm Convention without recycling exemptions in 2017. The ban of penta- and octa-BDEs was announced in China in 2014 (Li et al. 2021). Consequently, the use of PBDEs is declining, e.g., deca-BDE production in the USA decreased from 23,000 t in 2012 to <11 t in 2015 (Blum et al. 2019). Abundant data are available for the occurrence of PBDEs in indoor air, dust, and other environmental media (Ait Bamai 2020; Rauert 2014; Yu et al. 2016).

Hexabromocyclododecanes (HBCDs)

HBCDs are produced by bromination of cyclododecane in a batch process. HBCDs have a molecular formula of $C_{12}H_{18}Br_6$ (molecular weight 641.7), consisting of a ring of 12 carbon atoms to which 18 hydrogen and six bromine atoms are bound (as shown in Fig. 3). Due to the varying orientations of the bromine-carbon bonds, there are 16 stereoisomers of HBCDs, including six pairs of enantiomers and four meso configurations. The commercially available HBCDs are mainly (> 95%) comprised of three diastereomers, namely γ -HBCDs (75–89%), α -HBCD (10–13%), and β -HBCD (0.5–12%) (Szabo 2014). These HBCDs are mainly used as additive FRs in foams and expanded polystyrene that are used in numerous products, including upholstered furniture, interior textiles, car cushions, insulation blocks in building materials (e.g., walls, cellars, and roofs), packaging, and electric equipment (De Wit 2002). HBCDs are effective at low concentrations, e.g., 0.5% by weight in expanded polystyrene foams. However, they can also be present in fabrics, textiles, rubber, and plastics from 1–30% by weight (Rauert 2014). Table 3 lists the selected physicochemical properties of α -, β , and γ -HBCDs.

Compared to PBDEs, the available data on the health effects of HBCDs is still limited. According to the limited data, HBCDs are thought to affect the thyroid system via hepatic enzyme induction; and in cell culture, HBCDs were found to exert antagonistic effects on progesterone, androgen, and oestrogen receptors (Rauert 2014). Due to the environmental persistence and the potential toxicity of HBCDs, measures have also been implemented to reduce their production/use. In 2011, HBCD was included in the ECHA (European Chemicals Agency) list of substances subject to authorization under the Registration, Evaluation, Authorization, and Restriction of Chemicals (REACH) framework, with HBCD use not permitted without authorization after 2015 (UNEP 2011).

Compared to PAEs and PBDEs, much less studies have reported the concentrations of HBCDs in indoor air and dust. Nevertheless, relative higher levels of HBCDs were observed in indoor air (in Tokyo) and in indoor dust (in the UK and Belgium) among BFRs (Lucattini et al. 2018). The limited data on the toxicity and

indoor occurrence of HBCDs suggests that more concerns are required for the HBCD pollution in indoor environments.

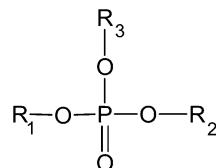

Despite the bans and phaseouts, products and materials in use or reuse will release the regulated BFRs. Meanwhile, the production and use of popular alternative FRs, such as organophosphate esters (OPEs), have increased sharply in recent decades, which results in their ubiquitous existence in the environment and human tissues worldwide.

Organophosphorus Flame Retardants (OPFRs)

Due to the environmental and health concerns about BFRs, organophosphorus flame retardants (OPFRs) were developed. Different groups of organophosphorus compounds, such as esters, phosphonates, and phosphites, are used in different applications (mostly as additives). These compounds are frequently used in plastics, textiles, and building materials as a replacement for BFRs (especially PBDEs) to maintain fire safety standards after their phaseouts (Marklund et al. 2003). Additionally, they are also widely used as plasticizers, stabilizers, and antifoaming, and as additives in lubricants and hydraulic fluids. Because OPFRs are always not chemically bound to the products, they may escape the products by volatilization, leaching, or abrasion, and subsequently reach different environmental compartments throughout the entire lifetime of the products (Marklund et al. 2003). Note “OPFRs” was also used as the abbreviation of “organophosphate flame retardants” in existing articles that only concerned about organophosphate flame retardants (the most commonly used organophosphorus flame retardants). In this chapter, the term “OPFRs” is treated as the short for “organophosphorus flame retardants.”

The most commonly used OPFRs are organophosphate esters, i.e., organic esters of phosphoric acid (Blum et al. 2019). The general structure of organophosphate flame retardants is shown in Fig. 4. R_1 , R_2 , and R_3 can be either alkyl chains or aryl

Fig. 4 General structure of organophosphate esters (most commonly used OPFRs)

groups, and they may be halogenated or nonhalogenated. Halogenated organophosphate esters are mainly used as additive FRs in furniture, textiles, building materials, polyurethane foam, and electronics, while nonhalogenated esters are also used as plasticizers in consumer products, textiles, and construction materials (Chupeau et al. 2020).

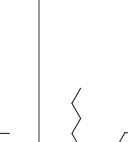

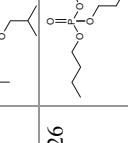

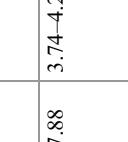

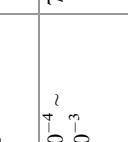

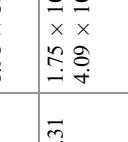

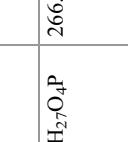

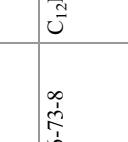

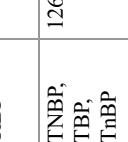

The global production and consumption of OPFRs were steadily increasing in recent decades. For example, the world production and consumption of organophosphate esters have sharply increased from 102,000 t in 1992 to 680,000 t in 2015 (Li et al. 2019). In Europe, the total consumption of OPFRs was 89,640 t in 2015, which was 18% of the total consumption of FRs and was twice as much as BFRs. Currently, OPFRs have become the second-largest flame retardants used in Europe, after aluminum hydroxide (Al(OH)_3) (Chupeau et al. 2020).

Most of OPFRs are liquid under room temperature. And compared with PBDEs, OPFRs tend to have higher vapor pressures and water solubility, and subsequently are expected to be less persistent in the environments (Blum et al. 2019). The selected physicochemical properties of some common OPFRs are listed in Table 4.

Similar to PAEs, OPFRs are also presented in all classes of indoor products investigated by Lucattini et al. (2018): electronics, building materials, textiles, furniture, health care/personal/cleaning products, and cosmetics. OPFRs can be detected in diverse environmental media, such as indoor dust, air, water, soil, sediment, and marine compartments. In summary, OPFRs are currently ubiquitous in both indoor and outdoor environments. Since the early 2000s, numerical studies have been conducted to investigate the levels of OPFRs in indoor dust and air. The detailed data have been well summarized in some recently published articles, such as Blum et al. (2019), Du et al. (2019), Li et al. (2019), and Chupeau et al. (2020).

Because the vapor pressures of OPFRs tend to be higher than those of PBDEs (comparing the data listed in Tables 2 and 4), it would be reasonable to assume that OPFR dust concentrations would be lower than PBDE dust concentrations. However, various studies have indicated that OPFR concentrations in indoor dust tended to be higher than PBDE concentrations in indoor dust from the early 2000s, mainly due to the increasing production and consumption of OPFRs (Blum et al. 2019). For example, Chen et al. (2020) found that PBDEs in Chinese indoor dust decreased gradually, while the concentrations of OPFRs increased gradually. Among all the kinds of OPFRs detected in indoor dust, TBOEP, TCPP, and TDCPP are the most concentrated in Europe (Chupeau et al. 2020). In China, chlorinated OPFRs (Cl-OPFRs, including TCEP, TCPP, and TDCPP) are the main OPFRs in indoor dust samples, and the OPFR concentrations in indoor dust was higher in

Table 4 Physicochemical properties of commonly used OPFRs

OPFRs	Acronyms	CAS	Formula	MW	Vapor pressure ^a	$\log K_{ow}$ ^b	$\log K_{oa}$	Structure

economically developed areas of China such as Beijing, Shanghai, and Guangzhou (Chen et al. 2020). Similar conclusions were obtained by Li et al. (2019), a global-scale investigation. They measured 20 organophosphate esters in 341 house dust samples collected from 12 countries during 2010–2014. Cl-OPFRs were found to be the predominant compounds (51% of total OPFRs) in indoor dust samples, followed by alkyl-OPFRs (31%, including TMP, TEP, TNBP, TIBP, TBOEP, TEHP, and tripropyl phosphate), aryl-OPFRs (17%, including TPHP, TMPP, EHDPP, and three others), and three oligomeric organophosphate esters (1%). Total OPFR concentrations in house dust from more industrialized countries (South Korea, Japan, and the USA) were one or even two orders of magnitude higher than those from less industrialized countries (Greece, Saudi Arabia, Kuwait, Romania, Vietnam, China, Colombia, India, and Pakistan).

The ubiquity of OPFRs in the environments indicate ubiquitous human exposure to OPFRs. People can be exposed to OPFRs through skin contact, ingestion of dust, inhalation, and dietary intake. The adverse effects of human exposure to OPFRs have not been studied to the same extent as for the phased-out PBDEs, and are relatively less well known. Nevertheless, available data from toxicologic and epidemiological studies and risk assessments all imply that there are health concerns at current exposure levels for OPFRs (Blum et al. 2019). In 2017, the US Consumer Product Safety Commission (CPSC) initiated efforts to assess and issue a report on the risks to consumer health and safety from the use of additive OPFRs in certain consumer products (USCPSC 2017). Recently, some studies have shown that some OPFRs may be carcinogenic, neurotoxic, and endocrine disruptors, and there are particular concerns on Cl-OPFRs (Pantelaki and Voutsas 2019). For example, animal and/or epidemiologic studies have indicated that TCEP and TCPP had elicited moderate acute toxicity, TCEP and TDCPP were suspected to be carcinogenic, and TDCPP had neurotoxic properties and has been associated with altered hormone levels and the reduction of semen quality (Chen et al. 2020; Li et al. 2019). Some nonhalogenated OPFRs may also be associated with adverse health effects, e.g., animal studies had indicated that TNBP and TPHP had neurotoxic properties, TBOEP had developmental toxicity, and TNBP might be carcinogenic (Chen et al. 2020; Li et al. 2019). Due to their adverse health effects, some authoritative organizations are now addressing the problem related with the OPFR pollution. For example, US EPA released a problem formulation for Cl-OPFRs used in furniture foams and textiles on August 13, 2015 (USEPA 2015). Additionally, US EPA designated TCEP as one of the 20 high-priority substances for risk evaluation under the Toxic Substances Control Act in December 2019 (USEPA 2019). Furthermore, the European Commission proposed to prohibit the entire class of organohalogen chemicals (including Cl-OPFRs) in electronic display enclosures and stands by April 1, 2021 (Blum et al. 2019). The timeline of some major regulatory milestones for both PBDEs and OPFRs (mainly from the USA, EU, and Canada) can be found in Fig. 1 of Blum et al. (2019).

In summary, the available evidences have shown that the replacement of PBDEs with OPFRs may be a regrettable substitution (Blum et al. 2019). Since 2016, a group from US EPA (led by Dr. Xiaoyu Liu) had conducted a series of studies to

develop methods and collect data for characterizing and understanding the fate and transport of OPFRs in indoor environments (Liang et al. 2018a; Liang et al. 2018b; Liang et al. 2019; Liu et al. 2016; Liu and Folk 2021). It is foreseeable that the OPFR pollution in indoor environments would become a hot research topic in the field of IAQ.

Per- and Polyfluorinated Alkyl Substances (PFAS)

Per- and polyfluorinated alkyl substances (typically referred to as PFAS) are a class of over 4700 synthetic chemicals in which hydrocarbons of one or more C atoms have their H substituents partially or fully replaced by F (Morales-McDevitt 2021; NIH 2019). The C-F bond is strong, thermally and chemically stable, highly hydrophobic, lipophobic, and resistant to oxidation (Buck et al. 2011). Therefore, PFAS have been widely used in commercial products and industrial applications since the 1940s for their water-resistant, stain-resistant, fire-resistant, and anti-stick properties (DeLuca et al. 2021). According to Glüge et al. (2020), PFAS are currently used in almost all industry branches and many consumer products, and more than 200 use categories and subcategories are identified for more than 1400 individual PFAS. For example, PFAS are widely used as water- and stain-resistant coatings for cookware, food packaging, personal care products, carpet, upholstery, and outdoor textiles – they are all ubiquitous indoors (Eichler and Little 2020).

According to the Organization for Economic Cooperation and Development (OECD), PFAS are categorized as nonpolymeric or polymeric (OECD 2013). Nonpolymeric PFAS are comprised of four families: (1) perfluoroalkyl acids (PFAAs), which mainly include perfluoroalkyl carboxylic acids (PFCAs) and perfluoroalkane sulfonic acids (PFSAs); (2) compounds derived from perfluoroalkane sulfonyl fluoride (PASF); (3) fluorotelomer (FT)-based compounds; and (4) per- and polyfluoroalkyl ether (PFPE)-based compounds. Both PASF- and FT-derived or based products have the potential to degrade to long-chain PFSAs and PFCAs. The term “long-chain” PFAS refers to (1) PFCAs with 7 and more perfluoroalkyl carbons; (2) PFSAs with 6 and more perfluoroalkyl carbons; and (3) substances that have the potential to degrade to long-chain PFCAs or PFSAs. Polymeric PFAS are comprised of three groups: (1) fluoropolymers, e.g., polytetrafluoroethylene (PTFE); (2) side-chain fluorinated polymers that are composed of nonfluorinated backbones with per- and polyfluoroalkyl side chains (they are potential precursors of PFSAs and PFCAs); and (3) perfluoropolyethers that consist of backbones containing carbon and oxygen with fluorines directly attached to carbon. Table 5 lists the selected physicochemical properties of over 40 PFAS. Note, most of PFAS properties listed in Table 5 are predicted values, which should be associated with huge uncertainties and should be used with caution. For example, the vapor pressure of 10:2 FTOH (CAS 865-86-1) was measured to be 140 Pa while predicted to be 3.2 Pa at 25 °C according to Eichler and Little (2020). Generally, the huge number (still increasing rapidly) and diverse physicochemical properties of

PFAS make the research about the environmental transport, human exposure, and health risks of PFAS extremely challenging (Nakayama et al. 2019).

The most consistent feature of all PFAS is that their perfluorocarbon moieties break down very slowly (or even do not) under environmental conditions (Wang et al. 2018; Wang et al. 2017). Existing studies have estimated that PFAS such as perfluoroalkanes have lifetimes up to thousands of years (Ivy et al. 2012). Therefore, PFAS can be present in the environment for centuries or longer, even if the PFAS productions, applications, and environmental releases cease immediately. As such, PFAS have often been nicknamed “forever chemicals” (Kwiatkowski et al. 2020). The extreme persistence of PFAS, combined with their propensity for accumulation and mobility, has resulted in PFAS being ubiquitous globally, even in remote regions like the Arctic (Kwiatkowski et al. 2020). Concerns about the adverse effects of PFAS on human and environments have been raised since the 1990s (Morales-McDevitt 2021). PFAS have been proven to be linked to adverse effects for flora and fauna (including humans), e.g., developmental toxicity, neurotoxicity, immunotoxicity, carcinogenicity, thyroid malfunction, low birthweight, infertility, early menopause, elevated cholesterol, and fatty liver disease (Arvaniti and Stasinakis 2015; Buck et al. 2011; Morales-McDevitt 2021; Venkatesan and Halden 2013). In addition, precursors such as perfluoroctane sulfonamides (FOSAs) and perfluoroctane sulfonamide ethanol (FOSEs) have been found to have estrogenic effects (*in vitro*) and can be transformed to more stable compounds under natural conditions (Fromme et al. 2015).

Due to their longer usage, longer persistence in the environments, and potential higher health risks, perfluoroctanoic acid (PFOA) and perfluoroctane sulfonic acid (PFOS) are the two most well-studied PFAS (Kwiatkowski et al. 2020). They are also termed “long-chain” PFAS (OECD 2013). In 2008, PFOS, PFOA, and their salts were included in the Annex B of the Stockholm Convention. As a result, PFOA and PFOS have been largely replaced by shorter-chain PFAS, branched PFAS, and perfluoroether compounds (Eichler and Little 2020). However, short-chain PFAS may not be safe alternatives. Several studies have demonstrated that short-chain PFAS can be equally environmentally persistent, even more mobile in the environment, and more difficult to be removed than long-chain PFAS. Increasing evidences suggest that they are associated with similar adverse toxicological effects as long-chain PFAS (Kwiatkowski et al. 2020).

Given their ubiquitous presence, it should be important to understand the fate and transport of PFAS, especially in indoor environments where people spend most of their time and abundant PFAS-contained products are used. However, most focus has been on outdoor exposure and contaminated sites. Limited knowledge about PFAS behavior indoors and the contribution of specific exposure pathways is available, although some studies have investigated PFAS levels in indoor air and dust (which usually exceed those in outdoor media) (Eichler and Little 2020; Harrad et al. 2010; Shoeib et al. 2005). According to the traditional definition of SVOCs (vapor pressures between 10^{-9} and 10 Pa at environmental temperature), Eichler and Little (2020) concluded that many PFAS, especially long-chain, ionizable PFAAs, could be treated as SVOCs. They subsequently

proposed a framework to model human exposure to PFAS in indoor environments based on the current knowledge of (relatively) well-studied indoor SVOCs, especially PAEs. Nevertheless, the framework is currently infeasible due to the lack of thermodynamic and transport parameters that are necessary to describe PFAS behavior indoors. Overall, much more attentions should be paid for the ubiquitous, persistent, complex, and increasing PFAS pollution in indoor environments.

Conclusions

Due to the increasing demands for more comfortable and convenient homes and workplaces, lots of synthetic materials and products have been manufactured and subsequently used indoors. A vast of semi-volatile organic compounds (SVOCs) is added as additive or solvent to facilitate the production or enhance the performance of these materials and products, leading to the ubiquity of SVOCs in indoor environments. SVOCs can be slowly emitted from source materials/products and, depending on their physicochemical properties, can be partitioned among gas phase, airborne particles, settled dust, and other indoor surfaces. Human exposure to indoor SVOCs can occur via inhalation, ingestion, or dermal uptake. Some SVOCs have been proved to be associated with diverse health risks, which have led to product reformulations in some cases. Specific SVOCs have physicochemical properties that span vast ranges, e.g., vapor pressures and octanol-air partition coefficients can vary over ten orders of magnitude. Additionally, SVOCs have long indoor persistence (e.g., years) even after the primary source is removed. Therefore, it is relatively challenging to understand and characterize the fate, transport, and human exposure of SVOCs in indoor environments. Recent studies on these topics are summarized in several other chapters of this handbook, including ► Chaps. 23, “Source/Sink Characteristics of SVOCs,” ► 25, “Predicting VOC and SVOC Concentrations in Complex Indoor Environments,” ► 13, “Interaction Between Gas-Phase Pollutants and Particles,” ► 16, “Sampling and Analysis of Semi-volatile Organic Compounds (SVOCs) in Indoor Environment,” and ► 38, “A Modular Mechanistic Framework for Assessing Human Exposure to Indoor Chemicals.” However, existing studies have mainly focused on several classes of SVOCs, such as phthalates and flame retardants (PBDEs and OPFRs). Insufficient knowledge is presently for available many other SVOCs (e.g., phthalate alternatives and PFAS). In addition, different classes of SVOCs have always been investigated separately, with relatively little cross-communication. Due to the limited information and understanding, guideline values for SVOCs in air and other indoor media are rare (except for some PAHs). The above issues warrant further study. Certainly, except for SVOCs released from indoor materials and products (discussed in this chapter), attention should also be paid to indoor SVOCs related to other sources/processes, e.g., processes that occur indoors (combustion) and intrusion from outdoor air.

Abstract

Fragrance is used in consumer products around the world. However, fragrance has been associated with adverse effects on indoor and outdoor air quality and human health. Fragranced consumer products can emit and generate potentially hazardous compounds including formaldehyde and fine particulate matter. This chapter focuses on the volatile compounds emitted from fragranced consumer

products as reported in laboratory headspace analysis, environmental chambers experiments, and measurements of volatile compounds within indoor environments. First, the chapter provides information on the methods for measurement of volatile organic compounds (VOCs) emitted from products, the volatile compounds (i.e., VOCs and aldehydes) detected in environmental chamber studies, and the volatile compounds detected within indoor environments. Second, it analyzes and synthesizes data findings and research findings on product ingredients, emissions, and indoor air quality. Third, the chapter offer strategies and methods to improve indoor air quality. Key findings and results from the synthesis are as follows. Headspace analysis of fragrance consumer products revealed that terpenes were present in all fragranced products tested, but absent in all fragrance-free products tested. Environmental chamber experiments demonstrated that terpenes are among the most prevalent (and reactive) ingredients in fragranced consumer products, and that they readily react with other chemicals (e.g., ozone) to generate a range of secondary and potentially hazardous pollutants, including formaldehyde. Indoor air quality surveys (i.e., large population-based studies and targeted studies) revealed the terpenes were among the most frequently detected VOCs in offices, homes, and other everyday environments. These findings suggest that exposure to primary and secondary pollutants from fragranced consumer products is ongoing, and that risk assessment and management would be advantageous. Studies also demonstrated that approaches to improve indoor air quality can be relatively straightforward and effective. For instance, fragranced products can be removed or replaced by fragrance-free alternatives, almost entirely reducing terpene emissions. Finally, fragrance-free policies offer a beneficial, longer-term, and larger-scale solution to improve indoor air quality.

Introduction

Everyday consumer products, especially those containing a fragrance, have emerged as a major source of indoor air pollutants. This chapter explores the emissions and effects of fragranced consumer products and the implications for indoor air quality. Special emphasis is given to methods to measure volatile emissions from products and within indoor environments.

“Fragranced consumer products,” as termed in this chapter, is a product that “contains an added fragrance or that is largely comprised of fragrance” (Steinemann 2019a). Fragranced products cover hundreds of everyday items, such as air fresheners, deodorizers, cleaning supplies, laundry detergents, fabric softeners, essential oils, candles, soaps, personal care products, colognes, and hand sanitizers.

A “fragrance” in a consumer product is a scent and, despite its singular name, it is a formulation of dozens of chemicals, such as volatile organic compounds (VOCs). Nearly 4,000 ingredients have been documented for use in the composition of a fragrance (IFRA 2020). A fragrance is generally intended to “provide an aroma, to mask an odor, or both” (Steinemann 2019a).

Fragranced consumer products are an interesting and important dimension of indoor air quality for several reasons:

First, in studies around the world, volatile chemicals, such as terpenes, from fragranced consumer products are among the most abundant pollutant indoors (e.g., Wang et al. 2017; Mandin et al. 2017). A reason is that fragranced consumer products are pervasive in society – used in homes, workplaces, schools, public buildings, health care facilities, transportation, and other indoor environments. Consequently, exposure has become almost unavoidable. For instance, in large-scale population studies across four countries (United States, Australia, United Kingdom, and Sweden), an estimated 99.1% of adults are exposed to fragranced products, at least once a week, from their own use (98.3%), from others’ use (90.6%), or from either or both (Steinemann 2021).

Second, adverse health effects from exposure to fragranced products are also pervasive and can be severe. In the aforementioned international studies, 32.2% of adults report health problems, such as breathing difficulties and migraine headaches, when exposed to one or more types of fragranced products, such as air fresheners, laundry products, and cleaning supplies. Further, 9.5% of adults report the effects can be disabling. Among vulnerable subpopulations, the prevalence of adverse effects is higher. For instance, 57.8% of asthmatic individuals and 75.8% of autistic individuals report adverse effects from fragranced products (Steinemann 2019c).

Third, relatively little is known about the actual ingredients in these products. No law in any country requires the disclosure of all specific ingredients in a consumer product (apart from foods, drugs, and cosmetics). Moreover, no law requires the disclosure of all specific ingredients in the fragrance mixture added to any product. However, studies found that typically fewer than 4% of all volatile ingredients, and 5% of all potentially hazardous air pollutants, are actually disclosed on product labels or safety data sheets. Thus, and paradoxically, an important source of exposure to pollutants indoors, fragranced consumer products, is exempt from full disclosure of the ingredients that contribute to the pollutants (Steinemann 2021).

Fourth, economic and societal consequences are compelling. In the international studies, 9.0% of adults have lost workdays or a job, within a past year, due to exposure to fragranced products in their workplace. Direct personal costs from exposure exceeded \$132 billion USD (Steinemann 2019b). Fragranced product exposures can also restrict access in society. For instance, 13.3% of the public report they are unable or reluctant to use the restrooms in a public place because of the presence of an air freshener, deodorizer, or scented product (Steinemann 2019b).

Fifth, and optimistically, improvements to indoor air quality can be readily and effectively achieved – with fragrance-free policies, practices, and products. Across four countries, a strong majority of the general public would prefer that workplaces, health care facilities, health care professionals, hotels, and airplanes were

fragrance-free rather than fragranced. Fragranced products can be removed entirely (such as with air fresheners) or replaced with fragrance-free versions (such as with laundry products). The result can be mutually beneficial to indoor air quality, human health and well-being, and the environment (Steinemann 2019a, 2021).

The specific aims of this chapter are to (1) provide information on the methods for measurement of VOCs emitted from products, VOCs in chamber studies, and VOCs within indoor environments, (2) analyze and synthesize data findings and research findings on product ingredients, emissions, and indoor air quality, and (3) offer strategies and methods to improve indoor air quality. This chapter will focus on VOCs, while recognizing that products can emit additional types of pollutants.

Measurement Methods and Techniques

This section provides background information and details of the methods and techniques used to analyze and quantify volatile compounds emitted from products, in environmental chamber studies, and within indoor environments. It includes details of the sampling strategies, sampling media, as well as techniques to analyze and quantify volatile compound data. The methods selected for this chapter include headspace GC/MS analysis, environmental chamber experiments, and measurement of volatile compounds within indoor environments.

Measurement of VOCs Emitted from Consumer Products

Overview

Gas chromatography-mass spectrometry (GC/MS) is an analytical method widely used to analyze and identify the chemical components in samples. When GC/MS is equipped with a column (e.g., coated capillary) for VOCs, it can be used for separation, analysis, and characterization of VOCs from samples. Among the different sampling techniques for GC/MS (e.g., direct injection, headspace sampling, automated thermal desorption), headspace sampling is used for the analysis of volatile chemicals in solid, liquid, and gaseous samples. A benefit of headspace sampling is that direct liquid or solid injection to the GC/MS is avoided. This approach means that the complex sample matrix in a liquid or solid sample can be simplified to the gas phase (EPA 1997; EPA Method 5021A 2014; Bicchi 2000).

For analyses using static headspace gas chromatography, liquid or solid samples are placed in a closed vial where an equilibration between the sample and the gas phase is established. This allows the capture and injection of the headspace gas into the GC/MS using a gas-tight syringe. A wide range of organic compounds can be detected using this method (provided they have sufficient volatility). The method is designed for analysis of samples containing low concentrations of VOCs. This procedure can be applied to solid samples with high concentrations of VOCs or to oily materials that may not be appropriate for the low-concentration technique (EPA 1997; EPA Method 5021A 2014).

GC/MS analysis of volatile organic compounds using headspace gas chromatography measurements generally follow the guidelines found in US EPA Compendium Method TO-15 (EPA 1999) and EPA Method 5021A (EPA 2014).

This section provides detailed information on headspace GC/MS measurements for analysis of fragranced consumer products, as used in our prior studies (e.g., Nematollahi et al. 2018a, b, 2019).

Details of Headspace Analysis Techniques

Headspace GC/MS measurements of products were performed using a Shimadzu GC/MS-QP2010 Plus instrument coupled to an automated Shimadzu AOC-5000 sample injection system. Approximately 2 g of each product were weighed into a 10 mL amber vial. Each vial was then tightly sealed with a magnetic screw cap with a PTFE/silicone septum. Samples were incubated at 40 °C for 1 h immediately prior to injection of 2.5 mL of the headspace into the injection port heated at 240 °C (split ratio 25). Separation was performed on a BPX-VOL capillary column (30 m × 0.25 mm, 1.4 µm film thickness) using helium as the carrier gas (flow rate 30 cm/s). The oven temperature was kept at 35 °C for 3 min, then increased by 5 °C/min to 220 °C and held at this temperature for 5 min. The total run time was 45 min. The mass spectrometer ion source and interface temperatures were maintained at 200 °C and 240 °C, respectively. The mass spectrometer was operated in full scan mode between 25 and 400 m/z. Blanks were analyzed periodically each day to account for any background impurities (Nematollahi et al. 2018a). The volatile sample components were identified based on the mass spectral library of the National Institute of Standards and Technology NIST Version 2.0 (Stein 2008).

This analysis focused on the VOC emissions emitted from products, even though other chemical classes (such as semi-volatile or nonvolatile organic compounds) could also be presented in the products. Moreover, this analysis focused on the primary VOC emissions emitted from products, even though secondary pollutants (such as formaldehyde) could also be generated. This leads to the need for chamber studies to understand the effects of interactions with other chemicals such as ozone.

Measurement of VOCs in Chamber Studies

Overview

Over the past 30–40 years, environmental chamber studies have been used to investigate the volatile emissions from consumer products and other materials. Environmental test chambers provide a precisely controlled environment that can be used to investigate the types and concentrations of emissions as well as the influence of environmental factors such as temperature, relative humidity, and air flow (Salthammer 2009).

Typically, a product (or sample) is placed in the chamber and the emissions of VOCs and other compounds are monitored by extracting air samples from the chamber. Air samples are collected onto sampling media (e.g., Tenax sorbent tubes) for subsequent analysis by thermal desorption (TD)/gas chromatography

(GC)/mass spectrometry (MS) (Destaillets et al. 2006). Controlled chamber experiments allow a more realistic understanding of the volatile emissions from products. In some experiments, oxidants such as OH radical or ozone are introduced into the chamber to investigate chemical reactivity of product emissions and simulate real world air pollutant interactions. Such experiments allow an understanding of the primary and secondary pollutants generated upon interaction with other gaseous pollutants in the chamber.

Details of chamber methods are included in the ISO 16000 series. For example, ISO 16000-6 (2021) provides methods for determination of VOCs in indoor and test chamber air (ISO 2021). The American Society for Testing and Materials (ASTM) also provides several emission chamber test methods, such as small-scale environmental chamber determinations of organic emissions from indoor materials/products (ASTM 2017).

Details of Chamber Study Techniques

Several authors have investigated VOCs emissions from fragranced consumer products in environmental chambers. Studies have focused on primary emissions from air fresheners and cleaning products (e.g., Singer et al. 2006a), and secondary organic aerosol (e.g., fine particles) generated from ozone-initiated reactions with fragranced products (Singer et al. 2006b; Coleman et al. 2008; Destaillats et al. 2006). This section will briefly summarize some of the methods used in chamber studies of air fresheners, with focus on the methods used to evaluate primary emissions and secondary reaction products (e.g., formaldehyde, PM_{2.5}).

First, we will focus on the methods used to evaluate primary volatile emissions from an air freshener in a large chamber (50 m³) as reported by Singer et al. (2006a). The chamber was made with conventional construction materials (e.g., wood, plywood, gypsum wall board) and included the following items: a small laminated table (surface area: 1.16 m²) positioned in the middle of the room and a series of air mixing fans in each corner. It was mechanically ventilated at approximately 0.5 h⁻¹ with an outdoor air supply that passed over a bed of activated carbon to remove ozone and organic compounds. Temperature was controlled but relative humidity was not. In the study, five readily available cleaning products and one plug-in air freshener were evaluated in the chamber under a series of product usage scenarios.

The air freshener was a “plug-in” type that contained unsaturated terpenoids (scented oil) dispersed by a heated dispenser. During the tests, the device was operated at the highest of three possible settings achieving an emission rate of 1.5 g per day. Air samples were collected on to Tenax sorbent tubes at pump flow rates of between 1.8 and 5.5 cm³/min for between 2 and 5 min (Singer et al. 2006a).

Samples were analyzed by thermal desorption gas chromatography/mass spectrometry (TD-GC/MS) in accordance with USEPA Method TO-1 (USEPA 1984). For details, see Singer et al. (2004).

Next, we will consider studies that evaluated primary and secondary emissions from air fresheners, including secondary organic aerosols (SOAs) from chemical interactions with oxidants. Destaillats et al. (2006) studied the reaction of ozone with terpene emissions from air fresheners and cleaning product in a 198 L stainless-

steel chamber lined with a Teflon film. (Teflon was used to reduce surface-related interactions and ozone decomposition.) The chamber had two inlet ports, one outlet port, and was operated under constant flow and positive pressure. Product gas-phase components (e.g., an air freshener) was introduced into one port, and an air stream containing ozone was admitted at the second inlet. Ozone was produced by UV irradiation of an airstream and measured using a calibrated ozone sensor; before and after each run, and at the outlet of the chamber. The temperature and relative humidity (RH) in the chamber were logged continuously. Airflow into the chamber was “zero quality” compressed air adjusted to obtain a RH between 40% and 60%. The chamber was located in a temperature controlled (23 ± 0.5 °C) room with volume of 20 m³ (Destaillets et al. 2006). Key variables explored in the study were ACH (between 1 and 3 h⁻¹), reaction time, and ozone concentration (high: 120–130 ppb, moderate: 60 ppb).

Sampling of VOCs followed similar methods reported in Singer et al. (2006b). To monitor levels of secondary pollutants, the study also detailed methods to determine the concentrations of aldehydes, fine particulate matter, and OH radicals. Many of these methods are covered in other sections of this chapter, book. For further details, please see Destaillats et al. (2006).

Measurement of VOCs Within Indoor Environments

Overview

A review of the methods used for sampling and analysis of indoor VOCs found that there is no standard (global) approach for IAQ sampling or VOC reporting (Goodman et al. 2017). Among the most widely recognized sampling and analytical methods are the protocols published by the International Organization for Standardization (e.g., 16,000 series) and the US EPA (e.g., Compendium Methods TO17 for VOCs and TO11A for carbonyls and formaldehyde) (US EPA 1999a, b). Sampling methods can vary by approach, media, time, volume, and active or passive techniques (Goodman et al. 2017). Active sampling requires a pump or evacuated canisters whereas passive sampling is diffusion controlled. Active sampling approaches include SUMMA canisters, sorbent tubes, and multisorbent tubes. Passive sampling generally requires only a single sorbent due to the lower diffusion controlled adsorption rates. These are often in the form of a disc, radial, or tape monitors.

The sampling methods chosen are critical as they influence the reliability of data and determine whether the findings can be compared to other studies and to health-based guidelines. For example, to evaluate levels of formaldehyde for comparison to the WHO guidelines (i.e., WHO 2010), active sampling for 30 min is recommended.

Details of VOC Sampling Techniques

Large Population-Based IAQ Studies

There have been significant research efforts that aim to understand levels of VOCs and aldehydes within homes, schools, and offices across Europe (Mandin et al. 2017;

Trantallidi et al. 2015), homes in Canada (Zhu et al. 2013), and offices and homes in the UK and the USA (i.e., Wang et al. 2017; Girman et al. 1999). This section summarizes the methods used in three of these studies.

First is the OFFICAIR study, which evaluated the levels of VOCs and aldehydes in 37 new or recently renovated office buildings across Europe, during the summer and winter seasons of 2012–2013 (Mandin et al. 2017). A key objective of the study was to develop a framework and tools to support health-based risk assessments of IAQ in new or recently renovated office buildings. In each office building, 4 rooms were investigated (148 rooms in total) from 8 European countries (i.e., Greece, Portugal, Spain, France, Italy, Hungary, the Netherlands, Finland, Belgium, the UK, and Denmark). None of the rooms were naturally ventilated and almost all rooms were equipped with a ventilation system (92%) and a cooling system (95%). Tests were performed for targeted pollutants including 12 VOCs, 7 aldehydes, ozone, and nitrogen dioxide. VOC samples were collected using Radiello® passive samplers (120-2 diffusive body, 145 cartridge) for 5 days. The VOCs were analyzed using thermal desorption coupled with capillary GC/MS in accordance with the methods described in ISO 16017–2. The thermal desorption was performed by heating the sampling tubes to 300 °C for 10 min using helium with flow rate of 50 mL min⁻¹. The desorbed VOCs were injected onto the GC/MS via a heated transfer line at 200 °C and separated using a capillary column (60 m × 250 µm × 1.4 µm) (GsTEK-624). Helium was used as the carrier gas with a flow rate of 6 mL min⁻¹. The oven temperature was kept at 40 °C for 5 min, then increased by 6 °C·min⁻¹ to 230 °C, and kept there for 5 min. The mass spectrometer was operated in full scan mode between 35 and 300 amu. Aldehydes were collected using Radiello® DNPH passive samplers (120-1 diffusive body, 165 cartridge) for 5 days. The aldehydes were analyzed using high-performance liquid chromatography coupled with UV detection in accordance with the methods described in the ISO 16000–4 standard. For additional details, see Mandin et al. (2017).

Second is the Canadian population-based national indoor air quality survey conducted in 2009–2011 within 3,857 households, including 3218 houses, 546 apartments, and 93 other dwellings, across Canada (Zhu et al. 2013). In this study, there were almost twice as many older dwellings (>50 years) than the newer dwellings (<10 years). The tests were performed for 84 targeted VOCs. Samples were collected using passive sampling techniques that were deployed by study participants in their homes using sampling tubes (Carbopack B 60/80 sorbent media) for a period of 7 days. The tubes were made from stainless steel (ID 5 mm × 90 mm long) and packed with Carbopack B 60/80 sorbent media. Deployment included switching a protective brass end cap with a Teflon diffusion cap during sampling, replacing the protective cap at the end of the sampling period, and finally shipping the sample in a prepaid Canada Post envelope to the analytical laboratory. The VOCs were analyzed using thermal desorption (model ATD650, Perkin-Elmer) coupled with capillary GC/MS (Agilent). Thermal desorption was performed by heating the sampling tubes to 330 °C for 12 min using helium with flow rate of 60 mL/min. The desorbed VOCs were injected onto the GC/MS via a heated transfer line at 300 °C and separated using a capillary column (60 m × 250 µm × 1.4 µm) (GsTEK-624). The oven

temperature was kept at 45 °C for 3 min, then increased by 6 °C·min⁻¹ to 180 °C, then 30 °C·min⁻¹ to 250 °C and kept there for 10 min. The mass spectrometer was operated in full scan mode between 33 and 400 amu. For more details, see Zhu et al. (2013).

Third is the United States Environmental Protection Agency's Building Assessment Survey and Evaluation study (BASE), a major cross-sectional study of indoor air quality at 56 public and private office buildings across the USA, conducted during summer and winter of 1995–1998 (Girman et al. 1999). Samples collected included VOCs, aldehydes, particulate matter, radon, microbiological contaminants, carbon monoxide, carbon dioxide, temperature, relative humidity, as well occupant perceptions of IAQ. For VOCs, the analysis was performed for 46 targeted compounds, many of which were selected based on their potential to be irritants, carcinogens, and systemic toxicants (Girman et al. 1999). Samples were collected at three indoor locations and at one outdoor location during times of normal building occupancy. Active sampling (requiring low flow pumps) was used in the study and different higher flow rates were used: for the indoor samples, flow rates were 5 ml/minute, and for the outdoor samples, flow rates were 6–8 ml/min (due to expected lower outdoor concentrations). Samples were collected using multisorbent sampling media (Tenax-TA, Ambersorb XE-340, and activated charcoal) for 8–10 h. The VOCs were analyzed using thermal desorption coupled with GC/MS using a modified version of EPA Method TO-1 (Berkeley Analytical Laboratories, Berkeley, CA). Formaldehyde and acetaldehyde were also sampled (although the detailed method are not described here). For additional details, see Girman et al. (1999).

A strength of population-based studies is that a large set of data is collected from a large number of buildings, and this provides more meaningful information. These data are potentially more representative of the levels of indoor pollutants and exposures of the wider population. One limitation of these studies is that they are based on a brief window or “snapshot” in time and may not reflect the long-term levels of pollutants. Also, short-term (i.e., 30 min) exposure data are needed to assess acute health effects (e.g., for formaldehyde) and cannot be easily assessed in such large studies.

VOCs Within Indoor Environments

This section summarizes the methods used in a study that investigated VOCs at a large Australian university. Several categories of indoor environment were evaluated in the study including locations of campus services, restrooms, renovated offices, a green building, meeting areas, and classrooms. Analysis of 41 VOCs across 20 locations observed indoor concentrations higher than outdoor concentrations for 97% of all VOC measurements (493 unique comparisons). Because this chapter focuses on fragranced consumer products as sources, we will concentrate our analysis on three indoor categories where levels of volatile emissions were among the most prevalent compounds. These are campus services, restrooms, and classrooms. The sampling methods used in the study are described below.

Indoor air samples were collected and analyzed in accordance with USEPA compendium methods TO-17 and TO-11A (US EPA 1999a, b). In all cases, outdoor

air samples were collected within close proximity to, and simultaneously with, indoor air samples.

Further details of the methods used in this study are as follows. For VOCs (other than carbonyl compounds), two multi-adsorbent tubes in series (Markes Carbograph 1TD/Carbopack X) were connected to a SKC Pocket Pump 210-1002 (Eighty Four PA, USA) at a flow rate of approximately 35 mL per minute for 2.5 h (5 L). For carbonyl compounds, a single low pressure drop dinitrophenylhydrazine LpDNPH S10 cartridge (Supelco Cat No 21014) was connected to TSI Incorporated SidePak SP730 (Shoreview, MN, USA) at a flow rate of approximately 1200 mL per minute for 7 h (500 L). An ozone scrubber (Supelco Cat No 505285) was placed in front of the S10 cartridge to prevent ozone interference with the carbonyls. According to established methods, 10% of samples were reserved as blanks (Wallace et al. 1991). Temperature and relative humidity were measured using a portable weather station (Holman, WS5052B).

A total of 47 VOC tubes and 35 carbonyl cartridges (indoor and outdoor) were analyzed. Analysis of VOCs used a PerkinElmer TurboMatrix™ 650 automated thermal desorber (ATD) and a Hewlett Packard 6890A gas chromatography (GC)/mass spectrometry (MS)/flame ionization detector (FID) in accordance with US EPA method TO-17. An Agilent (DB5-MS) capillary column (60 m × 0.32 mm × 1 µm) was used for compound separation. Certified gas standards were used for calibration; these included a benzene, toluene, ethylbenzene, and xylenes (BTEX) standard (Air Liquide–Scott Specialty Gases, Longmont, CO, SA), and a BTEX plus isoprene standard (National Physical Laboratory, Middlesex, UK). Where a gas standard was not available, quantification of VOCs was done using the FID response factor of toluene. Only VOCs with concentrations greater than the method detection limit (MDL) of the analytical instrument were reported. For VOCs, the MDL was between 0.01 and 0.04 µg/m³ determined as the 95th percentile of the response from 7 field blanks.

Analysis of carbonyl compounds (such as formaldehyde) is important as they can be both primary and secondary emissions from fragranced consumer products. In the study, analysis of carbonyls used ultra-high performance liquid chromatography (UHPLC) consisting of a Thermo Scientific Dionex Ultimate 3000 RS system with diode array detector (DAD) and mass spectrometry (MS) detector in accordance with US EPA Method TO-11A. A rapid separation liquid chromatography (RSLC) Acclaim™ (No. 077973) carbonyl column (150 mm × 2.1 mm, particle size: 2.2 µm) was used for compound separation. The chromatographic conditions included a flow rate of 0.4 mL/min and an injection volume of 3.0 µL. The DAD was operated in the 220–520 nm wavelength range with 360 nm used for mono-carbonyl quantification. The peaks were separated by gradient elution with an initial mobile phase of 52% acetonitrile and 48% deionized water (18.2 ΩM cm, Millipore Milli-Q Advantage) for 8.3 min, followed by a linear gradient to 100% acetonitrile for 8 min, with a column temperature of 30 °C. A certified liquid standard (Supelco Carb Method 1004 DNPH mix 2 C/N 47651-U) containing 30 µg/mL of each derivatized carbonyl was diluted 1:25 in a volumetric flask. This prepared standard was then used to perform a four-point calibration (0.15, 0.30, 0.6, and 1.2 µg/mL).

For carbonyl compounds, the MDL was between 0.01 and 0.07 $\mu\text{g}/\text{m}^3$, determined as the 95th percentile of the response from 8 field blanks. All original concentrations were blank corrected.

As with many experimental protocols, the methods used in this study had several limitations. First, the durations for sampling (e.g., 2.5 h, 7 h), required to collect sufficient volume to meet MDLs, differed from the durations for health-based guidelines (e.g., 30 min), thus preventing direct comparisons. Second, ethanol concentrations are semiquantitative due to possible sample breakthrough of multi-sorbent tubes. Third, sampling was conducted during summer and autumn, which may not represent VOC levels during all seasons.

It is useful to know that the sampling duration and volume collected during VOC and carbonyl sampling can be adapted for situations that require compliance with acute exposure guidelines (e.g., formaldehyde, 30 min) or to capture peak concentrations of pollutants during short-term activities such as cleaning or use of a fragranced consumer product. For instance, in a study of volatile emissions from dryer vents, a single multi-adsorbent tube (Markes Carbograph 1TD/Carbopack X) was connected to an SKC sampling pump (AirChek 220-5000TC) at a flow rate of approximately 150 mL per minute for 1 h (9 L) (Goodman et al. 2018).

Product Ingredients, Emissions, and Disclosure

Volatile Ingredients and Disclosure

Volatile Ingredients Emitted

This section provides results from the analysis of 289 products including air fresheners, laundry products, cleaning supplies, personal care products, hand sanitizers, air disinfectants, sunscreens, baby products, essential oils, and car air fresheners, both green and regular products. (In these studies, “green products” are considered as products with the claim of “green,” or a related term such as “organic,” “natural,” “no petrochemicals,” “certified green,” “certified organic,” or “essential oils” for the entire product or specific ingredients. “Regular products” are the products other than those in the “green” category.)

Notwithstanding the regulatory protections on full ingredient disclosure, products can be chemically analyzed to determine their constituents. (Although some companies have taken voluntary steps to disclose ingredients used in their fragranced products, this information is often a consolidated list of chemicals, rather than specific chemicals in a specific product. In cases where specific product information is provided, the general term “fragrance” is listed rather than the individual and specific chemicals in that fragrance mixture. Thus, consumers still lack information about complete and specific ingredients and potential exposures from any particular product.) A set of studies analyzed volatile organic compounds (VOCs) emitted from common consumer products, both fragranced and fragrance-free versions, and green and regular versions (Steinemann 2015; Nematollahi et al. 2018a, b, 2019, 2021; Steinemann et al. 2020, 2021). Products were randomly selected from stores in

the USA and Australia (AU), although the same or similar products are also available internationally.

The studies used gas chromatography/mass spectrometry (GC/MS) headspace analysis to identify the VOCs emitted directly from each product as described in the section on “[Details of Headspace Analysis Techniques](#).” The top 20 peaks (highest concentration compounds) for each product were identified from the sample chromatogram using mass spectral library matches.

Some definitions for these studies are as follows:

“VOC occurrences” refers to the collective number of individual VOCs or ingredients emitted from the products.

“VOC identities” refers to the number of distinctly named VOCs emitted from one or more of the products.

Main results of seven studies (Steinemann [2015](#); Nematollahi et al. [2018a, b, 2019, 2021](#); Steinemann et al. [2020, 2021](#)) are provided below. A summary of these results are provided in Table 1.

1. Study of 37 common consumer products: air fresheners, laundry products, cleaning supplies, and personal care products. The GC/MS analyses found 559 VOC occurrences, representing 156 VOC identities. Among these VOCs, 230 VOC occurrences, representing 42 VOC identities, are classified as potentially hazardous. All products emitted potentially hazardous VOCs.

The most common fragranced product VOCs (> 80% of products) were limonene and beta-pinene. The most common fragrance-free product VOC (100% of products) was ethanol, which was also in fragranced products. The most common potentially hazardous VOCs (>75% of products) were ethanol and limonene. No significant difference was found in the emissions of hazardous air pollutants between green fragranced products and regular fragranced products.

Fewer than 3% of the VOCs and fewer than 6% of potentially hazardous VOCs were disclosed on the product labels, safety data sheets, or website. Further, among the fragranced consumer products (other than cosmetics), 91% did not disclose the presence of a “fragrance” on the label or safety data sheet. Among the fragranced cosmetics, 89% did not disclose “fragrance” on the safety data sheet, but all disclosed “fragrance” on the label, as required.

2. Study of 134 common consumer products: air fresheners, laundry products, cleaning supplies, personal care products, and sunscreens. The GC/MS analyses found 1,538 VOC occurrences, representing 338 VOC identities. Among these VOCs, 517 VOC occurrences, representing 69 VOC identities, are classified as potentially hazardous. Nearly all products (99%) emitted potentially hazardous VOCs.

The most common fragranced product VOC (77% of products) was limonene. The most common fragrance-free product VOC (40% of products) was ethanol. The most common potentially hazardous VOCs (> 40% of products) were limonene and ethanol. No significant difference was found in emissions of the most prevalent potentially hazardous VOCs between green fragranced products and regular fragranced products.

Table 1 Summary of top 10 prevalent compounds emitted from the products across 7 studies

^aClassified as potentially hazardous under Safe Work Australia, Hazardous Chemical Information System (SWA 2020)

Fewer than 10% of VOCs, and fewer than 4% of potentially hazardous VOCs, were disclosed on the product labels, safety data sheets, or website.

3. Study of 42 fragranced baby products: shampoos, lotions, hair sprays, and fragrance. The GC/MS analyses found 684 VOC occurrences, representing 228 VOC identities. Among these VOCs, 207 VOC occurrences, representing 43 VOC identities, are classified as potentially hazardous.

The most common fragranced baby product VOC (67% of products) was limonene. The most common potentially hazardous VOCs (>55% of products) were limonene, acetaldehyde, and ethanol. No significant difference was found in the emissions of the most prevalent potentially hazardous VOCs between green fragranced baby products and regular fragranced baby products.

Fewer than 5% of VOCs, and fewer than 13% of potentially hazardous VOCs, were disclosed on the product labels, safety data sheets, or website.

4. Study of 24 commercial essential oils. The GC/MS analyses found 589 VOC occurrences, representing 188 VOC identities. Among these VOCs, 124 VOC occurrences, representing 33 VOC identities, are classified as potentially hazardous.

The most common essential oil VOCs (> 70% of oils) were alpha-pinene, limonene, and acetone. The most common potentially hazardous VOCs (> 70% of oils) were limonene and acetone. No significant difference was found in the emissions of the most prevalent potentially hazardous VOCs between natural and regular essential oils. No ingredients were disclosed on any of the essential oil labels.

5. Study of 12 car air fresheners. The GC/MS analyses found 546 VOC occurrences, representing 275 VOC identities. Among these VOCs, 30 VOC occurrences, representing 9 VOC identities, are classified as potentially hazardous.

The most common car air freshener VOCs (>70% of products) were limonene, benzyl acetate, acetone, and ethanol. The most common potentially hazardous VOCs (67% of products) were acetaldehyde and methanol. No significant difference was found in the emissions of the most prevalent potentially hazardous VOCs between green and regular car air fresheners. Fewer than 2% of VOCs, and none of the potentially hazardous VOCs, were disclosed on the product labels, safety data sheets, or website.

6. Study of 14 commercial essential oils with therapeutic claims. The GC/MS analyses found 1,034 VOC occurrences, representing 378 VOC identities. Among these VOCs, 251 VOC occurrences, representing 60 VOC identities, are classified as potentially hazardous.

The most common essential oil VOCs (> 90% of oils) were acetaldehyde, alpha-phellandrene, alpha-pinene, camphene, limonene, methanol, terpinolene, 3-carene, acetone, beta-phellandrene, ethanol, and gamma-terpinene. The most common potentially hazardous VOCs (> 90% of oils) were acetaldehyde, limonene, methanol, acetone, ethanol, and 3-carene.

Fewer than 1% of VOCs, and fewer than 1% of potentially hazardous VOCs, were disclosed on the product labels, safety data sheets, or website.

7. Study of 26 commonly used pandemic products: hand sanitizers, air disinfectants, multipurpose cleaners, and handwashing soap. The GC/MS analyses found 399 VOC occurrences, representing 172 VOC identities. Among these VOCs, 127 VOC occurrences, representing 46 VOC identities, are classified as potentially hazardous. Nearly all products (99%) emitted potentially hazardous VOCs.

The most common fragranced product VOC (40% of products) were limonene, ethanol, alpha-pinene, beta-pinene, and acetaldehyde. The most common potentially hazardous VOCs (25% of products) were limonene, ethanol, acetaldehyde, 3-carene, and methanol. No significant difference was found in emissions of the most prevalent potentially hazardous VOCs between green fragranced products and regular fragranced products.

Fewer than 4% of VOCs, and fewer than 11% of potentially hazardous VOCs, were disclosed on the product labels, safety data sheets, or website.

Across the 7 studies, the 289 products emitted collectively 5,349 VOC occurrences, representing 981 VOC identities. The most prevalent compounds in fragranced products were terpenes (limonene, alpha-pinene, beta-pinene), which were not found in fragrance-free products. The most prevalent compound in fragrance-free products was ethanol, which was also a common compound in fragranced products. Across the studies, the 289 products emitted collectively 1,486 potentially hazardous VOC occurrences, representing 130 VOC identities, which represents 28% of all VOC occurrences.

Relations Between Emissions and Listed Ingredients

Across the studies, on average, fewer than 4% of all VOCs, and fewer than 5% of potentially hazardous VOCs, were disclosed on any product label, safety data sheet, or website.

Ingredients in fragranced consumer products are not required to be specifically and fully disclosed, in any country (Lunny et al. 2017; Steinemann 2015; Steinemann et al. 2011). Main components of the regulations are as follows:

No law in any country requires the full disclosure of all ingredients in a chemical mixture termed “fragrance,” not on the product label, safety data sheet, or website. Instead, a product may list the general term “fragrance” (or another legally approved term, such as “perfume” or “parfum”) instead of listing all individual ingredients in that fragrance.

No law requires that consumer products (other than foods, drugs, and cosmetics) disclose all specific ingredients on the label, safety data sheet, or website. Further,

these products are typically not required to even list the general term “fragrance,” so consumers may not be aware that a product actually contains a fragrance mixture.

For the other classes of consumer products (i.e., foods, drugs, and cosmetics), while they do need to list all ingredients on the label (although not on the safety data sheet), the general term “fragrance” may be used instead of the complete and specific ingredients in that fragrance mixture.

Thus, and paradoxically, a major source of exposure to pollutants, fragranced consumer products, is exempt from full disclosure of the ingredients that contribute to the pollutants. Consequently, the public, professionals, and agencies lack information to understand the links between emissions, exposures, and effects on air quality and health.

Emissions Evaluated in Chamber Studies

This section summarizes results from chamber studies with focus on the primary and secondary emissions from fragranced consumer products including air fresheners. Key findings from each of studies (i.e., Singer et al. 2006a; Destaillats et al. 2006) are provided below.

In a chamber study of primary VOC emissions from an air freshener, among the most prevalent VOCs detected were unsaturated ozone reactive terpenes (e.g., d-limonene), and terpenoids (e.g., linalool, beta-Citronellol), the concentrations of these compounds ranged between 7 and 160 µg/m³ (Singer et al. 2006a). Several other VOCs were also prominent, including benzyl acetate and bornyl acetate and detected at concentrations between 280 µg/m³ and 410 µg/m³, respectively. The emission rates for selected VOCs from the air freshener were 7.7 mg/day for alpha-Citral, 39 mg/day for d-limonene, and 460 mg/day for bornyl acetate (Singer et al. 2006a). The study revealed the emission of terpenes and terpenoids from air fresheners can reach levels of tens to hundreds µg/m³.

Destaillats et al. (2006) focused on the secondary pollutants generated when emissions from fragranced products (such as an air freshener) reacted in the presence of ozone found that the production of secondary pollutants such as aldehydes and particles was mainly dependent on ozone concentration, but also influenced by parameters such as the air change rate. The air freshener in the study had more than 30 components including the following five compounds which exhibited significant reactivity to ozone: d-limonene, linalool, linalyl acetate, dihydromyrcenol, and β-citronellol. Table 2 summarizes results from chamber studies conducted with focus on this group of five compounds as well as the volatile oxidation products generated after interaction with different levels of ozone. When the reactive components of the air freshener were in the chamber with high ozone levels (3ACH), the resulting concentrations of volatile oxidation products were detected: formaldehyde (41 ± 0.4 ppb), acetone (41 ± 5), glycolaldehyde (13 ± 0.3), formic acid (24 ± 6), and acetic acid (36 ± 23). Experiments conducted at moderate ozone concentrations (approximately half) notably reduced the levels of volatile oxidation products detected (Table 2). A scanning mobility particle sizer

Table 2 VOCs and reaction products of an air freshener with ozone

	High ozone (3ACH)	Moderate ozone (3ACH)
Species	Concentration (ppb)	Concentration (ppb)
Ozone	126 ± 6	63 ± 0.5
<i>VOC components</i>		
d-limonene	121 ± 2	108 ± 3
Linalool	176 ± 3	170 ± 4
Linalyl acetate	66 ± 7	57 ± 3
Dihydromyrcenol	241 ± 3	242 ± 6
β-citronellol	19 ± 1	19 ± 1
<i>Volatile oxidation products</i>		
Formaldehyde	41 ± 0.4	16 ± 2
Acetaldehyde	ND	ND
Acetone	41 ± 5	14 ± 0.6
Glycolaldehyde	13 ± 0.3	7 ± 0.3
Formic acid	24 ± 6	14 ± 6
Acetic acid	36 ± 23	ND

ND = not detected

Data in this table was adapted from Destaillats et al. (2006)

(SMPS) (3071A, TSI Inc) detected particle nucleation events immediately after reactants (i.e., air freshener VOCs and ozone) were mixed in the chamber. Nucleation events were followed by a significant degree of secondary particle growth (Destaillats et al. 2006).

This environmental chamber study demonstrates the potential impact of ozone-initiated chemistry on the formation of secondary volatile pollutants and particles from air fresheners. Given the everyday and widespread use fragranced consumer products such as air fresheners, and the close proximity of humans, use of air fresheners may contribute to indoor exposure to certain secondary air pollutants, including formaldehyde (Destaillats et al. 2006).

VOCs from Product Use Indoors

This section will summarize results from several population-based studies across Europe, Canada, and the USA, as well as a study that investigated indoor levels of VOCs and carbonyl compounds at a large Australian university. In all of the studies in this section, the focus will be on the levels of volatile compounds associated with emissions from fragranced consumer products.

Population-Based Studies

This section provides results of volatile compounds within indoor environments from four population-based studies across Europe, Canada, the UK, and the USA. Main results of the three studies (Mandin et al. 2017; Zhu et al. 2013; Girman et al. 1999) are provided below.

1. *Study of 148 rooms in 37 office buildings across 8 European countries.*

Among the 19 targeted pollutants in this study, all were detected in at least 75% of the offices in both summer and winter seasons. Among the VOCs detected, the highest average concentration was measured for toluene in summer ($4.7 \mu\text{g m}^{-3}$) and for d-limonene in winter ($13 \mu\text{g m}^{-3}$). Compared to other studies of indoor air quality in office buildings, concentrations of benzene, toluene, ethylbenzene, and xylene were lower; and concentrations of α -pinene and d-limonene were higher in the OFFICEAIR buildings. In terms of the potential adverse health effects of volatile compounds, the 5 day average indoor concentrations for formaldehyde and ozone were lower than WHO indoor and ambient air quality guidelines; and for acrolein, α -pinene, and d-limonene, levels were lower than the estimated thresholds for irritative and respiratory effects (Mandin et al. 2017).

2. *Study of 3,857 households, including 3,218 houses, 546 apartments, and 93 other dwellings, across Canada.*

Among the 84 targeted VOCs, 47 were detected in more than 50% of Canadian homes. Among the 47 VOCs detected, 33 of them were higher in houses than in apartments, while only 4 were lower in houses than in apartments. The detection frequencies ranged from 51.62% for 1-propanol to 99.95% for toluene, ethylbenzene, and o-xylene. Compared to previous Canadian population-based studies, the arithmetic means of VOCs in this study were 2–5 times lower than those VOCs in the 1992 study, and the geometric means of VOCs were comparable to those reported in Europe. The VOCs detected within the indoor environments could be emitted from a number of possible common sources, including consumer products (Zhu et al. 2013). Further analysis of the data from this study, including levels of VOCs and associated health effects of the participants, has revealed that exposure to limonene may increase asthma prevalence (Dales and Cakmak 2019).

3. *Study of 56 public and private office buildings across the USA.*

Forty-eight VOCs were measured indoors at quantifiable concentrations. Eight VOCs, including acetone, toluene, m- and p-xlyenes, o-xylene, n-decane, n-undecane, n-dodecane, and nonanal, were detected in all samples. Further, 26 VOCs were found in 81–99% of the samples. Seven, VOCs, including acetone, toluene, d-limonene, m- and p-xlyenes, 2-butoxyethanol, and n-undecane, had the largest average indoor concentrations. Finally, 12 VOCs, including acetone, toluene, d-limonene, m- and p-xlyenes, 2-butoxyethanol, n-undecane, benzene, 1,1,1-trichloroethane, n-dodecane, hexanal, nonanal, and n-hexane, showed highest concentration frequency distributions compared to average indoor concentrations (Girman et al. 1999).

These studies showed that the VOCs within indoor environment can be emitted from several common sources, including fragranced consumer products. These findings can be used to inform risk assessment and risk management of exposure to VOCs within indoor environments. For example, in the OFFICEAIR Study, the use of consumer products (e.g., cleaning and personal care products) was found to be an important determinant of aldehyde and VOC levels in the

buildings. Strategies for reducing emissions included replacement with lower emitting alternative products (Mandin et al. 2017).

Indoor Air Environments at a University

We include selected results from this study as they provide a useful example of emissions associated with fragranced consumer products in everyday indoor locations, namely restrooms, classrooms, and campus services.

Among the 41 compounds analyzed, 17 were detected in all indoor and outdoor locations (i.e., 100% of measurements were above MDL). The concentrations of VOCs in outdoor (ambient) air were also evaluated in the study. These compounds were isobutane, n-butane, ethanol, 2-methylbutane, benzene, toluene, ethylbenzene, o-, m-, p-xylene, α -pinene, d-limonene, formaldehyde, acetaldehyde, acetone, methyl glyoxal, and hexaldehyde (Goodman et al. 2018). Notably, the hazardous air pollutants formaldehyde, benzene, toluene, and o-, m-, p-xylene were detected in all indoor and outdoor locations. In addition to these 17 compounds, 5 compounds (i.e., styrene, β -pinene, eucalyptol, naphthalene, and glyoxal) were detected in all indoor locations, and in up to 75% of outdoor locations. Benzothiazole was the only compound present in all indoor locations, but not at all outdoors.

Table 3 provides the ratios of indoor concentrations to corresponding outdoor concentrations (I/O ratios) for campus services, restrooms, and classrooms (i.e., three of the six indoor categories). Indoor concentrations were higher than outdoor concentrations for nearly all VOCs measured (above MDL).

Within each environment, the compounds with the highest I/O ratios were as follows: d-limonene (331) and ethanol (168) in campus services; ethanol (290) and d-limonene (123) in restrooms; and hexaldehyde (214) and styrene (84) in classrooms (Table 2). For terpenes and terpenoids, the highest I/O ratios were for d-limonene, measured in campus services and restrooms, and for α -pinene and β -pinene, measured classrooms (Fig. 1).

Table 4 shows the 12 most prevalent compounds in each category of indoor environment, ranked by concentration. Across all three environments, the most prevalent compounds at the highest GM concentrations were ethanol, formaldehyde, acetaldehyde, acetone, toluene, n-butane, 2-methylbutane, and d-limonene.

Explanations for higher levels indoors can be explored using the distinguishing features of each indoor environment.

In campus services, ethanol, d-limonene, n-butane, acetone, 2-methylbutane, and formaldehyde were among the most prevalent compounds at the highest concentrations. Many of the compounds identified in campus services have been associated with consumer products and cleaning supplies in previous studies (Steinemann 2015; Nazaroff and Weschler 2004).

In restrooms, ethanol, isobutane, d-limonene, acetone, and formaldehyde were among the most prevalent compounds at the highest concentrations. These compounds are frequently detected in studies of air freshener emissions and cleaning products (Steinemann 2015; Kim et al. 2015; Uhde and Schultz 2015). Yurdakul et al. (2017) identified cleaning agents and air fresheners as sources of VOCs in university offices. In another study, regular morning peaks in the concentration of

a Compounds reported are all above MDL in >50% of locations with corresponding ambient levels above MDL.

b Ethanol concentrations are semi-quantitative due to possible sample breakthrough.

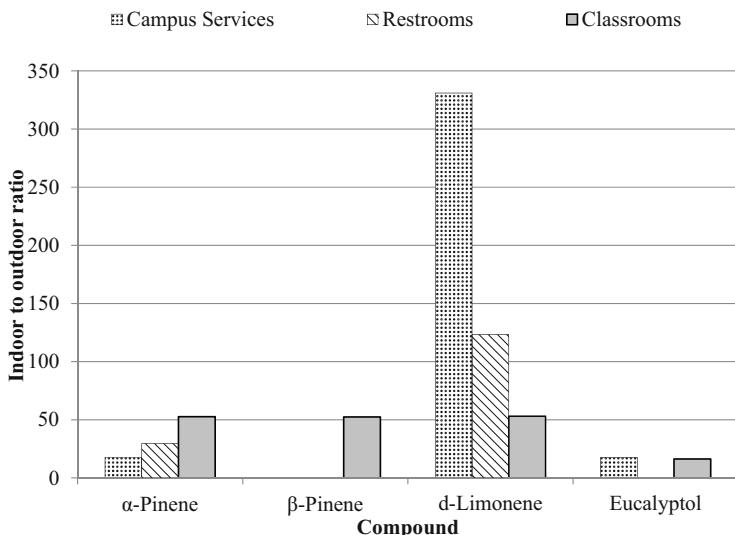

Fig. 1 Indoor to outdoor concentration ratios for terpenes and terpenoids

monoterpenes (range 5–17 ppb) were associated with cleaning activities (Solomon et al. 2008). By comparison, the highest combined concentration of monoterpenes (i.e., d-limonene, α -pinene, and β -pinene) in this study was $60.2 \mu\text{g}/\text{m}^3$ (10.81 ppb) measured in classrooms.

In classrooms, acetone, ethanol, toluene, formaldehyde, and α -pinene were among the most prevalent compounds at the highest concentrations.

Strategies to improve IAQ at a university can be relatively straightforward. For instance, where the primary sources are consumer products such as air fresheners and cleaning supplies, the university has successfully implemented a fragrance-free cleaning policy (in one building). Air fresheners are removed from restrooms, and fragranced cleaning products are used sparingly, if at all. An interesting extension of this study would be the comparison of indoor air quality levels before and after the implementation of fragrance-free policies, or a comparison of similar university environments with and without fragrance-free policies.

Improving Indoor Air Environments

Fragrance-Free Policies and Practices

A fragrance-free policy is a protocol, principle, or plan that is implemented to promote an environment without fragrance. Fragrance-free policies can be implemented by and can apply to a range of different groups and individuals, such as government agencies, industries, organizations, institutions, members, and employees. Fragrance-free policies can apply to a range of physical environments,

such as an individual building, a specific area or floor in a building, a campus with a collection of buildings, or all buildings and facilities of an organization.

A fragrance-free practice is a practical step or action to reduce or avoid emissions, exposures, and effects from fragranced products. A common practice is the use of fragrance-free products. Fragrance-free products can offer similar functionality but without the potential issues associated with fragranced products. For instance, a cleaning or disinfection product may be similarly effective at its primary function without the added fragrance. Further, changes from fragranced to fragrance-free products can reduce terpenes emissions in a relatively short time period.

“Fragrance-free” products are considered as products with the claim of “fragrance-free” or “no fragrance.” To note, “unscented” products are not included in this category, because they may actually contain a fragrance to cover the scent.

Changing from fragranced to fragrance-free laundry products can reduce concentrations of fragrance chemicals (i.e., limonene) emitted from dryer vents by up to 99% within 4 weeks (Goodman et al. 2019). While the term “fragrance-free

products” is not intended to imply emissions-free products, they do offer an option for consumer product functionality without the fragrance compounds.

In addition, removing or discontinuing use of fragrance products can also reduce emissions and exposures. For instance, removing or turning off air fresheners in a restroom can reduce concentrations of fragrance chemicals within indoor environments by up to 96% within 2 weeks (Goodman et al. 2020). Because fragrance molecules can adhere to surfaces during product use, and be reemitted later even without the product in use, reduction may not be 100% immediately, but fragrance compound concentrations can decrease with time.

Moreover, the fact that fragranced products can constitute a barrier to participation in society can come under the auspices of disability legislation. The change to a fragrance-free product, the removal of the fragranced product, or a modification in facilities or operations to mitigate fragrance exposure, for instance, could be considered forms of reasonable accommodation. To this end, fragrance-free practices and policies have been implemented across the countries to accommodate sensitive and vulnerable individuals, as well as to reduce potential health risks and create a more healthful indoor air environment (Steinemann 2019a).

Switching to Fragrance-Free Products

This section presents the results from a study of the volatile emission from residential dryer vents. The study follows the sampling and analytical methods (as described in the section on “[Measurement of VOCs Within Indoor Environments](#)”) and further details can be found in Goodman et al. (2018). Concentrations of d-limonene at each phase of sampling and in each household are provided in Table 5.

In households using fragranced laundry detergent, the highest concentration of d-limonene from a dryer vent was $118 \mu\text{g}/\text{m}^3$ (mean $33.34 \mu\text{g}/\text{m}^3$). By contrast, in households using only fragrance-free detergent, the highest concentration of d-limonene from a dryer vent was $0.26 \mu\text{g}/\text{m}^3$ (mean $0.25 \mu\text{g}/\text{m}^3$). After households using fragranced detergent switched to using fragrance-free detergent, the concentrations of d-limonene in dryer vent emissions were reduced by up to 99.7% (mean 79.1%).

A strength of this study is the participation of households that use the products in everyday life, demonstrating the practicably achievable reductions in concentrations by switching products. Yet this strength has a corresponding limitation in that the households continued to wash clothing as normal, which may have subjected the machines to track-in fragrances from clothing during the 4-week period of using fragrance-free products. In addition, while reductions in d-limonene approached levels of fragrance-free households, it is conceivable that using fragrance-free products for a longer period of time would result in even further reductions, as the residual fragrance chemicals are removed from the machines and clothing. For instance, residual fragrance chemicals in machines could help explain the anomalous value for household #3 for sample (e) showing an increase in d-limonene.

This study demonstrated the improvements to air quality after switching from fragranced to fragrance-free products. It found that, by a change to fragrance-free laundry products, concentrations of d-limonene can be almost completely eliminated from the dryer vent emissions. This strategy may also reduce the formation and

concentrations of secondary pollutants such as formaldehyde, acetaldehyde, and ultrafine particles. Findings from this study can provide an important foundation for future research, and for demonstrating cost-effective strategies to reduce VOC emissions and personal exposures.

Removing Fragranced Products

This section presents the results from a study of indoor air quality emissions from air fresheners. It demonstrates how air quality within every day indoor environments can be improved by a relatively straightforward approach of switching off or removing the source of VOCs.

Concentrations of d-limonene at each phase of sampling and at each restroom are provided in Table 6.

In restrooms that used air fresheners (#1–4), the concentrations of d-limonene ranged from 5.15 µg/m³ to 9.68 µg/m³ (mean 6.78 µg/m³) on Day 1. After discontinuing use of air fresheners in those same restrooms, the concentrations of d-limonene ranged from (a) 0.23 µg/m³ to 0.72 µg/m³ on Day 3, (b) 0.35 µg/m³ to 1.31 µg/m³ on Day 7, and (c) 0.24 µg/m³ to 2.99 µg/m³ (mean 1.17 µg/m³) on Day 14.

In restrooms that did not use air fresheners (#5–8), the concentrations of d-limonene ranged from 0.23 µg/m³ to 2.29 µg/m³ (mean 0.84 µg/m³) on Day 1, and from 0.60 µg/m³ to 1.34 µg/m³ (mean 1.29 µg/m³) on Day 14.

Table 6 Concentrations and reductions of d-limonene during use, discontinued use, and no use of air fresheners

Restrooms with no use of air fresheners

Restroom #	No air freshener used (Day 1) (µg/m ³)			No air freshener used (Day 14) (µg/m ³)	
#5	2.29	—	—	1.34	—
#6	0.48	—	—	0.71	—
#7	0.23	—	—	0.60	—
#8	0.36	—	—	2.50	—
mean	0.84	—	—	1.29	—

Key findings are as follows: (1) After air fresheners were discontinued from use, concentrations of d-limonene decreased up to 96% (average 81%) over 2 weeks, and major reductions (i.e., 92%) were accomplished by Day 3. (2) For all samples in all restrooms after air fresheners were discontinued or were not used, d-limonene concentrations were lower than any of the initial samples when air fresheners were in use. (3) After air fresheners were discontinued from use, concentrations of d-limonene approached the lower levels of restrooms that had not used any air fresheners (Goodman et al. 2020).

Thus, these findings suggest that discontinuing the use of air fresheners can have an almost immediate benefit for air quality by reducing d-limonene concentrations. These findings are supported by a prior study of dryer vent emissions (Goodman et al. 2019), which found d-limonene concentrations up to 118 µg/m³ during use of fragranced laundry products, and less than 1 µg/m³ during use of fragrance-free laundry products. After switching from fragranced to fragrance-free products for 4 weeks, concentrations of d-limonene decreased as much as 99.7% (mean 79.1%).

Preferences for Fragrance-free Environments

Nationally representative population surveys, across the four countries (The USA, AU, The UK, SE), found that more people, at least twice as many, prefer fragrance-free environments to fragranced environments, such as workplaces, health care facilities and professionals, hotels, and airplanes. Among vulnerable subpopulations, preferences for fragrance-free environments are even higher. Interestingly, even among individuals who do not report fragrance sensitivity, a majority of these non-fragrance sensitive individuals would nonetheless prefer fragrance-free environments. Specific results are presented by Steinemann (2018a, b, 2019a, b).

For example, for workplaces: 47.8% (53.1%, 42.8%, 44.7%, 50.7%) of the general population would support a fragrance-free policy in the workplace, compared to 20.4% (19.7%, 22.2%, 23.3%, 6.4%) that would not. Also, 56.7% of asthmatic individuals would support fragrance-free workplace policies, compared to 17.7% that would not; 65.5% of autistic individuals would support fragrance-free workplace policies, compared to 24.0% that would not; and 40.4% of non-fragrance sensitive individuals would support fragrance-free workplace policies, compared to 23.4% that would not. Thus, more than twice as many individuals would support (than would not) fragrance-free policies in workplaces.

In summary, across all settings (workplaces, health care facilities and health care professionals, hotels, and airplanes), more than twice as people prefer fragrance-free to fragranced environments. Even a majority of individuals who do not report fragrance sensitivity would nonetheless prefer fragrance-free environments. These findings are juxtaposed with trends of putting fragranced air through indoor environments, even at potential risks to individuals who can experience severe health effects from exposure.

Conclusions

This chapter presented sampling and analytical methods for evaluating the types and concentrations of VOCs and aldehydes associated with emissions from fragranced consumer products. It analyzed and synthesized findings from studies conducted using headspace analysis, in environmental test chambers, and within indoor environments. Fragranced consumer products are ubiquitous in society and emit numerous volatile organic compounds including hazardous air pollutants. However, improvements can be readily made to indoor air quality. Fragranced products can be replaced by fragrance-free versions. Also, fragranced products can be removed entirely with a greater reliance on other approaches such as adequate ventilation. Finally, fragrance-free policies offer a beneficial and broader scale approach to improve indoor air quality.

Abstract

Appliances employ energy to provide services such as cooking, space heating, water heating, and lighting. Available energy is delivered either by a carrier such as electricity or by combustion of a wide range of fuels ranging from natural gas to liquid fuels to solid coal, wood, or waste. When combustion occurs indoors without direct venting, occupants are exposed to effluents, as they have been throughout human history. Cooktops and cooking stoves have a multitude of forms depending on the fuel and the type of food, and are the most likely appliances to release effluents to occupied space. Devices that provide space heat and water heat are often enclosed, vented, and isolated from the living space, although fugitive emissions can still occur. Lighting has mostly transitioned to electricity although some regions use liquid fuels with high emissions. The nature of combustion alters the mass, particle size distributions, and chemical composition of emissions, with gaseous and liquid fuels yielding lower emissions. Strategies for separating humans from combustion emissions include improving combustion and ventilation, processing fuel, using cleaner fuels, and altering the ways in which energy services are provided. Appliances form part of a complex system that includes humans, infrastructure, and expectations in addition to fuels and devices.

Introduction

Control of fire is the one event that indisputably brands humans and human society. Anthropologists use indicators of fire control to mark the beginning of humanity (Eiseley 1954; Rolland 2004), and some theorists suggest that the use of controlled heat to degrade food allowed humans to redirect their digestive energy into brain power (Wrangham 2009). Humans' reliance on fire inevitably resulted in proximity to combustion, and inhaling combustion products has been ingrained with human existence. Many of the transitions associated with a modern society were driven by a desire for convenience and progress, and they also distanced humans from fire. Hearth fire migrated from the center of the living space, to enclosure in fireboxes, to sequestration in boilers housed in basements or closets (Pyne 1995). Eventually, combustion left many buildings entirely, relegated to distant steam plants to produce electricity. Now, even those fires are starting to be replaced with energy sources other than combustion. As infrastructure to deliver electricity, water, and natural gas became commonplace, women and men spent less time on collecting fuel, tending

fires, and transporting water. In tasks such as laundering and heating water, energy from combustion supplanted human work, and automation replaced attention. Over time, the combination of devices, energy sources, energy-delivering infrastructure, and human practice and expectations has become an integrated, stable system that may resist replacement of individual elements (Shove 2003; Geels 2005).

Key players in this evolution have been appliances: devices that perform a specific task or set of tasks. This chapter reviews the appliances, both traditional and modern, that play essential roles in delivering energy services. The word “appliance” often refers to devices that are marketed. This chapter uses the term to encompass all devices that fulfill a desired service. Devices that incorporate combustion are emphasized because they are most likely to affect indoor air quality. Appliances in residential buildings appear prominently because they perpetuate the juxtaposition between humans and combustion. The chapter first discusses the energy services that appliances provide and the fuels they use, followed by descriptions of their physical form and function. Performance measures that quantify how appliances affect indoor air appear next, followed by some tabulations of those measures to compare different fuel and device combinations. The chapter closes with a summary of motivations and possible actions to reduce indoor exposure from appliance emissions.

Energy Sources and Energy Services

Fuels

Fuels that power appliances vary by end use and by location (Table 1). Natural gas, primarily composed of methane, has low cost and relatively low emissions. These features make the fuel popular in developed urban areas where distribution

Table 1 Fuels used for combustion that occurs in buildings

Fuel name (other names)	Supply chain
Natural gas	Piping infrastructure
Propane (liquefied petroleum gas, LPG)	Commercial delivery, purchase at outlets
Kerosene (heating oil, paraffin)	Commercial delivery, purchase at outlets
Heating oil	Commercial delivery
Wood	Self-collection, commercial delivery
Charcoal (coal)	Commercial sale, usually from production in rural areas
Coal	Commercial delivery, self-collection
Animal waste (dung)	Self-collection, often involving drying and shaping
Agricultural residue	Self-collection, often involving storage following harvest season
Biomass pellets	Commercial sale, usually from local production
Biomass or coal briquettes	Commercial sale, usually from local production

Fig. 1 Various forms of solid fuel for combustion in homes. Clockwise from top left: firewood and large stored wood, mid-hills, Nepal; large coal chunks and hand-formed flat coal bricks intended for household combustion, China; charcoal made in rural areas to be sold in urban areas, Liberia; corn cobs for igniting fires, China; formed charcoal “honeycomb” briquettes sold by a small commercial enterprise, Nepal; two sizes of firewood and kindling, Shaanxi, China. (Photos courtesy: T. C. Bond except charcoal, E. Floess)

infrastructure is available. Propane is a common fuel choice in rural areas where it is typically delivered via trucks and stored on-site in pressurized tanks. Kerosene is transported and stored as a liquid. Heating oil, which is compositionally similar to diesel fuel, is delivered via truck as a liquid and is most often used to fuel space heating appliances.

Use of solid fuel is common in rural areas and in regions with little infrastructure for electricity and natural gas (Fig. 1). Because solid fuels are often considered inferior energy sources, they often do not have high value and therefore are used locally to meet the needs of homes or small industrial installations. Solid fuels require more user effort and attention compared to other fuels, as the fuel may need processing (e.g., splitting wood) and loading (e.g., filling a pellet hopper), and the appliance requires more frequent and additional cleaning. The most widely used solid fuel is wood from the trunks or branches of trees and bushes. Use of agricultural waste, such as corn stalks and cobs, or rice straw and husks, is extensive where farms exist. Animal waste can also burn when dried. It tends to be used as fuel only in specific cultures, such as in South Asia and the Tibetan Plateau. Fossil-fuel coal is burned in homes and commercial enterprises when it is abundant due to regional coal deposits. Coal use is widespread in East Asia, South Africa, and formerly throughout the United Kingdom and the Northeastern United States. Gathered fuel may also include urban, construction, or household waste to augment the fuel supply and

promote ignition. Self-collected fuels are common when consumers cannot afford delivery of energy sources or when they prefer not to rely on commercially generated energy.

There is an extra challenge in achieving clean and complete combustion of solid fuels because breakdown of the parent fuel and mixing with air occurs simultaneously with oxidation of the combustible fuel products. Quality and repeatability of solid-fuel combustion depends on the dimensions, shape, moisture content, and heating value of solid fuel. Thus, solid fuels may be thermally or physically processed to improve uniformity. Charcoal is the solid residue of wood that has been pyrolyzed in the absence of air, and it burns more uniformly and steadily than wood does because the volatile matter, which causes fluctuating combustion, has already been removed. There is a robust trade between rural areas where charcoal is generated and demand in urban areas, particularly in Africa and South Asia (Mwampamba et al. 2013a). Pellets or briquettes made from biomass or coal can increase physical consistency and improve combustion performance. They are usually made from the original fuel ground to small sizes and constituted into regular shapes, using a binding agent (Whittaker and Shield 2017) or heat in conjunction with high pressure. Such intermediate fuels can create entrepreneurial opportunities, yet they have never become as extensive as the charcoal trade.

Energy Services

Discussion of energy use in buildings often focuses on appliances or broad categories known as end uses: cooking, space conditioning, water heating, and lighting. However, the immutable outcome of interest is neither the end use nor the energy source powering it, but the services provided: hot meals, thermal comfort, enjoyable bathing, and illumination (Fig. 2) (Fouquet 2008; Fell 2017; Brand-Correa et al. 2018). Table 2 summarizes some energy services, associated appliances, and the energy sources that provide power. Because food types and styles are numerous, cooking itself is not a single service; the heat needed may be rapid and targeted or gentle, slow, and thorough. Small farms and agricultural businesses need heat for food drying and processing, preparing animal food, or heating greenhouses.

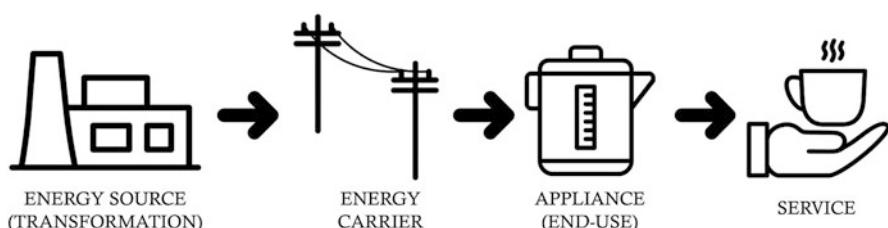

Fig. 2 Appliances fill the demand for energy services, powered by a variety of energy sources. Direct exposure to combustion effluents occurs when fuel combustion provides the source of usable energy and occurs within the appliance and indoor space

Table 2 Energy services and characteristics of appliances that provide them

Service (end use)	Appliance	Typical fuels	Venting
Fried, boiled, steamed food (cooking)	Stovetop burner	NG, LPG, kerosene (E)	Indoors
	Cooking stove	Charcoal, wood, AGR, animal waste, coal, biogas, pellets, briquettes	Indoors
Simmered or slow-cooked food (cooking)	Stovetop burner	NG, LPG (E)	Indoors
	Cooking stove	Kerosene, wood, charcoal, AGR, animal waste, coal, pellets, briquettes	Indoors
Bread (cooking)	Oven	NG, LPG, wood, AGR, animal waste, coal, briquettes (E)	Indoors
Grilled meat (cooking)	Grill	LPG, charcoal, wood, briquettes	Occurs outdoors
Safe food (food drying and preserving)	Food dryer	LPG, charcoal, wood, coal, briquettes (E)	Flue
Thermal comfort (space heating)	Central furnace or boiler	NG, heating oil, wood, coal (E)	Flue
	Wood stove	Wood	Flue (fugit)
	Fireplace	Wood	Flue (fugit)
	Gas fireplace	NG, propane	Flue or indoors
	Space heater	NG, propane (E)	Flue or indoors
Cleaning and bathing (water heating)	Storage water heater	NG, LPG (E)	Flue
	Tankless heater	NG, LPG (E)	Flue
	Cooking stove	Wood, AGR	Indoors
Convenient laundering	Clothes dryer	NG, LPG (E)	Flue
Illumination (lighting)	Hurricane lamp	Kerosene	Indoors
	Wick lamp	Kerosene	Indoors
Aesthetics	Fireplace	NG, wood (E)	Flue (fugit)
	Wood stove	Wood	Flue (fugit)

Fuels: *NG* natural gas, *LPG* liquefied petroleum gas or propane, *AGR* agricultural residue, *E* electric option is available that does not require indoor combustion. Venting: Indoors indicates frequent location, although portable appliances may be used or even installed outdoors. *Fugit* fugitive emissions to the indoor space may occur during door openings or in cases of poor installation

Commercial buildings and schools provide space conditioning and lighting, and some, such as hospitals and prisons, cook for large numbers of people. In some regions, recreational uses such as saunas are popular.

Fire and smoke also provide services beyond those typically associated with energy. Smoke yields distinct food tastes, and in some regions, it is used to preserve building materials or prevent pest infestation. People enjoy observing fire, and wood fireplaces or wood stoves with glass doors are often desirable. Fireplaces fueled by natural gas are more convenient and cleaner burning than wood fireplaces, but to achieve luminous flames and an appearance similar to prototypical fires, their combustion is deliberately imperfect. The desire for secondary services can be a justification to continue use of combustion-based devices in homes.

Energy and End Use Data

Energy carriers delivered via infrastructure, electricity and natural gas, are well metered except for losses and theft. Sales records exist for commercially refined and delivered fuels, such as LPG, heating oil, and kerosene. However, fuels that are collected or traded are not easily monitored. National agencies might report annual consumption data, but this information is often extrapolated from surveys of a limited part of the population in a specific timeframe, and then scaled to population for the relevant year. These reports are shared by national agencies such as the Energy Information Administration in the United States and The Energy and Resources Institute in India. The International Energy Agency, the United Nations, the Food and Agriculture Organization, and British Petroleum gather international energy consumption data. However, traceability of energy data sources is low, and data are shared among agencies; agreement between two data sets usually means they have originated with the same source, rather than providing independent confirmation.

Despite the governing role of the desired service in choosing fuels and appliances, data describing the contribution of each end use to residential and commercial consumption are scarce. Many national surveys inquire about households' primary fuel source but not about end uses. Even when detailed information on specific appliance use exists, quantities of energy used by each appliance are not recorded. Sales of appliances are reported, but disposal is not, so the number and type of appliances in use is not well constrained. This lack of data means that information about combustion appliances that affect indoor air is not known for any individual home without direct observation.

Figure 3 summarizes estimated energy supply for various household end uses in three large regions. Because of the paucity of data, different methods produced the percentage attributions: device surveys in the United States (Energy Information Administration 2015); household surveys in China (Zheng et al. 2014); and reported national fuel consumption combined with proxies in Africa (Winijkul et al. 2016). In all regions, lighting and appliances rely on electricity, while cooking is supplied by electricity and natural gas in the United States, by a diverse mix of sources in China, and dominated by solid fuel in Africa. Space heating, when required, uses more energy than cooking and is more likely to be supplied with cheaper solid fuels. Past government policies in China have favored district heat, which is often supplied by coal but not produced in the home.

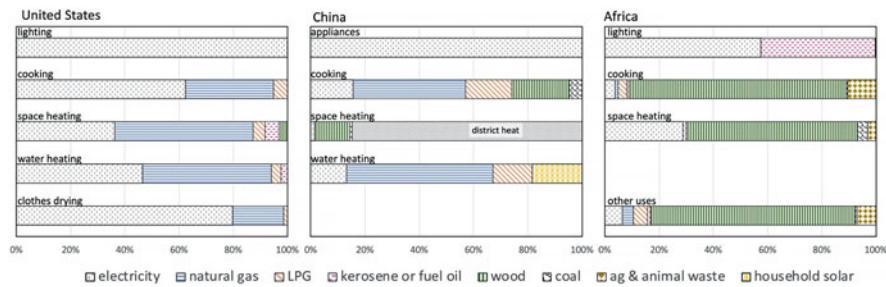

Fig. 3 Main energy sources or carriers providing household end uses. (Left) The United States, 2015; percentages based on number of devices reported in homes (Energy Information Administration 2015). (Center) China, 2012; apportioned energy among end uses based on surveys (Zheng et al. 2014). (Right) Africa, 2010: estimated apportionment among end uses using population and use proxies (Winijkul et al. 2016)

Physical Appliances

This section reviews the diverse forms and functions of combustion appliances that are likely to affect indoor air. Of greatest concern are fuels which are likely to yield products of incomplete combustion (PICs) in large quantities. Even with relatively clean-burning fuels such as natural gas, perfect combustion does not occur in real-world settings, and some pollutants like carbon monoxide (CO) and oxides of nitrogen (NO_x) are generated. These imperfections are more pronounced when the fuels contain impurities, or the appliance is insufficiently cleaned or maintained. Even when combustion is complete, if combustion is not vented, oxygen is depleted and carbon dioxide (CO₂) is elevated in indoor air. Combustion also generates water vapor, which can damage building materials and promote mold growth; in turn, those issues can result in health conditions such as asthma (Mudarri and Fisk 2007).

Cooking Appliances

The most common indoor cooking combustion appliances are stovetop burners, cooking stoves, and ovens. Other appliances not discussed here include outdoor grills, smokers, oil fryers, and butane torches. The most commonly used indoor cooking appliances (cooktops and ovens) are unvented, meaning that they emit all combustion emissions to the indoors. It is generally advisable to use local ventilation when cooking to exhaust combustion emissions and other contaminants generated by the cooking process, which include particulate matter and organic compounds.

Cooktops powered by combustion generate flames that are directly applied to cooking vessels, such as pots, pans, griddles, and woks. The vessel is heated by convection from the flames or exhaust gasses, and by radiation if hot solid fuels or surfaces are present. Household cooktops (Fig. 4) consist of two to five burners,

Fig. 4 Various forms of gas burners. Left to right: single burner connected to an outdoor biogas digester (Nepal, courtesy T. C. Bond); dual-burner cooking appliance supplied by a liquefied petroleum gas cylinder (Tonga, courtesy E. Floess); four-burner gas cooktop connected to natural-gas piping infrastructure (Europe, licensed)

usually of differing sizes, and high-end residential, restaurant, or commercial cooktops can contain many more. Single- or dual-burner appliances are common when households use delivered fuel. Liquid and gaseous fuels are delivered above atmospheric pressure, so the burner power can be modulated with a valve that alters the rate of fuel supply, changing the flame's size and heat release rate.

Cooking stoves are differentiated from cooktops because they have combustion chambers, usually for burning solid fuels. Solid-fuel combustion occurs in several steps, beginning with heating of unburned fuel before ignition, so retaining heat in the chamber is an essential part of continuous combustion. The combustion chamber may be partly enclosed with the flames contacting the pot directly, or it may be fully enclosed, with the heat transferred across a heat-conducting material (Fig. 5). There is a wide variety of strategies to heat pots (Fig. 6), and a similarly great diversity of stove forms depending on the fuel and the food (Westhoff and German 1995). In the simplest cooking “device,” the three-stone fire, the fuel structure itself serves as a combustion chamber. Cooking stoves include supports for either cooking vessels or foods. Controlling the rate of combustion is more difficult and less precise when burning solid fuel, which usually does not have a regular feeding mechanism. Heat release rates can be controlled by the speed of adding new fuel or by limiting airflow for oxidation.

Programs that redesign cooking stoves to improve efficiency and reduce exposure have been numerous. People have sought to improve combustion and reduce smoke for over 200 years (Franklin 1786; Rosin 1939). Widespread sharing of cooking-stove improvements for resource-constrained areas that rely on solid fuel is a more recent phenomenon. Partial enclosure of the combustion chamber with a C-shaped ridge of mud or clay is one of the simplest improvements. Some early “improved” mud stoves were found to worsen the combustion (Smith et al. 2000a) as the thermal mass drew heat away from the reaction. There has been more attention to assessing performance in the intervening years. Insulating combustion chambers is one improvement strategy, found in stoves such as the charcoal-burning Ceramic

Fig. 5 Three Central American stoves with similar cooking functions. (Left) Stove has a partly enclosed combustion chamber and no venting to outdoors. (Center) Stove built in local factory with enclosed, insulated combustion chamber, plancha (flat-top grill) and chimney. (Right) Site-built “Justa” stove with insulated combustion chamber, plancha, chimney, and décor. In this region, the plancha design serves to cook tortillas as well as to heat cooking pots. (Photos courtesy: T. C. Bond)

Jiko (Kinyanjui and Childers 1983) and “Rocket”-type wood stoves (Bryden et al. 2005). Adding chimneys to remove smoke from the living space and increase draft is another possible modification. However, chimneys increase both cost and maintenance requirements.

Combustion improvement in solid-fuel cooking stoves is also an area of active design and development (Reed and Larson 1997; Urban et al. 2002; Shan et al. 2017; Still et al. 2018; Pundle et al. 2019). Modifications include separate control of primary air introduced below the firebox, and secondary air supplied above the combustion. Mechanical fans can create mixing either above or below the fire, and thermoelectric generators can power them when electricity is not available. Separating fuel devolatilization from gas-phase combustion can yield cleaner combustion when stable; this strategy is sometimes called “gasification” by stove designers (Reed and Larson 1997; Mukunda et al. 2010; Clark et al. 2017). Cooking stoves have also been designed to optimize combustion with more reliably performing processed fuels like pellets and briquettes.

Gas ovens usually have one main burner beneath the floor to heat air, which in turn heats the food or other contents. These burners are not adjustable and operate at a fixed fuel consumption rate. During normal operation, the main burner ignites until the oven reaches the set temperature. Temperature is maintained by extinguishing and reigniting the burner, and is determined by the percentage of on-time and the ambient temperature. Ovens may have a second burner for broiling, which provides high and directed heat at the top of the main oven cavity, used for crisping or charring foods such as meats. Some ovens have a lower drawer for broiling that uses the main burner as the heat source. Burners for broiling typically operate continuously, only turning off if the oven overheats. Some older electric ovens required having the oven door partly open during broiling; this practice is outdated and was never applicable to gas broilers.

Fig. 6 Strategies for pot heating when burning solid fuel. Clockwise from top left: three-rock fire (Liberia, courtesy E. Floess); mud-constructed stove with iron bars to hold pot (Tonga, courtesy E. Floess); ceramic-lined, metal-clad insulated charcoal stove (Thailand, courtesy L. Childers); factory-manufactured metal coal stove with primary and secondary air provision (Eswatini, courtesy C. Pemberton-Pigott); multi-pot mud and clay stove with sunken pot holders to improve heat transfer (Nepal, courtesy T. C. Bond); masonry coal cooking stove that also heats water (China, courtesy T. C. Bond). Some of the photographs are taken outdoors, but all of the stove types are used indoors

Space Heating Appliances

Combustion devices for space heating produce heat from combustion and transfer it to the living space. Compared with cooking services, heat for comfort has fewer requirements for heating rates and characteristics. The primary requirement is that most of the heat reaches the air and structure of the living area, instead of escaping in the exhaust gas. Heating appliances include central warm-air furnaces, central hot-water and steam boilers, heating stoves that are free-standing or installed in a wall unit, masonry stoves, and fireplaces. Many climates do not require space heating at all, and people in some regions, instead of using a separate device to heat the space, operate the cooking appliance longer during cooler weather.

Central heating (Fig. 7) is popular because it is convenient and automated. The most common primary heating appliances in the United States homes are central

Fig. 7 Two versions of central heating appliances. (Left) Natural-gas furnace that distributes warm air throughout a building (the United States, licensed). (Right) Multifunctional coal stove that provides space heat by circulating hot water throughout a building and includes a surface for cooking (China, courtesy T. C. Bond). Both devices are vented to outdoors

forced-air furnaces (59% of all households, including electrically heated homes). These devices heat air either through combustion of natural gas or LPG, through electrical resistance, or with electric heat pumps, and distribute the warm air to all indoor spaces through ducts in wall cavities. In addition to space heating, these systems also provide air filtration and can accomplish space cooling and dehumidification. Boilers, or hydronic heating devices, are more common in the rest of the world. They heat water and circulate it around the living area through piping, transferring heat to indoor spaces via radiators. “Combi” boilers, paired with an indirectly heated tank, produce hot water both for space conditioning and for washing and bathing. Central-heating appliances are often housed in basements, closets, garages, or even outdoors in the case of wood boilers. They are almost always vented to outdoors with integral flues. Special cases of central heating include ducting hot exhaust under sleeping surfaces (*kangs* in China) or liquid-based heating of floors and walls (radian heat).

Free-standing heating stoves that burn solid fuels include combustion chambers, similar to cooking stoves. These devices have a similar general form in many regions (Fig. 8). Most often, the combustion chamber is fueled by hand, and the heating rate is controlled by the rate of air supply. The combustion chamber and chimney transfer heat to the living space through radiation and convection, and some stoves include fans to increase convection. Most of these stoves have flues to vent combustion products outdoors, so their main influence on indoor air quality is through leaks in

Fig. 8 Free-standing heating stoves, which have similar form around the world. From left to right: wood stove, Alaska, USA (courtesy P. W. Francisco); wood stove with viewing door, Germany (courtesy E. Floess); coal stove, China (courtesy T. C. Bond)

the flue or its connection to the stove, or through fugitive emissions when doors are open for feeding.

There are two general methods for limiting emissions below minimum certification levels in wood heating stoves: catalytic and secondary combustion (non-catalytic). Both methods allow the stoves to achieve more complete combustion, reducing pollutant emissions and generating additional heat. Some “hybrid” stoves utilize both methods. In catalytic stoves, the exhaust gasses are channeled through a ceramic element inside the stove. This element is coated with precious metals and enables additional chemical reactions, increasing the overall combustion completeness. Effectiveness depends on sufficient contact time between the smoke and the catalytic element. At high burn rates, the smoke may move too quickly through the catalyst for effective pollutant conversion. The catalyst does not work well at low temperatures, and it can become overloaded when emissions are very high during starting and reloading. At these times, the exhaust flow must bypass the catalyst to avoid fouling. The catalyst is a consumable component and must be replaced periodically at intervals determined by stove use, fuel quality, and user behavior.

Combustion improvements without catalysts involve control and preheating of air (Brunner et al. 2009). Air is preheated with a heat exchanger in the exhaust and supplied to the firebox after the primary combustion zone, where it is mixed with the combustion gasses to facilitate additional combustion. Non-catalytic stoves require higher temperatures than catalytic stoves, and those temperatures can hasten degradation of internal components.

Fireplaces and masonry heaters serve a decorative purpose in addition to providing space heat, and they are often located in the main living space. These devices usually have large thermal mass that draws heat from the combustion until it comes to equilibrium, so they provide the most effective space heat when they are operated

continuously. Similar to heating stoves, exhaust products are drawn away from the living space by the draft induced by buoyancy, and fugitive emissions are the main source of indoor air contaminants.

Free-standing or wall-mounted propane, kerosene, or natural-gas burners also provide space heating. Exhaust products can be either vented to outdoors or to indoors; the latter are sometimes advertised as “vent-free” or “ventless.” Ventless space heaters and fireplaces emit all combustion byproducts indoors and are nominally 100% efficient because no heat is lost through a flue. The relatively clean burning of natural gas or propane is the argument for allowing unvented combustion, yet these devices have high exhaust flows and allowing indoor emissions can be controversial. Appliance manufacturers usually recommend opening a window or using mechanical ventilation to avoid negative results, but this guidance relies on user compliance.

Water Heating Appliances

Hot water is used directly for bathing, cleaning, and washing clothes in addition to its application as a working fluid to circulate heat. Both storage water heaters and tankless or on-demand water heaters can be powered by natural gas, liquid fuel, or electricity. Boilers similar to those used for space heating are employed with solid fuel (see previous section). A simple but time-intensive method of obtaining warm water is heating a large pot on a stove used for cooking.

Common storage water heaters rely on natural draft to exhaust the combustion gasses, which rise due to buoyancy through the appliance and the flue. A draft hood, located between the top of the appliance and the bottom of the flue, allows ambient air to mix with the combustion gasses, relieving negative pressure around the burner and preventing downdrafts from extinguishing the flame. This opening in the combustion path also poses a potential hazard if there is a negative pressure in the building, which might be caused by an exhaust fan or improperly balanced conditioning system. In such a case, the buoyancy force might be insufficient to overcome the pressure difference, and the warm exhaust gasses can enter the living space. Some “power vent” water heaters use electric fans to propel exhaust gasses through the flue. Although these appliances reduce the risk of combustion gasses getting into the indoor air, they are more expensive to purchase and operate, and they do not work without electrical power.

Lighting Appliances

Lighting appliances generate illumination so that people can conduct activity when daylight is not available. In regions with electrical infrastructure, lighting is almost wholly electrical; some combustion-powered appliances such as street lighting are maintained for historical or aesthetic reasons, but it occurs outdoors. Because lighting is a small fraction of the total household energy demand in

resource-constrained regions, it is feasible to supply it even with limited electrical services or with solar power.

When lighting cannot be supported by electricity, illumination occurs through combustion that is deliberately not ideal (Fig. 9). The glow of an orange flame is caused by carbon particles that are the product of incomplete combustion, so that the sooty burning of kerosene or paraffin in simple wick lamps provides illumination. Emissions from this type of lighting can be extremely high. “Hurricane” lamps can enclose a glowing flame before burning out carbon particles, reducing emissions. Open flames in cooking stoves are also used for illumination.

Other Appliances

When electrical service is unreliable, households and businesses maintain backup generators powered by natural gas, propane, gasoline, or diesel fuel, with either two-stroke or four-stroke construction. In some world regions, regular, targeted power cuts occur to balance loads on central electrical plants, a practice known as

Fig. 9 Two fuel-powered lighting appliances. (Left) Kerosene wick lamp showing characteristic smoke. (Courtesy: N. Lam and A. Pillarsetti). (Right) Enclosed hurricane lamp (licensed)

“load shedding” (Koirala and Acharya 2022). Although generators are kept outdoors, they may be operated in close proximity to the living space, such as in courtyards.

Space cooling and refrigeration are consequential in energy consumption, but are almost completely supplied by electricity, and thus do not affect indoor air quality except for managing moisture content. An exception is combustion of natural gas or propane in absorption pumps, which can drive cooling cycles.

Clothes drying appliances are used extensively in some parts of the world, like the United States, and very little in other regions. Most clothes dryers are electric, but some are powered by gas or propane combustion. In combustion appliances, a large airflow vents the combustion gasses and moisture from the clothes to outdoors. Buildup of lint or other obstructions can impede this flow and allow harmful gasses to enter the living space.

Some recreational appliances are not discussed extensively here because they have limited application or because they often have little direct input to indoor concentrations. These include heaters for pools, spas, and saunas; cooking devices such as fire pits, smokers, and charcoal grills; and torches for lighting common spaces.

Appliance Performance Affecting Indoor Air

Appliance characteristics that affect indoor air are: (i) efficiency of converting energy sources to provide energy services; (ii) contaminants produced during energy conversion, which is often a matter of combustion quality; and (iii) escape of contaminants from the device within the indoor environment (Fig. 10).

National and international methods and standards are in force for many appliances. For example, cooking stoves have national or regional standards (AEPC 2016; ANSI 2016; Standards Administration of China 2017) as well as international test procedures and guidelines (ISO 2018a, b). Heating stoves and water-heating devices also have national or regional efficiency and emission standards. Method guidance specifies procedures for operating the device during a test, for measuring contaminant concentrations and other operational characteristics, and for interpreting the data to determine a performance metric. Standards provide maximum or minimum benchmarks for the measured performance metric. These benchmarks may tighten over time as design innovations improve performance.

When performance is sensitive to operational parameters, as it is in biomass stoves or small combustion devices, specifying methods and setting performance standards becomes more challenging. Some of the features responsible for variability may be tightly constrained during compliance testing to achieve reproducibility, so that performance during standardized testing may differ from the in-use performance that affects true indoor and outdoor concentrations (Johnson et al. 2008; Roden et al. 2009). Caution is advised in translating compliance-testing results to infer the influence of appliances on contaminant concentrations.

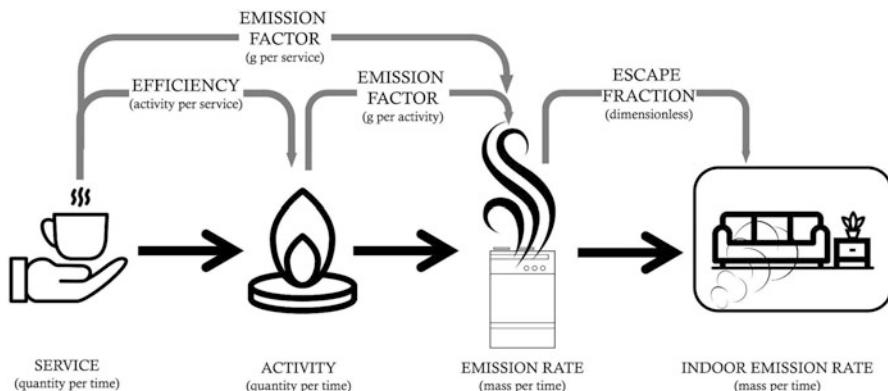

Fig. 10 Relationship between performance measures (upper row) and physical behavior relevant to indoor air quality. Device emission rate has also been used as a performance measure. The emission rate to the indoor environment is needed for models of indoor concentration

Even when contaminants are completely discharged outside the building shell, the exhaust can create a *neighborhood effect*; that is, elevated contaminant levels localized around groups of emitters, which may be returned to the indoor space through re-infiltration. This influence is not further discussed in this chapter, but in areas of high population density, its contribution to indoor air pollution should be recognized.

Efficiency and Energy Intensity

The term *efficiency* refers to a ratio between the quantity of energy used for the desired purpose and the quantity of energy supplied to the device. Efficiency affects indoor air quality because a more efficient device achieves the same service with less energy and less conversion. Appliance performance is often reported in terms of the service, rather than the quantity of energy used. For example, the amount of energy needed to transform the dough of baguette or chapati into the baked product does not appear even in technical discussions about appliances. A common measure related to efficiency is *energy intensity*, or the amount of energy required to perform a service. Another simple performance measure is the rate of energy consumption of a device of a certain size. This measure is appropriate for appliances, such as ovens, that provide many services.

Emission Factors and Emission Rates

An *emission factor* is the ratio between the mass of an emitted contaminant and a defined measure that quantifies the activity emitting the contaminant. The activity in the denominator may be the mass of fuel burned or the service achieved, such as

energy delivered to a cooking pot or lumens of light provided. Emission factors presented as mass of contaminant per mass of fuel burned ($\text{g}_{\text{contam}}/\text{kg}_{\text{fuel}}$) are closely related to the quality of combustion. Emission factors normalized to the service provided (e.g., $\text{g}_{\text{contam}}/\text{MJ}_{\text{service}}$) inherently incorporate the device efficiency as well; a less efficient device produces more contaminants to deliver the same service. Service-based emission factors communicate the causal relationship between service demand and contaminant release, but they can obscure the separate contributions of energy efficiency and of transformation quality.

Emission rates ($\text{g}_{\text{contam}}/\text{s}$) are needed for models of contaminant concentration (Fig. 10). Emission rates are the product of emission factors, which characterizes the device, and the rate of activity, which depends on the user and the situation.

Measured contaminant *concentrations* (g/m^3) are relevant to human exposure, but they alone do not provide emission factors that characterize device performance, or emission rates that are useful for modeling, because the amount of dilution with clean air after combustion is unknown. Determining emission rates requires measurement of the device exhaust flow in addition to concentrations, and then emission factors can be quantified if activity rates are also known. Alternatively, emission factors from carbon-based fuels can be determined by relating the carbon dioxide concentration to the carbon in the original fuel, and then emission rates can be found by applying activity rates. The latter method, known as the *carbon-balance method* or *ratio method*, is somewhat less accurate for fluctuating combustion because it does not account for covariation between emission factors and activity rates. In some measurement methods, either oxygen or carbon dioxide are used to adjust contaminant concentrations to those that would be measured at a certain percentage of excess air supplied to the combustion, and emission factors can be determined from these reports.

Capture and Unintended Releases

Combustion products become indoor contaminants unless they are removed from the environment. The most effective removal occurs by enclosing the entire reaction chamber and exhausting it through a pipe or chimney. Buoyancy, created by the heat of the reaction, is often the driving force expelling the products. The expulsion may also be assisted by a fan. Ventilation devices such as fans or exhaust hoods capture exhaust after it escapes from the appliance. Removal after release is less effective because spillage into the indoor space can occur and cool air entrained into the exhaust products reduces buoyancy. Some appliances, such as cooking stoves and unvented natural-gas fireplaces, have no design for removing combustion products from the indoor space. Some cooktops appear to have ventilation, but the exhaust is returned directly to the living space. For example, microwaves positioned over cooktops contain fans, but these recirculate air rather than exhausting it. Some appliances are designed to remove combustion products but release a small fraction of the generated products through backdrafting (Rapp et al. 2013), poorly sealed joints, or intentional breaches such as door openings during fuel feeding. These leakage or fugitive fractions are not well quantified.

Leaks can occur in fuel delivery systems such as connections, pipes, and pressure cylinders (Merrin and Francisco 2019). Although the device itself is not responsible for these releases, they can be attributed to the presence of the appliance.

Characteristics of Emissions

This section reviews numeric values for some of the performance metrics listed in the previous section. Study results summarized here are representative and not comprehensive; new measurements are reported frequently for highly variable devices like solid-fuel cooking stoves. The tabulation presented here provides a general comparison among devices and fuels. It is useful to identify when performance differs significantly by appliance; under those conditions, mitigation may occur by switching to better fuels or appliances. Recognizing appliances with variable performance also shows where reducing fluctuations and achieving robust performance can produce improvements in indoor and outdoor air quality.

Combustion processes govern emission magnitudes and characteristics. Complete combustion transforms fuel carbon into CO₂, and hydrogen into water. Flame temperature, fuel quality, combustion air quantity, and fuel-air mixing can affect combustion completeness and generate pollutants. PICs range from droplets of the fuel itself to incompletely oxidized compounds such as methane and CO. Flames' orange glow is caused by radiation of soot or black carbon particles (Saito et al. 1987). Light emission during oxidation of certain hydrocarbons is responsible for the appearance of blue flames (Gaydon et al. 1955). Products of incomplete combustion can be eliminated from the exhaust by giving them time to oxidize, by keeping them at elevated temperatures where oxidation reactions are favored, and by ensuring they are mixed with air. These principles are summarized in the aphorism "time, temperature, and turbulence." Emission of PICs is favored when air-fuel mixing is poor and when air entrained into combustion exhaust reduces the temperature. In contrast to PICs, nitrogen oxides, which originate from nitrogen in either air or fuel, form more easily at high temperatures. Appliances with exposed combustion chambers, such as cooktops, cookstoves, or fireplaces, have less control over the factors dictating combustion completeness and are more likely to produce pollutants.

Emissions from solid-fuel combustion are highly variable because of the complexity and diversity of processes. Combustion of large, unprocessed solid-fuel pieces involves a succession of processes: drying, pyrolysis, and release of volatile matter, gas-phase combustion of that volatile matter, and then oxidation of the remaining solid char. These steps occur sequentially, and the release rate of combustible organic matter varies as the pyrolysis front penetrates into the fuel. Imperfect mixing between gas-phase fuel and air causes flickering flames and escape of pollutants. The evolution of these processes depends on interaction between the fuel and the heat available within the combustion chamber, which in turn depends on loading practice. In addition to process fluctuation, the parent fuel has a variety of sizes, moisture contents, densities, and compositions, and may be heterogeneous even within a single piece of fuel. Initiating combustion requires additional material

that is more amenable to ignition, which can add substantial fuel mass (Thompson et al. 2019) and emissions of varying composition (Fedak et al. 2018).

Emission Factors

Mass emission factor, or mass of contaminant emitted per kilogram of fuel burned, is the characteristic that is easiest to measure, and thus, the most often reported. Emission performance can vary even among devices that are apparently similar. Performance differences originate in fuel quality, operator practice, and transient behavior caused by duty cycles (on-off switching). Specifically for solid-fuel stoves, comparative measurements of many devices (Jetter and Kariher 2009; MacCarty et al. 2010) and varying fuel types (Chen et al. 2006) have been reported, and meta-analyses have summarized performance across many studies (Shen et al. 2021). Despite this extensive work, variability among similar solid-fuel burning devices is not predictable.

Table 3 summarizes emission factors of fine particulate matter, carbon monoxide, and nitrogen oxides from some devices for the purpose of contrasting fuel and device combinations. For solid fuels, variability in CO and PM_{2.5} emissions is high, ranging over about a factor of 10 for each fuel-device combination. Carbon monoxide is a substantial part of the emission, representing about 10% of the fuel carbon. Gaseous, liquid, and pellet fuels emit much lower and less variable CO and PM_{2.5}. NOx emission factors have less variability and are similar among all fuel-device combinations.

Particle Size Distributions

Combustion produces mainly fine particles, less than 2.5 μm, by nucleation of gases to form new particles and by condensation of cooling gasses onto existing particles. Peaks of particle-number distributions mainly appear around 0.1–0.2 μm, known as the *accumulation mode*, or around 0.01–0.03 μm, known as the *nucleation* or Aitken mode. When particle precursors have similar chemical composition and temperature histories, all condensable material forms simultaneously and nucleation occurs, so that large numbers of nucleation-mode particles are formed. Initial particle sizes are determined within the highly reactive combustion zone, and as the plume cools through heat loss and entrainment of fresh air, condensation of semi-volatile material and coagulation among particles increases particle sizes (Chang et al. 2004). When particle precursors have similar chemical composition and temperature histories, all condensable material forms simultaneously and nucleation occurs, so that large numbers of nucleation-mode particles are emitted. This phenomenon occurs in combustion of gaseous fuels and sometimes liquid fuels. Combustion that produces high concentrations of precursors with varying volatility is more likely to yield nucleation early in the plume evolution that provides sites for later condensation of material, as is the case with solid-fuel combustion. In combustion without flues, most

^aAssumptions for converting natural-gas emission factors: non-condensing appliances, LHV = 34.6 MJ/m³; Condensing appliances, HHV = 38.3 MJ/m³, density at standard conditions: 0.711 kg/m³

^bHigher values are for cycling

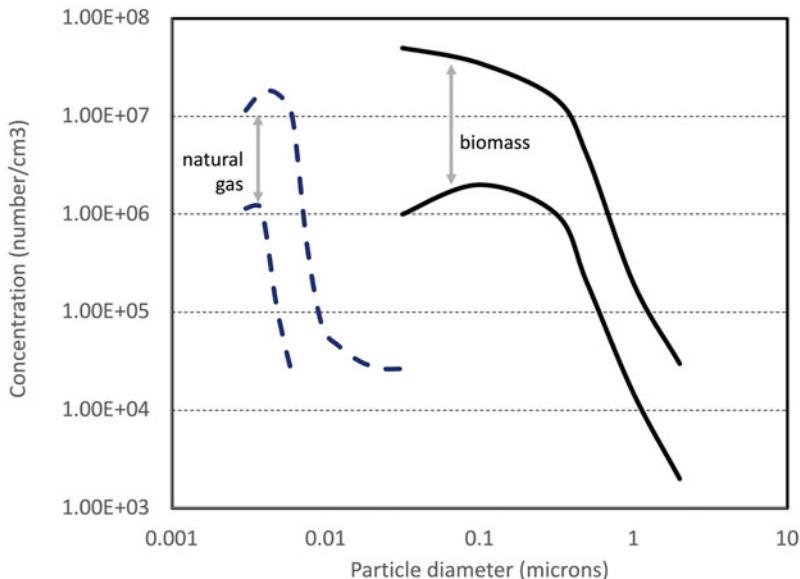

Fig. 11 Range of particle size distributions emitted from biomass (Li et al. 2007) and natural gas (Minutolo et al. 2008). Concentrations are normalized to 3% excess air

of this transformation takes place within the first few seconds, while temperatures and particle concentrations are high (Mena et al. 2017). Coarse particles, larger than $2.5\text{ }\mu\text{m}$, are usually emitted only when particles of ash or unburned fuel are present and when the exhaust air has enough draft to lift them.

Figure 11 compares particle sizes and concentrations from combustion of natural gas and of biomass. There have been many measurements of size distributions indoors or in plumes that are dominated by combustion products. These reports confirm that typical size distributions have number peaks in nucleation or accumulation modes; that particle sizes from gas, propane, and charcoal combustion are more likely to appear in the nucleation mode, and that unprocessed biomass fuels usually produce accumulation-mode particles (Ogulei et al. 2006; Tiwari et al. 2014; Shen et al. 2017; Xue et al. 2018). A few studies show that better combustion tends to make more, smaller particles that are less likely to be visible and that may have different health effects than larger ones (Masekameni et al. 2018). Most measured size distributions are not adjusted to a common dilution that allows comparison of the total number emitted from each fuel or service; Fig. 11 shows some exceptions.

Chemical Composition of Particles

Both the parent fuel and the combustion process affect the composition of emissions. When combustion yields only nucleation-mode particles with low mass, standard

chemical analysis may not be possible. Spectroscopic analysis has shown that very small particles from natural gas combustion may include molecules that contain only one or two aromatic rings (Minutolo et al. 2008).

The formation processes of accumulation-mode particles govern their overall composition. A special sequence of reactions very near flames builds graphitic structures through addition of carbon radicals to form soot or *black carbon* (Haynes and Wagner 1981; Frenklach 2002; Michelsen et al. 2020). Soot-forming reactions are favored when the parent fuel contains aromatic compounds (Han et al. 2021). Unburned fuel that is incompletely oxidized or completely unaltered is emitted in both particulate and gas phases (Simoneit et al. 1993; Schauer et al. 2001; Zhang et al. 2018). In atmospheric chemistry and source apportionment studies, this material is broadly termed *organic carbon*. Poor combustion can produce large quantities of organic carbon, with instantaneous emission factors ranging over four orders of magnitude; in contrast, black carbon emission factors have less variability (Weyant et al. 2019).

Fuels contain inorganic components such as metals, which are emitted either after vaporization, reaction, and condensation, or by mechanical release (Flagan and Friedlander 1978; Linak and Wendt 1998). Manufactured fuels contain ash-forming elements such as calcium and potassium, as well as heavy metals, depending on the origin of the feedstock (Chandrasekaran et al. 2012). These compounds appear in respirable particulate emissions (Kleeman et al. 1999; Johansson et al. 2003; Sanchis et al. 2014).

Sample treatment, especially dilution, affects the reported composition of emitted gases and particles, as well as mass emission factors for the separate phases. Many combustion emissions contain semi-volatile organic material (May et al. 2013) for which partitioning between gaseous and particle phases depends on concentration and temperature (Lipsky and Robinson 2006). This phenomenon can produce large differences in particulate emissions measured using heated sampling lines, compared with those measured after dilution or cooling.

Only a small percentage of the hundreds of organic compounds emitted from biomass combustion are amenable to quantification by gas chromatography. Levoglucosan is a primary constituent that is often used as a tracer (Simoneit et al. 1999; Weimer et al. 2008). Other identified components include polycyclic aromatic hydrocarbons, sugars other than levoglucosan, resin acids, substituted phenols, and substituted syringols (Evans and Milne 1987; Schauer et al. 2001; Fine et al. 2002; Bi et al. 2008).

Prospects for Reducing Exposure

Human exposure to indoor combustion products has decreased throughout history because of shifts associated with modernization. These changes provided cleaner and more convenient fuels or energy carriers through infrastructure or supply chains. They isolated fires in enclosed fireboxes and allowed their separation from the living space through automation. This societal and technological transformation continues.

When modern infrastructure has been developed, exposure to combustion products becomes a matter of preference and comparative cost. Some people prefer to heat with wood or to cook with natural gas even when other energy sources are available. Natural gas is often much cheaper than electricity, and unprocessed solid fuels can be cheaper still when they are self-collected.

Government, industry, and donor programs designed to improve indoor air quality through action on appliances have a variety of motivations. Although improved health may be one of the most obvious benefits, governments usually lack standing to regulate people's behavior in their own homes. Consumer safety and protection is a motivation for regulating appliance efficiency and emissions through standards. Combustion products travel outdoors and lead to deterioration of urban or regional air quality, so device emission limits may be imposed under ambient-air regulations. Governments enact national energy policy by imposing tariffs or taxes that favor certain fuels. Avoiding deforestation has sometimes been a driver for curtailing wood or charcoal use.

The desire to reduce climate change also leads to new perspectives on combustion. All carbon-based fuels generate the greenhouse gas carbon dioxide (CO₂) when burned, the largest contributor to anthropogenic climate change. In the context of reducing greenhouse-gas emissions, it is envisioned that most energy services in buildings will be provided by electricity generated without combustion – by solar photovoltaic panels, wind turbines, hydroelectric installations, or nuclear power plants. This scenario also assumes that indoor combustion will wane in popularity. A common assumption is that biomass fuels are preferred for climate protection over fossil fuels because they are “carbon-neutral” – that is, the emitted CO₂ is rapidly taken up by regrowth. This assumption is valid only when biomass is renewably harvested (Bailis et al. 2017) and when the products of incomplete combustion do not also have climate impacts (Smith et al. 2000b; Bond et al. 2004).

Improved Combustion and Appliances

Emissions from solid-fuel combustion are comparatively high and cooking emissions often occur indoors, so the effects of this combustion on human health are large (Soriano et al. 2020; Yun et al. 2020). Particular attention has been given to improving combustion in cooking stoves and disseminating those devices where solid-fuel use is common. Increased efficiency and reduced emissions can decrease exposure. Strategies such as retaining heat, increasing turbulence, or gasification (outlined in the section “Physical Appliances”) are deployed in factory-built cooking stoves or by programs that develop and implement improved-stove projects. Collaborations such as the Clean Cooking Alliance have gathered parties ranging from entrepreneurs to development organizations to public health professionals who share interest in affecting change.

Despite widespread agreement that modified combustion could improve indoor air quality, there are many challenges to displacing “traditional” combustion. Some cooking stove designers have neglected to consult with users or ensure good

performance, yielding poor products and a lack of market confidence. Manufacturers may respond to user demands to make stoves more marketable, and some of these changes may decrease combustion quality while increasing usability. An example is increased firebox dimensions to accommodate large fuel sizes, which require less feeding but produce smoke more easily. Users continue to employ traditional stoves if the replacements do not fulfill all the services required, a phenomenon known as “stacking” (Ruiz-Mercado and Masera 2015; Shankar et al. 2020). Household resources are often directed to achieve convenience, income generation, or added services such as mobile communications, instead of improved health. This low priority for health can be exacerbated when women, the predominant cooks and stove users, do not have strong voices in household decisions (Lindgren 2020). For these reasons, adoption and persistence of improved cooking stoves can be poor (Mobarak et al. 2012; Ramanathan et al. 2017). This apparently daunting set of obstacles reflects the insufficiency of effecting change in a complex system through simple technological replacement.

In contrast to solid-fuel appliances, modern gas appliances have relatively complete combustion and generate low amounts of pollutants other than CO₂. Even in this relatively clean burning, perfectly complete combustion is unrealistic outside of controlled laboratory settings (Lebel et al. 2022). Appliances naturally generate small quantities of pollutants, which increase as the appliance ages, fouls, and degrades. Although the large number of appliances worldwide may produce meaningful amounts of pollutants in the aggregate, complete elimination of pollutants by addressing each individual unit may not be feasible or cost effective.

Preventative maintenance of appliances aids in extending life span and keeping their performance. This maintenance is usually initiated by individual consumers, although it may be implemented by heating, ventilation, and air conditioning professionals. Inspection of stoves and ovens includes cleaning and ensuring that all elements such as burner caps and bases are correctly positioned, and that flames are symmetrical, consistent, and not excessively luminous. Preventative maintenance visits for combustion heating appliances, sometimes referred to as “clean and tune,” can include a wide range of services depending on the equipment type and condition, client requests, and the technician themselves. Technicians inspect and clean burners, adjust burner firing rates, and examine the condition of mechanical components such as blowers, pumps, and valves. They inspect heat exchangers, exhaust pipes, and fuel supply lines for integrity. On central warm-air systems they measure static pressure or temperature rise between supply and return air to determine whether the furnace is moving the appropriate amount of air. They use measured flue gas temperature and composition to assess appliance efficiency and excess air, and diagnose combustion issues. When the service reveals problems, the technician completes minor repairs, or recommends upgrades or replacements.

Venting and Ventilation

Ventilation and venting strategies remove combustion effluents from indoor air with varying efficiency (Fig. 12). In spaces without mechanical ventilation, air exchange

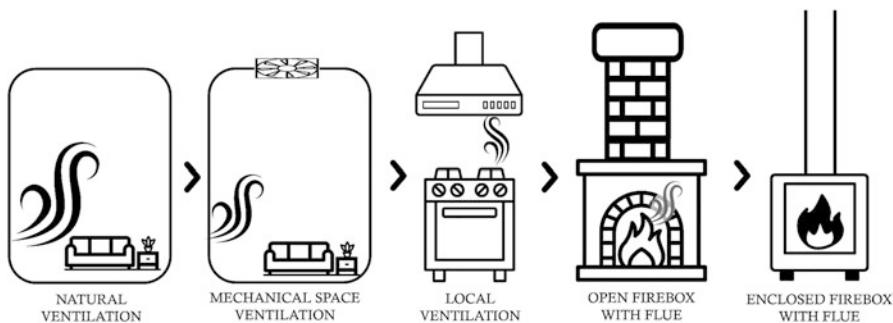

Fig. 12 Appliance ventilation and venting strategies for removal of combustion effluents, from least directed (left) to most directed (right)

is driven only by naturally occurring pressure differences. Air exchange rates can be very high in buildings where envelope sealing is limited; however, these “leaky” buildings are associated with resource-limited situations where emission rates may also be high.

Mechanical ventilation is incorporated into well-designed buildings, and as buildings have gotten more airtight to increase energy efficiency, intentional ventilation has become increasingly important to maintain adequate indoor air quality. Standards such as ASHRAE 62.2 in the United States (ASHRAE 2019) dictate minimum ventilation requirements for residential buildings to provide necessary fresh outdoor air. However, regardless of ventilation rates, exposure occurs if effluents are allowed to escape into the occupied space. Standards also specify local ventilation requirements in kitchens and bathrooms, removing contaminants generated from activities such as cooking and bathing before they completely disperse into the occupied space, and emission plumes may be incompletely captured by this local ventilation (Lunden et al. 2015). Exhaust hoods relying on natural draft have also been employed when electricity is unavailable (Bates 2008).

The most reliable venting strategy is the complete enclosure of combustion products within a firebox, attached to a flue with sufficient draft to expel pollutants. Openings between the firebox and the occupied space allow escape of combustion effluents, and also allow entrainment of fresh air, reduce exhaust temperatures, and diminish the buoyancy that creates draft.

Fuel Processing

Homogeneous fuels increase the reliability and predictability of combustion. Liquid and gaseous fuels have already undergone refinement, and it is in large part this isolation of fuel with specific volatility that enables clean and reliable combustion. Homogenizing solid fuels can also improve consistency, so that processed fuels are favored for their convenience; this transformation can also reduce emissions. The fuel is first broken down either thermally, or physically by grinding or pulverizing. The product of decomposition can either become pellets by forming it into small

pieces of consistent size and shape, or into briquettes by reconstituting the fuel with a binder. Processed, dried solid fuel may be advantageous in regions where residue from agricultural, forest, or mining activity is widespread (Zhi et al. 2009; Akowuah et al. 2012; Mwampamba et al. 2013b), although it is still more expensive than self-collected fuel.

Fuel Switching

An “energy ladder” of increasing fuel desirability, from waste to wood to gas and electricity, has been posited (Hosier and Dowd 1987; Leach 1992; Smith et al. 1994). Although this shift does describe aggregate transitions, the simple energy ladder does not account for the adaptive behavior exhibited by individuals (Masera et al. 2000; Hiemstra-van der Horst and Hovorka 2008), who use multiple fuels and devices to meet a variety of energy needs.

Countries including India and Indonesia have decades-long histories of subsidizing cleaner-burning fuels such as kerosene and liquefied petroleum gas, largely as measures to improve energy provision for impoverished people (Balachandra 2011; Thoday et al. 2018), although there is active discussion about which groups have benefited most from these subsidies (Rao 2012; Soile and Mu 2015). The consequences of indoor solid-fuel use for user health and ambient air quality have stimulated further action to examine and incentivize use of cleaner fuels, especially LPG (Gould and Urpelainen 2018; Thomas et al. 2022). Energy policy in China has emphasized banning residential coal in favor of LPG and electrified appliances, especially in the highly populated areas in the northeast (Liu et al. 2021). Some of these efforts have been tempered by supply limitations. Imported fuels like LPG are subject to price and supply volatility, especially during periods of political instability. Electrical grids that have supported only lighting and mobile phone charging may not have the capacity to transmit sufficient energy to handle peak heating or cooking loads.

Contrasting with efforts to adopt liquid or gas combustion and switch away from solid fuel, some high-income regions are beginning to move away from combustion entirely to avoid greenhouse-gas emissions (Nadel 2019). In 2019, the city of Berkeley, California, passed legislation to ban natural-gas connections to new, low-rise residential buildings. Within the next 2 years, 54 cities and counties in the United States, including New York City, passed similar legislation. These initiatives may have political consequences; in response to city-level initiatives, other states reacted by passing or proposing legislation that prohibited local bans.

Alternative Service Provision

Energy consumption and emissions can be greatly reduced by devices that provide similar services but deliver heat in a different way. Microwave ovens cook more rapidly by exciting water molecules inside food rather than relying on convective or

radiative heat transfer. Induction cooking also avoids heat transfer by heating the vessel directly through magnetic induction. Retained-heat cookers provide insulated compartments to keep heat from escaping a cooking vessel, avoiding the need to maintain its temperature with low-power combustion.

Some of the greatest shifts in reducing exposure are accomplished not by replacing devices or fuels, but by altering behavior so that people obtain desired services through completely different means. As people gain income and lose leisure time, they remove cooking from the home by purchasing prepared foods or eating in restaurants. Less space heating is required when people wear warmer clothing or use electric blankets, adaptations that are enabled by lightweight textiles and inexpensive manufacturing. Such societal transformations are rarely predicted, only observed.

Conclusions

Appliances are key elements of complex energy systems that may result in indoor exposures. Physical components of these systems include the appliances themselves and the fuels they employ, which govern the form of combustion through fuel release and air-fuel mixing. Combustion quality affects quantities, particle size distributions, and chemical composition of emissions, and solid-fuel emissions are usually much greater than those of liquid or gaseous fuels. The combination of emission and ventilation or venting affects indoor exposures. Other social and technical components of these systems include energy device users, occupants, and their expectations for obtaining energy services; infrastructure, supply chains, and markets; and local and national policies on energy, environment, and health. Any of these factors may play a role in promoting or inhibiting transitions to cleaner indoor air.

Abstract

Electronic cigarettes (e-cigs) use, which is also called vaping, has increased considerably in recent years. Although e-cig was initially designed as an alternative to tobacco cigarettes (t-cigs), there has been a high demand for flavored e-cig products among never-smoking adolescents and young adults. As a result, many

bystanders are now at the risk of passive exposure to secondhand vaping (SHV) aerosols, which are spilled from the mouth before inhalation and exhaled by an e-cig user, especially in an indoor environment. This chapter summarizes the impacts of e-cigs on indoor air quality, chemical compositions of e-cig aerosols, factors affecting emissions, and associated respiratory and cardiovascular effects. The use of e-cigs in indoor environments leads to high levels of fine and ultrafine particles (UFPs) similar to t-cigs. Concentrations of chemical compounds in e-cig aerosols are generally lower than those in t-cig smoke, but a substantial amount of vaporized propylene glycol (PG), vegetable glycerin (VG), nicotine, and toxic substances, such as aldehydes and heavy metals, has been reported. Exposures to e-cig aerosols have biologic effects but only limited studies have focused on adverse respiratory and cardiovascular effects in humans. Nevertheless, the recent outbreak of the e-cig or vaping product use-associated lung injury (EVALI) that has been linked to cannabis products vaping raised serious public health concerns. Long-term studies are needed to better understand the health effects of exposures to e-cigs, especially SHV aerosols.

Introduction

Electronic cigarettes (e-cigs), also known as vaping devices, are battery-powered nicotine delivery systems widely used as alternatives to traditional tobacco cigarettes (t-cig). For t-cigs, the combustion of tobacco leaves releases nicotine and substantial amounts of toxic by-products. In comparison, e-cigs generate aerosols by vaporizing e-liquids, which typically contain propylene glycol (PG), vegetable glycerin (VG), nicotine, and flavoring additives.

As shown in Fig. 1, there are several generations of e-cig devices since e-cig was first invented in 2003. E-cigs have evolved quickly over time from the cigalike type to the more advanced tank style with customizable voltage and e-liquids, and to the recent pod-based vaping systems such as JUUL pods. Although hundreds of different e-cig brands with various design features are currently available on the market, most e-cigs consist of a cartridge, tank, or pod with the e-liquid, a heating element (i.e., atomizer with heating coil), and a battery. In the meantime, thousands of flavors such as tobacco, menthol, fruit, candy, and sweets added in e-liquids have been widely adopted by e-cig users. Due to the high customizability of e-cig devices, many users are now even adding tetrahydrocannabinol (THC) or cannabidiol (CBD) oil into e-liquids for vaping marijuana.

E-cigs are marketed as a safer alternative to t-cigs because they are combustion free, yet their use has also increased greatly among never-smoking adolescents. Since 2011, the use of e-cigs or vaping has gained popularity among young adults

worldwide. The global e-cig market has grown rapidly, with more than 70% in North America and Europe. The number of e-cig users has also increased markedly, especially among adolescents, despite the Food and Drug Administration (FDA)'s prohibition of sales to persons under the age of 18. In the USA, although the rates of t-cig use among youth have declined over years, the current e-cig use among high school students has increased from 0.2 million in 2011 to 3.0 million in 2020 (CDC 2020) (Fig. 2). Similar increases among adolescents have been observed in other countries, such as the UK, Canada, South Korea, New Zealand, Finland, and Poland. E-cigs are popular among adolescents likely because of their appealing flavors. The newly introduced sleek and discreet JUUL pods which use nicotine salts to deliver higher levels of nicotine also provide a smoother and easier transition to vaping.

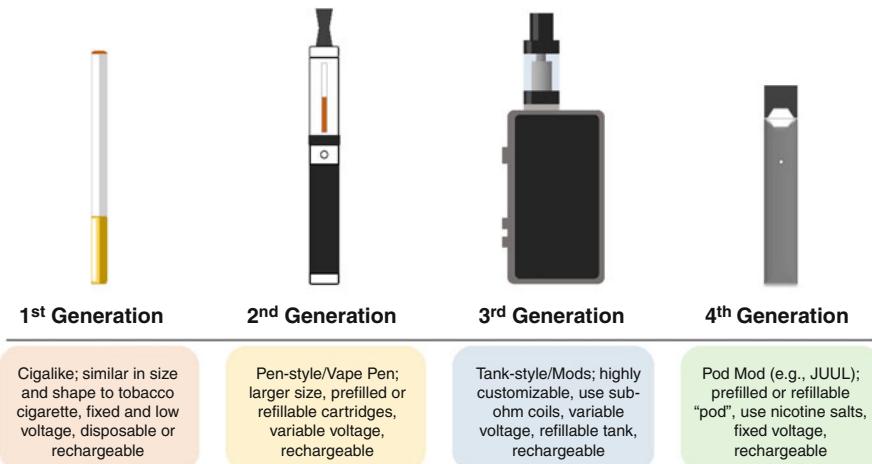

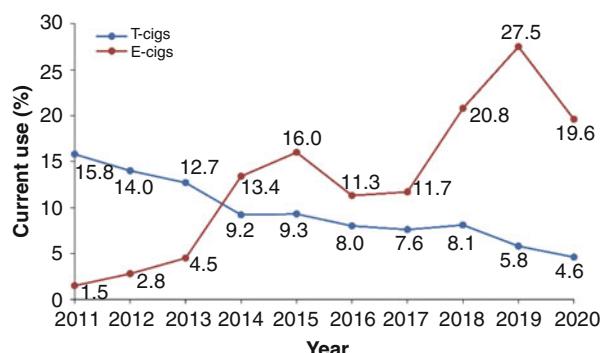

Fig. 1 Different generations of electronic cigarettes

Fig. 2 Percentage of high school students who currently use electronic cigarettes (e-cigs) and tobacco cigarettes (t-cigs) in the USA from 2011 to 2020. Based on data from the National Youth Tobacco Survey by the Centers for Disease Control and Prevention (CDC 2020)

Since 2019, many cases and deaths of e-cig or vaping product use–associated lung injury (EVALI) have been reported in the USA (Layden et al. 2019). E-cigs may not only pose health harms to active users but also bystanders. The majority of inhaled e-cig aerosols can be eventually exhaled, which may cause passive exposure to secondhand and even thirdhand vaping aerosols. E-cigs are commonly used in many places, such as homes, cars, restaurants, bars, and workplaces where vulnerable populations, such as children, adolescents, and pregnant women, might be exposed. The percentage of nonusers who were exposed to secondhand vaping (SHV) aerosols in an indoor environment ranged from 4% to 30% in Europe (Amalia et al. 2020). In the USA, more than half of middle and high school students were exposed to SHV aerosols (Gentzke et al. 2019). Exposure to SHV aerosols in indoor environments is of particular concern because people typically spend more than 80% of their time indoors, where emitted pollutants are not diluted as quickly or as extensively as outdoors. Yet, to what extent such secondhand exposures affect human health is poorly understood.

The process from e-cig emissions to passive exposures, and to potential health effects is presented schematically in Fig. 3 (Li et al. 2020b). The mainstream aerosols emitted from e-cigs are determined by many parameters related to e-cig devices and e-liquids. For an active user, the inhaled e-cig aerosols can be affected by puffing topography and related physiological factors. Due to e-cig use, SHV aerosols include a significant amount of particles that are exhaled by the e-cig user and a certain amount that are spilled from the mouth before inhalation (Logue et al. 2017). Once released into an indoor environment, e-cig aerosols are mainly affected by environmental parameters. The effects of such factors on e-cig particle concentrations and chemical compositions are discussed in later sections,

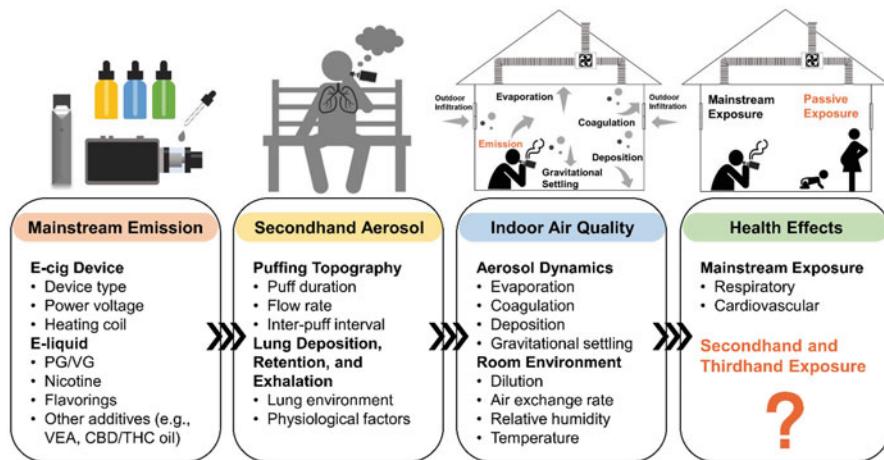

Fig. 3 Schematic process from e-cig emissions to passive exposures, and to potential health effects. (Adapted from Li et al. (2020b))

respectively. Both toxicological and epidemiological studies on health effects of e-cig aerosols are discussed in the “Health effects” section.

Particulate Matter in E-Cig Aerosols

Exposure to atmospheric particulate matter (PM) has been associated with mortality and morbidity in many epidemiological studies (Cohen et al. 2018; Burnett et al. 2018). Similar to t-cigs, high levels of fine particulate matter ($PM_{2.5}$, particles with aerodynamic diameters $\leq 2.5 \mu\text{m}$) and ultrafine particles (UFPs, particles with diameters $\leq 100 \text{ nm}$) have been observed in e-cig emissions (Li et al. 2020b). Exposure to outdoor $PM_{2.5}$ is a well-established risk factor for respiratory and cardiovascular diseases (Cohen et al. 2018). In addition, UFPs are also of great health concern because they have a greater surface area per unit mass than larger particles so that they can bind to more toxic chemicals (Terzano et al. 2010).

Particle Concentration and Size Distribution

Several indoor studies have reported high concentrations of $PM_{2.5}$ resulting from vaping (Fig. 4a), which could reach up to $1660 \mu\text{g}/\text{m}^3$ (Son et al. 2020), or ~66 times

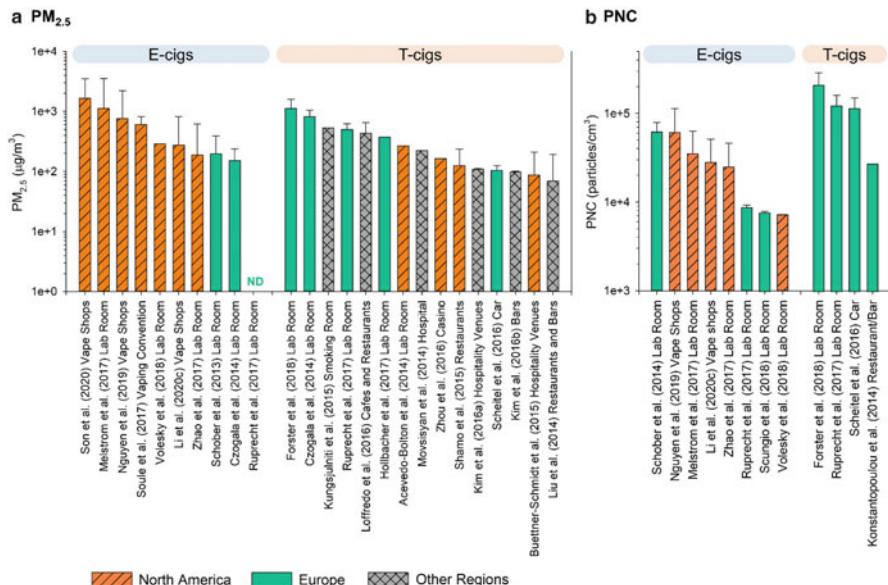

Fig. 4 Average concentrations of (a) $PM_{2.5}$ and (b) particle number concentration (PNC) from 13 studies on e-cigs and 16 studies on t-cigs in various indoor environments (i.e., laboratory settings and real-world public indoor spaces) by region. Abbreviation: ND not detectable. (Adapted from Li et al. (2020b) and references therein)

as high as the World Health Organization's recommended limit for 24-h outdoor concentrations of $25 \mu\text{g}/\text{m}^3$. In most cases, the reported indoor PM_{2.5} levels during vaping are above $150 \mu\text{g}/\text{m}^3$, which are similar to those produced by t-cigs. The impacts of e-cigs on indoor air quality are also similar to, if not greater than, other combustion-free nicotine delivery systems, such as waterpipe and "heat-not-burn" products (Forster et al. 2018; Fromme et al. 2009). The PM_{2.5} concentrations of $600\text{--}800 \mu\text{g}/\text{m}^3$, as reported in vape shops and vaping conventions, are about twice as high as those in hookah bars (Zhou et al. 2017). In comparison, the PM_{2.5} concentrations observed across a wide range of common indoor environments without e-cig use, such as homes, offices, schools, and day care, are from $8\text{--}52 \mu\text{g}/\text{m}^3$ (Morawska et al. 2017).

The indoor UFPs, which are approximately measured by the particle number concentration (PNC), can increase up to 20 times over the background during vaping ($0.7\text{--}6.2 \times 10^4 \text{ particles}/\text{cm}^3$; Fig. 4b) (Guo et al. 2010), but still lower than those from t-cigs ($7.0\text{--}21 \times 10^4 \text{ particles}/\text{cm}^3$) (Forster et al. 2018; Scheitel et al. 2016; Konstantopoulou et al. 2014) and other combustion-free nicotine delivery systems ($0.8\text{--}32 \times 10^4 \text{ particles}/\text{cm}^3$) (Fromme et al. 2009; Ruprecht et al. 2017; Forster et al. 2018). Similar to PM_{2.5}, indoor PNC from e-cig is also higher than other common indoor environments mentioned above (Morawska et al. 2017).

As shown in Fig. 4, studies on t-cig secondhand smoke (SHS) have been conducted worldwide, but studies on e-cigs are mainly from North America and Europe. The current prevalence of e-cig in other countries and regions is relatively low, but the e-cig market in many populous countries (e.g., China) is expanding rapidly. Thus, exposures to SHV aerosols will likely become a potential public health problem in those countries in the near future.

In addition to particle concentrations, particle size distribution is also important to respiratory health because smaller particles (especially UFPs) generally penetrate deeper into the lung. E-cig particles are primarily in the submicron size range, typically exhibiting a bimodal size distribution, with one mode located around 15–30 nm and the other around 85–100 nm (Schripp et al. 2013; Zhao et al. 2017; Scungio et al. 2018). Both particle concentration and particle size distribution can be affected by various factors as illustrated in Fig. 3 and discussed below.

Factors Affecting Indoor E-Cig Particle Concentrations

Changes in e-cig device, e-liquid, vaping topography, and indoor environment can all affect particle concentration and size distribution in e-cig aerosols, which may ultimately affect the lung deposition and exposure dose. Understanding the dynamics of e-cig particles in an indoor environment is important as it can guide exposure assessment and mitigation strategies.

E-Cig

E-cig device-related parameters: The heating element plays an important role in generating e-cig aerosols. Higher power voltage would transform more energy to

heat, resulting in higher heating coil temperature. More e-liquid can be vaporized at a higher voltage, thus the power level has been positively associated with both PNC and total PM mass concentration (Floyd et al. 2018; Gillman et al. 2016; Zhao et al. 2018). In addition, the particle sizes tend to be larger with an increasing voltage (Zhao et al. 2018; Lechasseur et al. 2019). The heating process is not consistent between brands and types of e-cigs due to the different design features, leading to large variations in e-cig emissions. For example, the tank style, which allows a higher voltage, can produce more particles than the cigalike type.

E-liquid compositions: Particle emissions from e-cigs are also influenced by the e-liquid compositions. More PG content in the e-liquid would produce a stronger “throat hit” feeling while more VG would generate thicker and larger visible “clouds.” Various volume combinations of PG and VG are available in the e-cig market to suit different e-cig users’ preferences. Higher PG/VG ratios tend to produce more particles (Baassiri et al. 2017; El-Hellani et al. 2018), while greater VG content increased the particle size (Lechasseur et al. 2019). Several studies reported that adding nicotine to e-liquids produces more particles (Fuoco et al. 2014; Manigrasso et al. 2015), while others did not (Zervas et al. 2018; Li et al. 2020a). The inconsistent results indicate how nicotine changes the e-cig emissions remains unclear, calling for future studies. In addition, e-cig aerosols are highly volatile. E-cig particles generated from nicotine-free e-liquid decay faster with increasing PG/VG ratios due to evaporation (Li et al. 2020a). However, this pattern was not observed with nicotine in the e-liquid. The recently introduced JUUL or other pod systems containing dissolved nicotine salts have raised even more health concerns due to their high nicotine content and popularity among adolescents, but have not been well studied (McKelvey et al. 2018).

Several studies have reported higher particle mass generated by tobacco flavor e-liquids than the menthol flavor (Zhao et al. 2018; Lee et al. 2017), while others observed little effects of flavors on particle emissions (Fuoco et al. 2014; Zervas et al. 2018; Manigrasso et al. 2015). Given the complexity of numerous flavoring additives, however, there is no conclusive evidence on the effects of flavors on particle emissions. Flavoring compounds in e-liquids have been largely linked to toxic chemicals which is discussed more later.

In recent years, the use of cannabis products such as THC or CBD in e-liquids as a method of delivering marijuana has emerged. The majority of the EVALI patients reported use of THC oil and a few reported use of CBD oil (Layden et al. 2019), suggesting the serious health risks of vaping cannabis products. A recent study (Wallace et al. 2020) characterized the emission from secondhand cannabis vaping, which had a higher $PM_{2.5}$ emission factor and lower particle removal rate than previous studies (Li et al. 2020a) found in e-cig aerosols without cannabis oil. Another study (Tang et al. 2021) reported that the presence of terpenoids in the e-liquid containing vaporizable cannabis concentrates resulted in significant levels of UFPs in the e-cig aerosol. Although the mechanisms of the EVALI outbreak has not been fully understood, the addition of vitamin E acetate used to dilute THC oil has been linked to it. The health effects of vaping cannabis products are discussed further below.

Vaping

Puffing topography (i.e., flow rate, puff duration, and inter-puff interval) and the process of inhalation and exhalation also affect e-cig aerosol emissions. In general, the particle concentration increases with higher puffing flow rates, longer puff durations, and greater puff frequencies (Gillman et al. 2016; Nguyen et al. 2019; Zhao et al. 2016). On the other hand, the particle size decreases with higher puffing flow rates and shorter puff durations (Zhao et al. 2016).

The inhaled e-cig particles tend to grow in human lungs under high humidity due to the hygroscopic effect, which is more prominent than t-cig smoke (Sosnowski and Kramek-Romanowska 2016). The initial particle size distribution plays an important role in the hygroscopic effect (Sosnowski and Odziomek 2018), where particles in the nanometer size range slightly increase their size, while particles greater than 0.5 μm become larger by more than 50%. These inhaled particles are deposited in the respiratory system, mainly through gravitational settling, impaction, and diffusion (Hinds 1999). Depending on the initial size, increasing particle size in the respiratory system may reduce the deposition due to diffusion but increase the deposition due to gravitational settling and impaction. Other physiological factors in the respiratory system, such as lung capacity, air flow, and breath pattern, might also affect e-cig aerosol dynamics.

Indoor Environment

A certain amount of aerosol can be spilled from the mouth before inhalation and the majority of droplets inhaled can be exhaled by an e-cig user. Once released into the room air, e-cig particles are subject to aerosol dynamics under various environmental conditions. In contrast to t-cig smoke, e-cig aerosols mainly consist of droplets that are more volatile because the e-liquid main ingredient, PG, has a relatively high saturation vapor pressure. E-cig particles have been observed to evaporate within seconds (Zhao et al. 2017). At high PNCs, coagulation is also an important particle removal mechanism that reduces the number of particles, but increases particle size (Floyd et al. 2018). In addition, e-cig particles can be removed from the room air by gravitational settling and surface deposition, leading to potential thirdhand exposures which also warrant future studies (Goniewicz and Lee 2015).

Increasing dilution or air exchange rate (AER) may enhance particle evaporation and reduce particle concentrations and particle sizes (Ingebrethsen et al. 2012; Floyd et al. 2018; Nguyen et al. 2019). Similarly, increasing temperature or decreasing relative humidity may also enhance evaporation and reduce particle size (Wright et al. 2016; Schripp et al. 2013). Because e-cig aerosols are dynamic, their concentrations decay rapidly over distances (>1.5 m) from the source (i.e., e-cig users), especially for PM_{2.5} mass concentrations (Zhao et al. 2017; Nguyen et al. 2019).

Effects of Proximity on SHV Aerosols

It has been shown that evaporation could occur to e-cig aerosol particles under a high dilution condition. After the SHV particles are released into indoor air, their spatial profiles provide information on how far e-cig particles can move in an indoor environment.

Vaping in a Laboratory Room

The PNC and $\text{PM}_{2.5}$ concentrations at different locations ranging from 0.8–2.5 m away from an e-cig user in an 80 m³ room are presented in Fig. 5 (Zhao et al. 2017). The mean PNCs were 1.7×10^4 , 3.4×10^3 , 2.1×10^3 , and 1.3×10^3 particles/cm³ at 0.8, 1.5, 2.0, and 2.5 m from the e-cig users, respectively, which indicate that PNC of SHV aerosols decreased quickly from the source (Fig. 5a). When the sampling location moved to 1.5, 2.0, and 2.5 m from the e-cig users, the PNC dropped to 20%, 12%, and 7% of what was measured at 0.8 m, respectively. Approximately, 80% of PNC dropped between 0.8 and 1.5 m, and only 7% of PNC remained beyond 2.5 m. Similarly, the mean $\text{PM}_{2.5}$ was 375, 15, 7, and 5 $\mu\text{g}/\text{m}^3$ at increasing distances (Fig. 5b). When the sampling location moved to 1.5, 2.0, and 2.5 m from the e-cig user, the $\text{PM}_{2.5}$ dropped to 4%, 2%, and 1% of what was measured at 0.8 m, respectively. About 96% of $\text{PM}_{2.5}$ reduction occurred between 0.8 and 1.5 m, which was greater than that of PNC. These data can be used to model the transport of e-cig particles in indoor environments and highlight the importance of proximity to e-cig users in secondhand exposure assessment.

Vaping in Vape Shops

In real world, vaping occurs in various indoor environments including vape shops, which are a new type of retailer, where customers can exclusively purchase e-cig products and sample e-liquids with a combination of flavors and varying levels of nicotine (Galstyan et al. 2019). In the USA, the growing vape shop industry accounts for 20% of the e-cig retail markets in 2019 and has proliferated globally over the past few years (Galstyan et al. 2019). While many states have established smoking bans in workplaces and public spaces, the use of e-cigs is unrestricted in vape shops. Nguyen et al. (2019) found that the PNC and $\text{PM}_{2.5}$ in vape shops fluctuated

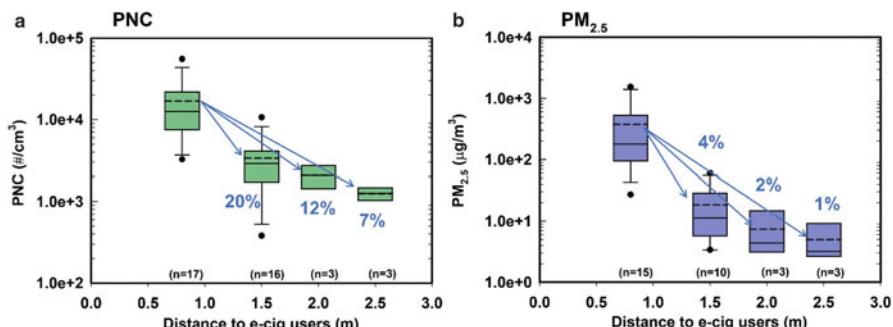

Fig. 5 (a) PNC and (b) $\text{PM}_{2.5}$ concentrations of secondhand vaping (SHV) aerosols at increasing distances from the e-cig users in an 80 m³ room. The dots above or below the boxes represent the outliers, which are beyond 1.5 IQR (interquartile range). The solid line in each box represents the median value, and the dash line in each box represents the mean value. (Adapted from Zhao et al. (2017))

dramatically and can even reach instantaneously up to 4.8×10^5 particles/cm³ and 37,500 µg/m³, respectively.

Figure 6 plots the mean PNC and PM_{2.5} concentrations measured over increasing distance from a vaping source in four vape shops (labeled as #1–4). Distances were designated based on the following degrees of proximity from the vaping source: (1) personal space (0.45 to <1.2 m); (2) social space (1.2 to <3.6 m); and (3) public space (3.6 m and beyond). Concentrations were compared at points within the personal space to public space except for vape shop #2, where concentrations were measured within the personal space to social space. Mean PNC and PM_{2.5} concentrations measured in the vape shops within the personal space of a vaping source were $2.0\text{--}12.6 \times 10^4$ particles/cm³ and 102–1858 µg/m³, respectively. From social space to public space, mean PNC and PM_{2.5} concentrations were $0.6\text{--}8.6 \times 10^4$ particles/cm³ and 34–1375 µg/m³, respectively. The observed decreasing concentration from the personal space to the social/public space suggests a proximity effect for SHV particle concentrations.

In contrast to the laboratory study (Zhao et al. 2017) that reported low indoor PM concentrations within the social space of an e-cig user (Fig. 5), high concentrations were still measured more than 4 m away from the vaping source in vape shops. As shown in Fig. 6, as much as 77% of PNC and 62% of PM_{2.5} measured within the personal space of a vaping source remained when measured at the public space. This is unlike the PNC and PM_{2.5} monitored in the laboratory room, where only 7% and 1% remained beyond the social space of the e-cig user. In the laboratory room, the AER was 4.1 h⁻¹ and spatial analysis was conducted after a short-term puffing by a single e-cig user. Even among the four vape shops, a greater percentage of remaining PM was observed in vape shops #1 and #4, where the AERs were lower and the average vaping frequency was higher than in shop #3 over a similar distance (~3 m).

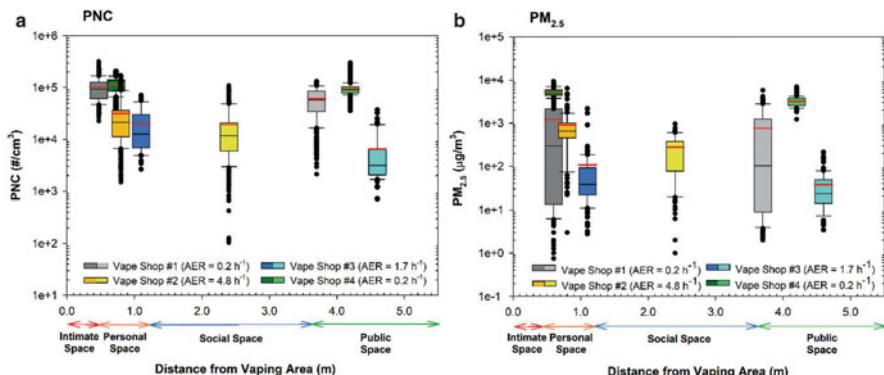

Fig. 6 (a) PNC and (b) PM_{2.5} concentrations at personal, social, and public distances away from vaping activity inside vape shops. From vaping activity, concentrations were measured at 0.6 and 3.7 m away in vape shop #1, 0.8 and 2.4 m away in vape shop #2, 1.1 and 4.6 m away in vape shop #3, and 0.6 and 4.2 m away in vape shop #4. (Adapted from Nguyen et al. (2019))

In general, factors contributing to the persistence and mixing of SHV aerosols in the vape shops include: (1) lower AERs, leading to exhaled e-cig vapor partial pressure buildup inside the shop and decrease in e-cig particle evaporation; (2) continuous puffing by multiple e-cig users, extending the proximity effect from aggregate emissions and leading to subsequent microplume transportation caused by turbulence; and (3) people moving around and the shop doors were usually closed. Overall, the high vaping density together with low AER in vape shops presents conditions that heighten the mixing potential of and sustained exposure to SHV aerosols unlike in laboratory or residential settings.

Transport of SHV Aerosols in Multiunit Indoor Environment

It has been well established that SHS can transfer from smoking units to smoke-free adjacent units through shared ventilation, open windows, holes in walls, hallways, and electric outlets in multiunit buildings. Analogous to SHS, these transfer mechanisms are also applicable to SHV aerosols.

Laboratory Multiunit Setting

The transport of SHV aerosols from a vaping room (Room V) to an adjacent nonvaping room (Room N) when the door connecting the two rooms was either open or closed is presented in Fig. 7 (Zhang et al. 2020). Door open condition represents a typical exposure scenario in a multizone indoor environment without any mitigation strategy. When the door was open, the PNC in Room V started to increase right after vaping began, peaked at the end of the vaping session, up to 2.7×10^4 particles/cm³, and returned to the background concentration within 40–50 min. Mean PNCs were measured at 2.0×10^4 particles/cm³ during vaping and 5.8×10^3 particles/cm³ during decay, respectively (Fig. 7a). In Room N, PNC started to increase 1 min after vaping began and increased up to 9.9×10^3 particles/cm³ about 3 min after vaping ended, suggesting a rapid transport of UFPs from Room V to Room N. The PNC returned to the background concentration about 40 min after vaping ended. Overall, mean PNCs were 5.7×10^3 particles cm⁻³ during vaping and 3.6×10^3 particles/cm³ during decay. Similarly, a smaller increase of PM_{2.5} concentrations was observed in Room N and less time was needed for it to return to the background concentration. In Room V, PM_{2.5} started to increase 1 min after vaping began, peaked coinciding with the end of the vaping session, up to 64 µg/m³, and then fell to near-background concentration in about 6 min. In Room N, after subtracting the background, the maximum PM_{2.5} concentration only reached 4 µg/m³ (Fig. 7c). When the door connecting the two rooms was closed, no spikes were observed in Room N for both PNC and PM_{2.5}, suggesting the effectiveness of door segregation (Figs. 7b, d).

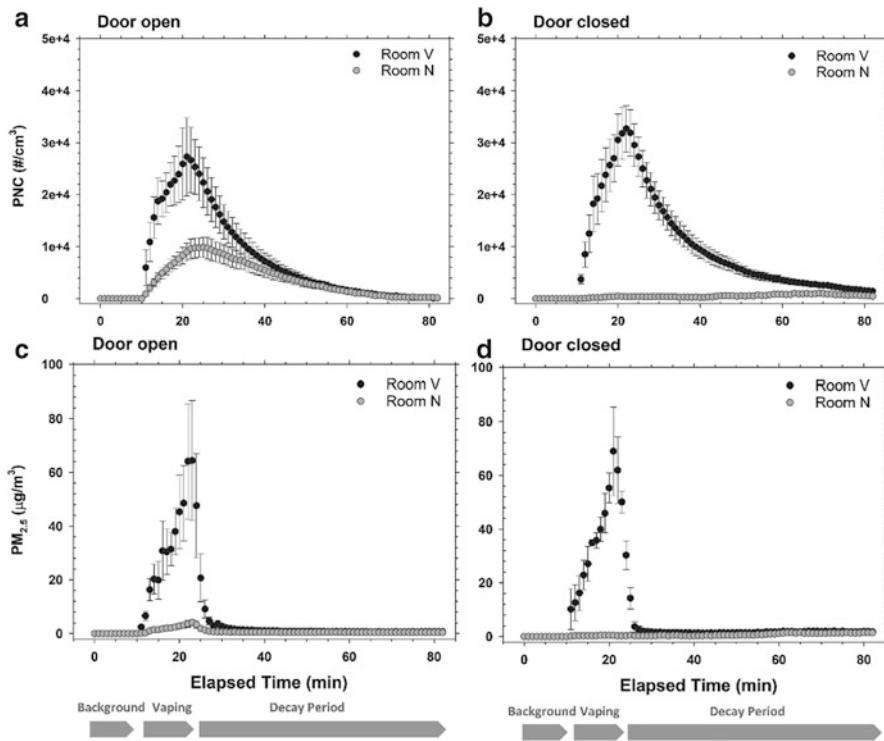

Fig. 7 The temporal trends of PNC and PM_{2.5} in the vaping room (Room V) and nonvaping room (Room N) when the door connecting the two rooms was open (**a** and **c**) and closed (**b** and **d**). Background concentration was subtracted. (Adapted from Zhang et al. (2020))

Vape Shops and Neighboring Indoor Spaces

Because vape shops are typically located in multiunit buildings with at least one neighboring business, such as an office, restaurant, retail store, or clinic, the SHV particles may also travel to these neighboring businesses. Exposure to the visible massive “clouds” produced in vape shops is an environmental and public health concern. A previous study (Li et al. 2020c) recruited six pairs of vape shops and their neighboring businesses in Southern California. The PNC and PM_{2.5} in the studied vape shops were significantly higher than their neighboring businesses. Out of the six studied pairs, PNCs in five vape shops and PM_{2.5} in two vape shops were significantly correlated with those in their neighboring businesses. A stronger correlation tends to be found in vape shops with higher vaping density (puffs/h/100 m³), defined as the total number of puffs per hour normalized by the shop volume. The weakest correlation was observed in the only pair that did not share the ventilation system. These results show that emissions from the vape shops can impact the indoor air quality in their neighboring indoor spaces.

Because no mechanical ventilation systems were actively in use for the studied vape shops and their neighboring businesses, natural ventilation through door opening was critical to reduce the exposure to SHV aerosols. The effects of door open and close on UFP transfer from a representative vape shop to its neighboring business are illustrated in Fig. 8. During the sampling period, the vape shop door was closed before 14:30 and open after 14:30. Following the PNC spikes in the vape shop, the PNC levels were also elevated in the nearby businesses. Shortly after the vape shop door was open, the PNC started to decay in the nearby businesses

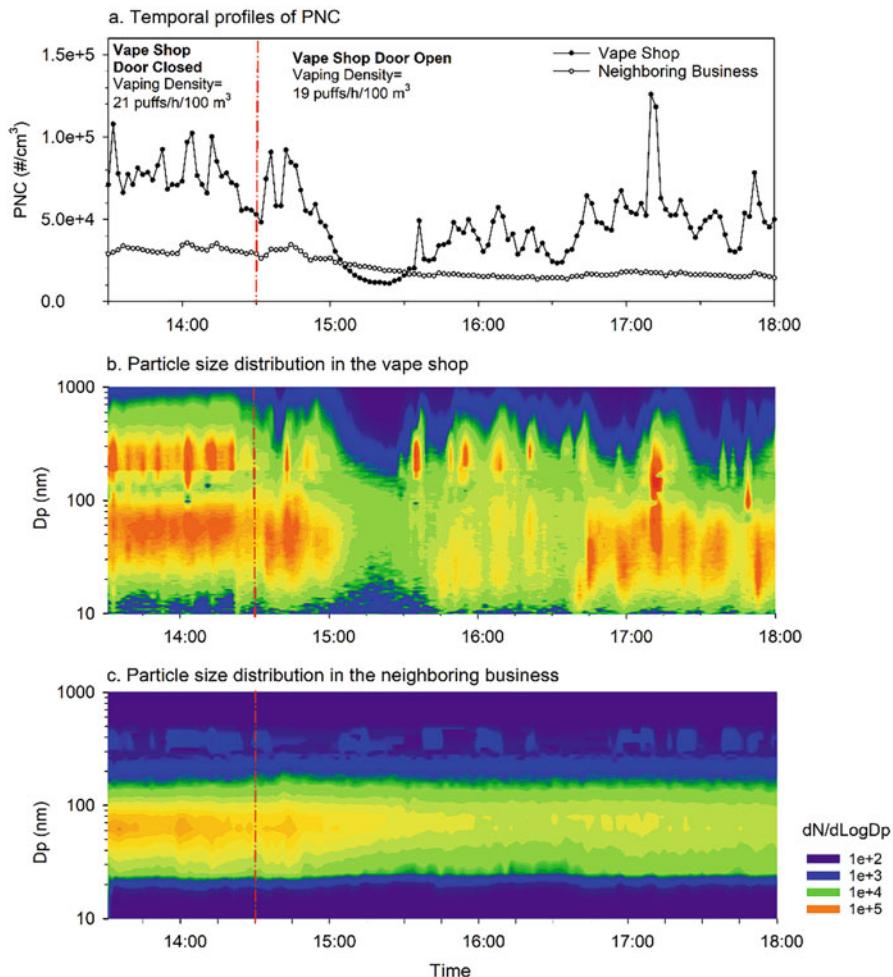

Fig. 8 Temporal profile of (a) PNC in a representative vape shop and its neighboring businesses as well as particle size distributions in (b) the vape shop and (c) neighboring businesses during overlapping business hours on a day with ventilation changes. Note: The door of vape shop was closed during 13:30–14:30 and the door was open during 14:30–18:00 (Li et al. 2020c)

(Fig. 8a). Consequently, the mean PNC decreased by 19% to 4.3×10^4 particles/cm³ in the vape shop and decreased by 33% to 1.8×10^4 particles/cm³ in nearby businesses.

Figure 8b, c present the contour plots of number-based particle size distribution for the vape shop and its neighboring businesses. The color intensity indicates the normalized PNC (dN/dLogD_p) for a given particle size at a given time. As demonstrated by Nguyen et al. (2019), the particles emitted in the vape shop was characterized by a bimodal particle number distribution of 60 nm and 250 nm when the shop door was closed. Meanwhile, UFPs largely penetrated into the neighboring businesses showing a single mode at 60 nm. Since UFPs may deposit deep into the human lung and induce greater adverse respiratory effects (Sturm 2016), the exposure to SHV related UFPs might bring more health concerns for employees and patrons in the neighboring businesses. After the door was open, PNC started to decrease immediately and the particle size distribution in the vape shop shifted to a single mode.

Opening and closing the vape shop doors changed the condition of ventilation in vape shops using natural ventilation. When the vape shop door was closed, an even stronger correlation in terms of PNC was observed. This was most likely a result of the enhanced particle concentration gradient between the vape shop and neighboring businesses because particles persisted and remained at high concentrations in the vape shop during door closed periods (Nguyen et al. 2019). However, no significant correlations between PNC in vape shops and that in neighboring businesses were observed when vape shop doors were open due to the enhanced dilution from outdoor air.

As a tracer compound, nicotine was detected in the air of all the studied vape shops and neighboring businesses. The mean concentration of the 24 h time-weighted average (TWA) nicotine measured in vape shops and neighboring businesses were $2.6 \mu\text{g}/\text{m}^3$ and $0.17 \mu\text{g}/\text{m}^3$, respectively. Assuming the nicotine measured in the neighboring businesses was all from its adjacent vape shop, the percentage of nicotine transfer ranged from 2.4% to 25%. The highest nicotine transfer rate (i.e., 25%) was observed in a pair likely because the neighboring businesses experienced significant impacts of both particle number and mass on their indoor air quality. Although the airborne nicotine levels varied depending on the level of nicotine in the e-liquids selected by e-cig users as well as the customer traffic, the identification of nicotine in all the studied vape shops and neighboring businesses confirmed that involuntary exposures to SHV aerosols occurred in those indoor environments.

Mitigation of SHV Aerosol Exposure in a Multiunit Setting

As discussed above, the effectiveness of mitigation strategies to reduce the transport of SHV aerosols from a vaping room (Room V) to its adjacent nonvaping room (Room N) in a multiunit laboratory setting has been investigated by Zhang et al. (2020). A total of six different experimental conditions were evaluated: (1) the

baseline scenario, in which the connecting door between the two rooms was open, the ventilation in both rooms was low, and no air purifier was operated; (2) the connecting door between the two rooms was closed; (3) the ventilation was enhanced in Room V; (4) the ventilation was enhanced in Room N; (5) an air purifier was operated in Room V; and (6) an air purifier was operated in Room N. Measurements were conducted for three sampling phases: a 10 min background measurement (Phase I), a 12 min vaping session (Phase II), and a 60 min decay period (Phase III).

Briefly, as shown in Fig. 9, when the door connecting Rooms V and N was closed (#2), mean PNC in Room N was significantly reduced by 87% to less than 1.0×10^3 particles cm^{-3} across Phase II and Phase III. It should be noted that mean PNC (1.0×10^4 particles cm^{-3}) in Room V was slightly higher relative to the baseline scenario (8.1×10^3 particles cm^{-3}) across both phases, likely because the dilution in Room N was inhibited. When ventilation was enhanced in Room V, mean PNC decreased by 42% in Room V and decreased by 46% in Room N during vaping and post-vaping sessions. Similarly, when ventilation was enhanced in Room N, mean PNC reduced from 8.1×10^3 to 6.4×10^3 particles cm^{-3} in Room V and significantly reduced from 3.9×10^3 to 1.2×10^3 particles cm^{-3} in Room N, respectively. When air filtration was increased in Room V, mean PNC slightly reduced by 17% in Room V and reduced by 23% in Room N across Phase II and Phase III. Similarly,

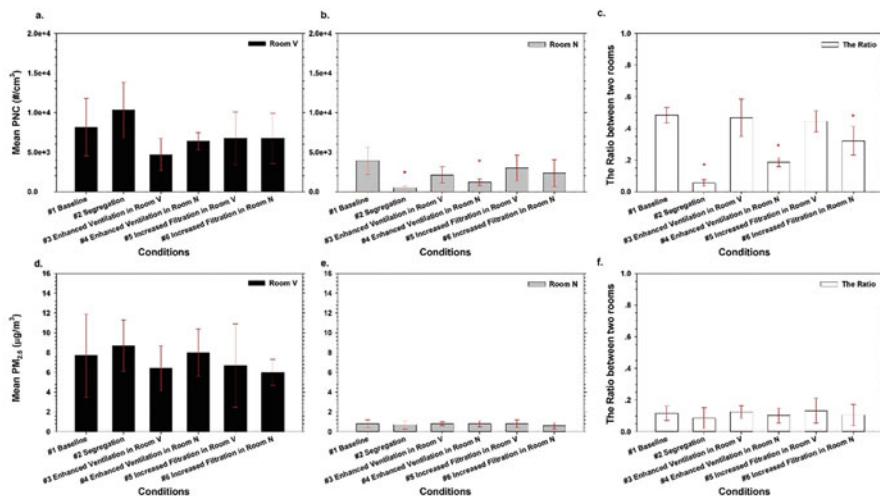

Fig. 9 Mean PNC due to e-cig use during vaping and post-vaping sessions in the (a) vaping room (Room V) and (b) its adjacent nonvaping room (Room N) and (c) the ratio between two rooms (i.e., Room N/Room V); mean PM_{2.5} due to e-cig use in (d) Room V and (e) Room N and (f) the ratio between two rooms; *indicates statistically significant ($p < 0.05$) based on the permutation test of the ratio between each condition and the baseline (#1). (Adapted from Zhang et al. (2020) under the terms of the Creative Commons Attribution 4.0 International License, <http://creativecommons.org/licenses/by/4.0/>)

when air filtration was increased in Room N, mean PNCs were reduced by 17% in Room V and by 40% in Room N across Phase II and Phase III.

As for PM_{2.5}, similar results were found under conditions #2–6 relative to the baseline scenario. In Room V, mean PM_{2.5} concentrations were measured at 6–9 µg m⁻³ across Phase II and Phase III under conditions #2–6. When the door connecting Room V and Room N was closed, peak PM_{2.5} concentrations increased from 64 to 69 µg m⁻³ in Room V. Peak value reduced by 38% to 40 µg m⁻³ when ventilation was enhanced in Room N. In Room N, under conditions #2–6, mean PM_{2.5} concentrations were about 1 µg m⁻³ and peak concentrations were less than 5 µg m⁻³ across Phase II and Phase III. Miller and Nazaroff (2001) have investigated the transport of SHS with a similar experimental design. The SHV particles (25–50 min) decayed much faster than SHS particles (120–240 min), presumably due to evaporation (Czogala et al., 2014).

To better understand the effects of tested mitigation strategies on the transport of SHV aerosols, the ratios of mean PNC and PM_{2.5} between two rooms are also presented in Fig. 9c, f. Segregation was the most effective method to reduce the transport of UFPs, in which the ratio was significantly reduced from 0.48 under the baseline condition to 0.06. Mitigation strategies applied in Room N, including enhancing ventilation (#4) and filtration (#6), significantly reduced the ratio to 0.19 and 0.32, respectively. However, when mitigations were applied in Room V, no significant differences were found. As for PM_{2.5}, the ratios were about 0.11 (0.09–0.13) with mitigations and no significant difference was found compared with the baseline (0.12). Overall, the transport of SHV aerosols could be effectively mitigated, especially by segregation. Other mitigations, including enhanced air ventilation and air filtration, could also increase particle removal.

Chemical Composition of E-Cig Aerosols

In addition to the physical characteristics, the effects of e-cig aerosols on health are largely determined by their chemical compositions. The most commonly reported chemicals in both mainstream and secondhand e-cig aerosols are PG, VG, nicotine, carbonyls, aromatic volatile organic compounds (VOCs), trace metals, and tobacco-specific nitrosamines (TSNAs) (Fig. 10) (Li et al. 2020b). Many chemicals are present in both gas and particulate phases. The partition between gas and particulate phases affects the concentration and fate of e-cig-emitted chemicals and warrants future study.

Chemical Profiles of E-Cig Aerosols

As shown in Fig. 10, the chemical profiles of mainstream and secondhand e-cig aerosols are similar, but as expected, the concentrations of most chemicals in the SHV are much lower than in the mainstream. Overall, the most abundant chemicals detected in the e-cig mainstream are PG and VG, followed by nicotine, carbonyls,

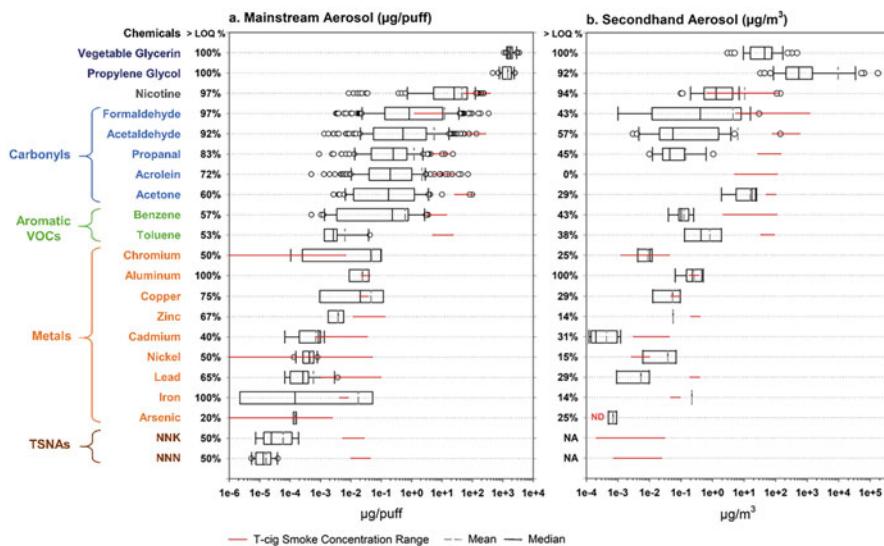

Fig. 10 Chemical compositions of e-cig aerosols including (a) emission rates of mainstream aerosols ($\mu\text{g}/\text{puff}$) from 37 studies and (b) concentration of secondhand aerosols ($\mu\text{g}/\text{m}^3$) from 11 indoor studies in which e-cig users vape in an indoor environment. Emission rates or concentrations of t-cig-emitted chemicals are presented in ranges (red line) as a reference group. All the data included are background-subtracted values, when applicable. “> LOQ%” indicates the percentage of available data points above the limit of quantification (LOQ). Abbreviations: VOCs = volatile organic compounds; TSNAAs = tobacco-specific nitrosamines; NNK = 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone; NNN=N'-Nitrosonornicotine (Li et al. 2020b and references therein)

aromatic VOCs, and trace metals. Most of the chemicals in the mainstream come from the major components of e-liquids: PG, VG, and nicotine. Although the FDA states that ingesting PG and VG in consumer and household products is safe, inhaling vaporized PG and VG at high concentrations could potentially irritate the lungs (Kienhuis et al. 2015), which is a unique health risk for e-cig aerosols (Liu et al. 2017). The significant amount of nicotine reported in the e-cig aerosols also poses several health risks. Existing evidence indicates that e-cig use can motivate youth to start smoking t-cig due to the highly addictive nature of nicotine (Glantz and Bareham 2018). In addition, nicotine contributes to adverse health effects on the cardiocirculatory, respiratory, and gastrointestinal systems (England et al. 2017; Benowitz and Burbank 2016; Mishra et al. 2015).

Other observed chemicals such as formaldehyde, acetaldehyde, propanal, acrolein, acetone, and benzene are likely produced by thermal degradation of PG and VG (Sleiman et al. 2016; Qu et al. 2019; Pankow et al. 2017). The detailed chemistry for the thermal degradation process of PG and VG is demonstrated in Fig. 11. E-cig-related aldehydes might also come from flavoring additives in the e-liquid (Khlystov and Samburova 2016). Aldehydes are cytotoxic and can have adverse respiratory effects. In addition, formaldehyde and acetaldehyde are classified by the

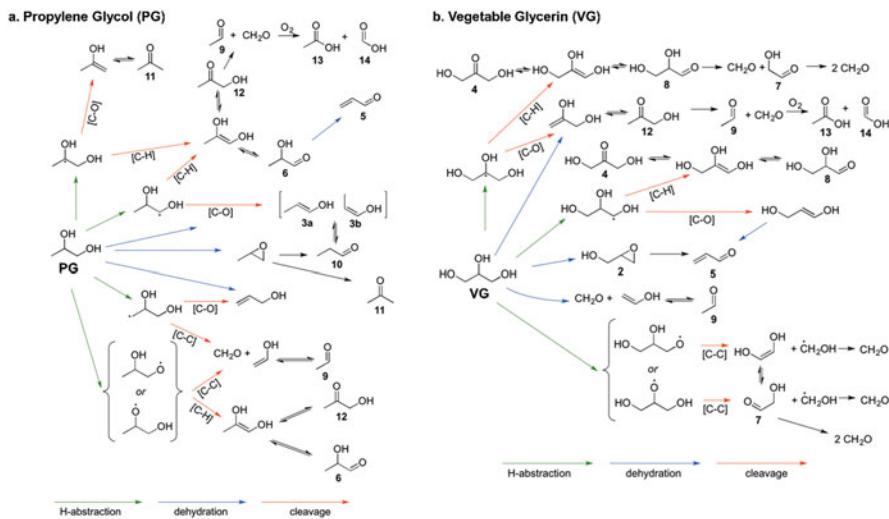

Fig. 11 Decomposition pathways of (a) propylene glycol (PG) and (b) vegetable glycerin (VG) in e-cig aerosols. The most prevalent reaction mechanisms involve oxidation and dehydration. Compound number definitions: 2, glycidol; 3a, b, propenol isomers; 4, dihydroxyacetone; 5, acrolein; 6, lactaldehyde; 7, glycolaldehyde; 8, glyceraldehyde; 9, acetaldehyde; 10, propanal; 11, acetone; 12, hydroxyacetone (acetol); 13, acetic acid; and 14, formic acid. (Adapted from Jensen et al. (2017) under the terms of the Creative Commons Attribution 4.0 International License, <http://creativecommons.org/licenses/by/4.0/>)

International Agency for Research on Cancer (IARC) as carcinogenic to humans (Group 1) and possibly carcinogenic to humans (Group 2B), respectively. In addition to the most commonly reported carbonyls, a few studies have also reported other compounds such as crotonaldehyde, methylglyoxal, glyoxal, dihydroxyacetone, butyraldehyde, benzaldehyde, isovaleraldehyde, valeraldehyde, and diacetyl in e-cig aerosols (Ward et al. 2020). Among the aromatic VOCs, the IARC lists benzene as a human carcinogen and toluene may be neurotoxic. One of the benzene formation mechanisms is decarboxylation of benzoic acid, suggesting the risk of using a large amount of benzoic acid in the pod system (Pankow et al. 2017). E-cig aerosols also contain a wide variety of VOCs at lower levels, such as acetonitrile, isoprene, ethanol, acetoin, and diacetyl, which likely originate from the flavoring additives (Lee et al. 2017; Klager et al. 2017).

The likely sources of trace metals, especially those with relatively higher concentrations (i.e., chromium, aluminum, and copper), are the metal-coated wires of the heating coils (Saffari et al. 2014; Williams et al. 2013). Inhaling trace metals might irritate the respiratory system and impair respiration (Williams et al. 2013). Cadmium, lead, chromium, arsenic, and nickel are also classified as human carcinogens. Many of these metals or metalloids were also identified in human biospecimens of e-cig users including urine, saliva, serum, and blood. Most metal or metalloid levels were comparable or higher than those identified in biospecimens of t-cig users (Zhao et al. 2020).

Although two studies found nicotine-derived nitrosamines, such as N'-Nitrosonornicotine (NNN) and 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK) (Goniewicz et al. 2014; Margham et al. 2016), which are strong carcinogens that may cause lung and oral cancers (Hecht et al. 2016), but whether these compounds are products of chemical reactions of nicotine or impurities of the e-liquid is not clear (Farsalinos et al. 2015). Less evidence exists in the literature on polycyclic aromatic hydrocarbons (PAHs) concentrations in e-cig aerosols which were reported either low or undetectable (Ward et al. 2020). On the other hand, reactive oxygen species (ROS) and free radicals in e-cig aerosols have also drawn some attention due to their potential to damage macromolecules and disrupt normal biological functions. ROS and free radicals were found in e-cig aerosols, although at lower levels than those found in t-cig smoke (Hasan et al. 2020; Son et al. 2019).

The concentrations of most chemicals in the e-cig mainstream aerosols are generally lower than those of t-cigs (Fig. 10). The only exceptions are PG and VG, which are major components of e-liquids and not present in t-cigs. Concentrations of trace metals in mainstream aerosols are similar in e-cigs and t-cigs. However, chromium, a carcinogenic and respiratory toxicant, is at higher concentrations in e-cigs, suggesting potential risks from chromium-coated wire in heating coils (Williams et al. 2013). The concentration of nicotine in e-cig mainstream aerosol is similar to or slightly lower than that in t-cig smoke. Of note, the nicotine content in a single JUUL pod with 5% nicotine strength is higher than that in 20 t-cigs which might lead to potential cytotoxicity and more significant addiction effects (Omaiye et al. 2019). The concentrations of carbonyls and aromatic VOCs are 10–1000 times higher in the mainstream emissions of t-cigs than in e-cigs. Because these compounds are highly toxic, the observed lower concentrations indicate that e-cig aerosols are likely less toxic than t-cig smoke (Cervellati et al. 2014). Alternatively, the mainstream emission rates of nicotine and degradation by-products such as formaldehyde, acetaldehyde, propanol, acrolein, acetone, and benzene in e-cig aerosols are at a similar level of “heat-not-burn” products (Cancelada et al. 2019), suggesting the impacts of combustion-free nicotine delivery systems on indoor air quality.

Factors Affecting Chemical Compositions

E-cig device: Chemical compositions in e-cig aerosols vary across different e-cig brands and types. The power levels and heating elements primarily determine the chemical emissions in e-cig aerosols. Extensive studies have investigated the relationship between the power and chemical concentrations in e-cig aerosols (Ward et al. 2020). When the power applied to the heating coil increases, carbonyl compounds (e.g., formaldehyde, acetaldehyde, propanal, acrolein, and acetone), aromatic VOCs (e.g., benzene and toluene), and trace metals in e-cig aerosols also increase (El-Hellani et al. 2018; Qu et al. 2019; Gillman et al. 2016; Pankow et al. 2017; Zhao et al. 2019). The types of atomizers in the tank-style systems can also affect the carbonyl emissions. For example, more carbonyls were produced using top-coil atomizers than bottom-coil atomizers, while sub-ohm coils with lower

resistance generated less carbonyls compared to supra-ohm tanks (Gillman et al. 2016). The tank-style systems with higher voltages were found to generate more toxic metals than cigalike or pod systems (Zhao et al. 2019). Similarly, nicotine yields were affected by the power outputs as well as the e-cig types and brands (Talih et al. 2015).

The first three generations of e-cig devices, ranging from cigalike to tank-style systems, use pure nicotine dissolved in the e-liquids. In contrast, the newest generation pod system (e.g., JUUL pod) uses a large amount of benzoic acid, as part of the nicotine salts formulation which brings more uncertainties on their health effects. The pod system was designed to have a lower power voltage but a higher nicotine dose to simulate t-cig smoking. As a result, higher levels of nicotine and lower levels of carbonyl compounds in the JUUL-generated aerosols were observed compared to other tank-style systems (Reilly et al. 2019).

E-liquid compositions: As previously discussed, the chemicals identified in e-cig aerosols are largely determined by the e-liquid compositions. The evidence in the literature suggests that the production of toxic chemicals, such as carbonyls and VOCs, has been associated with the flavoring compounds added to the e-liquid and the thermal degradation of PG and VG. Many chemical compounds such as acetaldehyde and acrolein were found in the e-cig aerosol but not in the e-liquid, suggesting the formation of toxicants during the heating process. Aldehydes formation was dependent on the PG/VG ratios. Certain chemicals, such as acetaldehyde, can be generated solely by PG degradation, while VG generates higher levels of formaldehyde and acrolein.

As to the flavoring additives, the aldehyde levels in e-cig aerosols from flavored e-liquids are significantly higher than those generated from pure PG or VG. Aldehydes concentrations increase as sucralose (an artificial sweetener) or diacetyl (a butter flavoring agent) concentration increases. Diacetyl and acetoin were found to be the most prevalent flavoring chemicals (Klager et al. 2017). Acetoin is a precursor to diacetyl in e-liquids, where diacetyl concentration was found proportional to acetoin. The inhalation of aerosols containing diacetyl may lead to the development of bronchiolitis obliterans or an irreversible respiratory disease, also known as “popcorn lung.” Another example is the formation of benzene in the e-cig aerosols. Benzene concentration increased with the addition of benzoic acid (an antimicrobial and flavoring agent) and benzaldehyde (an almond flavoring agent). Notably, the percentage of benzaldehyde transferred from e-liquid to e-cig aerosol is also higher with elevated PG content in the e-liquid. Higher nicotine delivery has also been associated with more PG content (El-Hellani et al. 2018). The reactions between PG and VG, together with nicotine and other flavoring additives, may have more complicated effects on the toxic emissions. Different from carbonyls and VOCs, e-liquid compositions have the minimal effects on the trace metals production.

Puffing topography: Similar to particle emissions, longer puff duration and greater puff frequency tend to generate more organic species (Zhao et al. 2018). Parameters such as puffing topography, e-cig type, and voltage sometimes interact with each other, resulting in combination effects on the chemical emissions (Beauval

et al. 2019). For example, increasing puff duration and frequency or decrease puff flow rate may result in higher heating coil temperature, where higher levels of carbonyls can be expected. However, varying degrees of these effects were observed depending on the wattage levels and e-cigs types. Interestingly, researchers found that conditions leading to formaldehyde formation tend to generate less acetaldehyde (Beauval et al. 2019). In general, the exhaled chemicals by the e-cig user can be quickly diluted in the environment, resulting in a low concentration. Nevertheless, little is known about the extent to which the inhalation and exhalation process affects the chemical compositions of the SHV aerosols.

Although a limited number of experimental studies focused on indoor chemical exposure, a modeling method has been successfully applied to predict the toxic intake and secondhand exposure levels (Logue et al. 2017). Logue et al. (2017) used the mass balance equation involving chemical emission rates, indoor volumes, air exchange rates, vaping patterns, and the leakage from the mouth before inhalation to evaluate the indoor pollutant levels in both home and bar scenarios. Key parameters, such as vaping patterns, type of atomizer, and the voltage which are linked to intake doses and indoor pollutant levels, need to be considered for future exposure assessment studies.

Thirdhand Exposure

Besides the secondhand exposure, the deposited residuals from vaping might be reemitted into the gas phase and serve as a potential source of thirdhand exposure (Khachatoorian et al. 2019; Goniewicz and Lee 2015). In a multiunit building, Khachatoorian et al. (2019) detected tobacco-specific residues, including nicotine, minor alkaloids, and TSNAs, on surfaces in an indoor space adjacent to a vape shop, suggesting potential thirdhand exposures to e-cig emissions. Given the limited data, thirdhand exposures to e-cig residues and associated health effects are poorly understood and warrant future study.

Health Effects

In Vivo and In Vitro Studies

In general, studies have shown that e-cig aerosols are less toxic than t-cig smoke (Oh and Kacker 2014). However, substantial evidence indicates that e-cig aerosols are not safe to cells in vitro or to animals in vivo. Results from in vitro studies have identified the biologic effects on various cell types such as normal human bronchial epithelial cells, vascular endothelial cells, and macrophages (Merecz-Sadowska et al. 2020). Associated with elevated ROS levels, e-cig aerosols may induce cytotoxicity and genotoxicity. Exposure to e-cig aerosols has been shown to decrease cell viability, increase pro-inflammatory cytokine production, and induce gene dysregulation, DNA damage, and alveolar macrophage apoptosis (Merecz-

Sadowska et al. 2020). Although PG and VG are generally considered safe if added to food, the inhalation of aerosolized PG and VG may promote asthmatic inflammation and elevate mucin expression in airway epithelia (Gotts et al. 2019). Regarding cytotoxicity and pro-inflammatory effects, PG was found to be more toxic than VG (Ma et al. 2020). Certain toxic effects have been linked to the addition of flavoring chemicals such as diacetyl, acetoin, and cinnamaldehyde, which may trigger inflammation and ROS production. In contrast, aerosols generated by flavorless e-liquids can also induce adverse effects such as dysregulation of gene expression and inflammatory protein secretion. Although the effect of nicotine on cells varies, adverse cellular responses of both nicotine-dependent and nicotine-independent effects have been found. Researchers also found that e-cig aerosols induce oxidative stress, inflammatory cytokine production, and cytotoxicity regardless of the addition of nicotine to the e-liquid (Ma et al. 2020).

Similarly, e-cig aerosols have been found to impair lung functions in animals, with inflammation and immune abnormalities as the likely underlying mechanisms (Dinakar and O'Connor 2016). Other acute effects include increased mucins and cytokines, and impaired autophagy. Chronic exposure induces elevated inflammation, weight loss, and emphysema (Gotts et al. 2019). A study has reported that the bronchoalveolar lavage fluid cellularity, mucin production, and lung oxidative stress marker associated with e-cig aerosols were at a comparable or even higher level than t-cig smoke (Glynnos et al. 2018). In addition to pulmonary effects, both short-term and chronic uses of e-cig aerosols were found to impair aortic endothelial function and perturb the cardiovascular system (Olfert et al. 2018). Moreover, e-cig aerosols also present marked carcinogenicity (Lee et al. 2018) and neurological toxicity (Nguyen et al. 2018) in animals. However, it remains controversial whether the dosages used in animal studies are relevant to human exposures, and whether the results are consistent across different species.

Human Studies: Active Exposure to E-Cig Aerosols

The respiratory and cardiovascular effects of e-cig aerosols were also examined in human studies, most of which have focused on the effects of active e-cig use with only a few studies on secondhand exposures. As indicated by circulating concentrations of cotinine, doses in active exposure studies are generally higher than those in secondhand studies. Overall, results of these studies suggest likely short-term effects of e-cig aerosols (≤ 2 h of exposure) on preclinical endpoints.

Respiratory Effects

Most human studies on the respiratory system examine the effects of short-term (≤ 1 h) exposure among a small number of healthy subjects. Lung function is one of the most commonly studied endpoints, but the results of different studies are inconsistent. Active e-cig use by healthy t-cig smokers over 5 min slightly but significantly reduced lung function measures (i.e., forced expiratory volume in 1 s [FEV1] and forced expiratory flow [FEF] 25%) in a randomized crossover trial

(Ferrari et al. 2015). However, similar effects were not observed in two crossover trials (one randomized and one nonrandomized), in which active vaping over 5 or 30 min did not change any lung function measures among healthy t-cig smokers (Flouris et al. 2013; Vardavas et al. 2012). In contrast, more consistent results were reported for airway resistance, which was significantly increased after active e-cig use or passive exposure in two clinical trials, as determined by impulse oscillometry (Vardavas et al. 2012; Tzortzi et al. 2018). In addition, a case-control study found substantially altered respiratory proteomic profiles among e-cig users indicative of impending airway obstruction (Dang et al. 2018). Nevertheless, the clinical importance of these early changes is not clear. It is still unclear whether increased airway resistance induced by e-cig aerosols will become worse over time and eventually contribute to decreased lung function.

Studies have also assessed the short-term effects (≤ 2 h) of e-cig aerosols on exhaled nitric oxide, a biomarker of airway inflammation associated with increased risk of asthma and bronchitis (Taylor et al. 2006). Several studies report no effect (Flouris et al. 2013; Ferrari et al. 2015), and other studies show either increased (Schober et al. 2014) or decreased exhaled nitric oxide concentrations after exposures (Vardavas et al. 2012; Tzortzi et al. 2018). In two cross-sectional studies of adolescents, e-cig use was significantly associated with a greater odds of asthma attacks (odds ratio [OR], 1.12; 95% CI, 1.01 to 1.26) (Kim et al. 2017) and chronic bronchitis symptoms (OR, 1.70; 95% CI, 1.11 to 2.59) (McConnell et al. 2017).

Between August 2019 and February 2020, the EVALI outbreak had resulted in 2807 cases and 68 deaths in the USA which underscored the acute health effects of vaping. Most patients have shown respiratory symptoms (i.e., cough, chest pain, and shortness of breath), constitutional symptoms (i.e., weight loss, fevers, and chills), and gastrointestinal symptoms (i.e., nausea, vomiting, diarrhea, and abdominal pain). EVALI has different pathologic findings, including acute fibrinous pneumonitis, diffuse alveolar damage, or organizing pneumonia (Butt et al. 2019). Investigations have found that THC, sometimes with vitamin E acetate, in most of the e-liquids is used by the EVALI patients. Vitamin E acetate has been considered as a possible agent that disrupts lung surfactant function and causes respiratory impairment. Although the development of EVALI has been associated with vaping, the cause of the lung injury has not been explicitly determined yet. Nevertheless, vaping cannabis products may pose a health risk of passive exposure to bystanders, where the associated health effects are largely unknown.

Cardiovascular Effects

The effects of active e-cig use on cardiovascular biomarkers have been documented. Both habitual and short-term e-cig use can cause a cardiac-autonomic imbalance, as indicated by heart rate variability. Nicotine has been suggested as a likely cause (Moheimani et al. 2017). The existing evidence also suggests that active e-cig use induces systemic oxidative stress and inflammation, and impairs endothelial function (Skotsimara et al. 2019). Although oxidative stress and inflammation are important in the pathogenesis of cardiovascular diseases, to what extent the observed cardiovascular effects of e-cigs are clinically relevant is unclear. The cross-sectional

National Health Interview Surveys of 2014 ($n = 37,000$) and 2016 ($n = 33,000$) found that daily e-cig use was associated with myocardial infarction (OR, 1.79; 95% CI, 1.20 to 2.66) (Alzahrani et al. 2018), but more evidence is needed, especially from long-term large cohort studies, before e-cig use can be linked to cardiovascular diseases.

Human Studies: Passive Exposure to SHV Aerosols

Evidence of passive exposures to SHV aerosols on respiratory and cardiovascular effects in humans is limited. Increased cotinine levels in biospecimens of nonsmokers due to passive exposure to SHV aerosols confirm that nonsmokers, including vulnerable populations, are at risks of exposures to nicotine and other toxicants exhaled by e-cig users (Flouris et al. 2013). In a nonrandomized crossover trial on SHV aerosols, a 1 h passive exposure did not significantly affect the lung function among healthy nonsmokers (Flouris et al. 2013). However, another study observed minor alterations in respiratory mechanics and exhaled biomarkers after a 30 min exposure to SHV aerosols, where an obstructive airway indicator (i.e., resonant frequency) was increased and fractional exhaled nitric oxide was reduced (Tzortzi et al. 2018). Similarly, a 30 min exposure to SHV aerosols also induced sensory irritations, including ocular, nasal, and throat-respiratory symptoms, which have been found positively associated with VOCs (Tzortzi et al. 2020). According to two cross-sectional surveys, exposures to SHV aerosols were associated with asthma exacerbations in the adolescent population (Bayly et al. 2019; Alnajem et al. 2020), suggesting potential adverse respiratory effects of passive exposures, at least among susceptible populations. Two studies that assessed the complete blood count and oxidative stress biomarkers, respectively, found no differences before and after the 1 h passive exposure among healthy nonsmokers (Flouris et al. 2012; Poulianiti et al. 2016). However, no cumulative or long-term cardiovascular effects were examined.

Conclusions

The evidence in the literature supports that use of e-cig degrades indoor air quality and bystanders are at risk of passive exposure. Indoor particle concentrations due to e-cigs are similar to those due to t-cigs. Similar to SHS, SHV aerosols can transfer from a vaping room to an adjacent vaping-free room in multiunit buildings. Indoor air pollution due to e-cigs could potentially be reduced by enhancing ventilation and air filtration. Unfortunately, studies on mitigation measures that may inform policy are still limited. Future studies also need to focus on identifying vulnerable populations and monitor places that may contribute to high levels of passive exposures, such as vape shops, vaping conventions, and other indoor environments with no restrictions on e-cig use.

Although studies of SHV aerosols are limited, their chemical composition profiles are similar to those of mainstream e-cig aerosols but at much lower concentrations.

E-cigs generate fewer carcinogenic and toxic compounds than t-cigs, but they still produce substantial amounts of PG, VG, and nicotine, as well as some toxic compounds such as aldehydes and heavy metals. Given the uncertainties of the chemical products of the heating process and the complexity of flavoring including cannabis additives, the e-cig design features and e-liquid compositions should be further studied to better understand their effects on e-cig aerosol toxicity to inform future regulations.

Evidence obtained from cell cultures and animal models has demonstrated the adverse health effects of e-cig use. Current human studies have focused on the acute effects and early biomarkers and have suggested potential respiratory and cardiovascular effects from e-cig aerosols. However, results from these studies are inconsistent, calling for large cohort and long-term studies that examine the linkage between e-cigs and clinical end points. In addition, the contribution of cannabis products and vitamin E acetate to EVALI and the associated passive exposure also warrant further research.

Although the effects of e-cigs on human health are not yet fully understood, the high levels of indoor air pollutants produced by e-cigs call for precautionary measures to protect public health. Many countries have taken steps to restrict e-cig use in public spaces. As of July 2021, 20 states and 990 municipalities in the USA have already expanded smoke-free laws to include e-cigs and have prohibited their use in smoke-free places. In certain places, such as casinos, bars, and other gaming venues where t-cigs are allowed, e-cig use can further worsen indoor air quality. Until the long-term health effects are fully established, we recommend restricting the use of e-cigs in public indoor spaces to protect bystanders from passive exposures to SHV aerosols.

Abstract

This chapter provides an overview of the section on Indoor Air Particles. This section focuses on the physical processes that affect particle concentrations and some major sources. Penetration of particles from the ambient aerosol into the indoor environment is an important source of indoor particles. The particles depending on their size can then deposit and can be resuspended. Semi-volatile species partition into particles and the gaseous phase depending on factors such as vapor pressure at typical indoor temperatures and solubility into organic phases. The dynamics of these processes are presented in separate chapters that are

outlined here. This chapter also introduces a number of major primary indoor sources such as cooking emissions and the use of personal care products. Different cooking styles can produce major differences in emission rates. Personal care products can directly emit particles and semi-volatile compounds, some of which can react with infiltrated ozone in chemistry described in the indoor air chemistry section.

Keywords

Particulate matter · Particles · Indoor sources · Ambient sources

Introduction

Particles have been an indoor air pollution problem from the time that humans first built fires in their caves. Fresh air was found in the ambient atmosphere. However, with increasing population and urbanization, particles in the ambient atmosphere became a problem. In 1157, unendurable air pollution from wood smoke led Eleanor of Aquitaine, wife of Henry II of England, to flee Tutbury Castle in Staffordshire, England. In 1257, Eleanor of Provence, Queen Consort of Henry III, had to leave Nottingham for Tutbury Castle because of the heavy coal smoke since coal had replaced wood due to deforestation (Brimblecombe 1976). The coal burning in London became such a problem that in 1306, Edward I banned coal burning when Parliament was in session.

In 1661, John Evelyn published “Fumifugium or the Inconvenience of the Aer, and Smoake of London Dissipated” and suggested moving industry out of London. Then in December 1930, there was a high haze episode in the Meuse Valley, Belgium resulting in 63 deaths in this industrialized river valley. In October 1948, in Donora, PA, there were 20 deaths while 6000 became sick in a 4.5-day inversion. Then in December 1952, there was the largest and most obvious of all modern air pollution events in London, England in which the government reported 4000 deaths, but recent work has suggested it was more likely between 10,000 and 12,000 deaths (Stone 2002; Bell et al. 2004). There continued to be episodes in the 1950s and 1960s including another London episode in 1962 leading to initial legislation in countries like the United Kingdom and the United States finally recognizing air pollution as a public health issue.

With the 1964 Report of the US Surgeon General on smoking and health that concluded that cigarette smoking caused cancer (US DHEW 1964), interest started to move toward indoor airborne particles. However, there were no large-scale studies of indoor particles until 1979 when the Harvard Six-City Study began indoor particulate matter (PM) measurements that extended until 1988 and included at least 1400 homes (Spengler et al. 1981, 1987). It was followed by the New York State ERDA study in 433 homes in two New York State counties in 1986 (Sheldon et al. 1989) and Particle Total Exposure Assessment Methodology (PTEAM) study of 178 homes in Riverside California in 1990 (Clayton et al. 1993). These studies

provided the initial indication that indoor airborne particles and indoor sources of particles also made significant contributions to peoples' exposures to airborne particulate matter and the indoor particles required appropriate assessment to fully understand the role of airborne particulate matter on human health.

This chapter provides an introduction to the nature and concentrations of particles to which people are exposed indoors.

Sources

Primary

Cooking

There are two sources of particulate emissions when cooking. One is from the source of heat (i.e., the stove and the pan) and the other is the cooking process itself. Both of these sources are covered in detail in their respective chapters in this handbook. Much of the world cooks with direct combustion-generated heat including natural gas, propane, liquid petroleum gas (LPG), kerosene, and solid fuels (wood and other biomass and coal) split about 50:50. Properly tuned natural gas combustion produces ultrafine particles with a geometric mean (GM) mobility diameter of 19.46 nm and a geometric standard deviation (GSD) of 1.36 while a propane flame aerosol had a GM of 26.51 nm and a GSD of 1.25 (Li and Hopke 1993). However, Wallace et al. (2008) found 4.2 nm from a single gas burner. Tiwari et al. (2014) reported that LPG produced particles with GM of 52 nm and a GSD of 1.23. Kerosene had a GM of 62 nm and a GSD of 1.41. For solid fuels, they reported GM (GSD) values of 1.23 nm (1.78), 48 nm (1.98), and 152 nm (1.89) for firewood, coal, and dung cake, respectively. Wang et al. (2020) report results for residential biomass and coal combustion and compares their results to a number of prior studies showing a wide variety of particle diameters depending on the exact nature of the fuel and combustion appliance. Depending on the nature of the appliance and how well it is vented to the outside atmosphere, there can be substantial input of particles into the cooking area resulting in high indoor particle number and PM concentrations. Even with chimneys, there can be short-circuiting back into the house if the chimney is not properly configured to produce good dispersion into the ambient surroundings. There can also be ultrafine particle emissions from electrical cooking surfaces (Wallace et al. 2008). They hypothesize that organic constituents that condense onto the heating elements volatilize and then nucleate to form <10 nm particles.

Cooking the food produces additional particles as reviewed by Amouei Torkmahalleh et al. (2017). Few people vent their stoves to outside of their homes. Thus, cooking represents a major short-term source of particle emissions. One of the main mechanisms occurs in frying in oils when water from the food vaporizes to form bubbles that burst and eject small oil droplets into the air. Just heating the oil or melted solid fats to above their smoke temperature will evolve particles. There are also the occasional issues of food burning and producing high short-term particle

concentrations. The size distributions of many specific cooking activities are reported by Ogulei et al. (2006) including emissions from frying, broiling, and boiling.

Heating

For many people, the same stove used for cooking is also used for room heating, particularly in those homes using solid fuels. Thus, similar sized particles would be emitted into the indoor space whether the stove is being used for cooking and/or heating. However, in more developed countries, central heating with the combustion appliance vented to the outside of the dwelling is more typical. Thus, similar fuels as for cooking may be burned but in more efficient and better vented appliances and thus delivering a much lower load of particles to the home's interior. It is possible that the central heating systems may have leaks and thus emit particles into the indoor air even with an efficient chimney (e.g., Li and Hopke 1991).

Cleaning

Although house cleaning is done to reduce the level of contamination in the indoor space, it also has the potential for adding particles to the indoor air in several ways. First, there is resuspension that will be presented in much greater detail in its specific chapter. Using sweeping tools like a broom will lift particles greater than 1 μm (Ji 2020) resulting in increased concentrations of PM_{2.5} and particularly PM₁₀. Vacuuming also increases the airborne PM concentrations, but their effectiveness in particle suspension depends on the nature of the floor covering (bare or carpet) and the nature of the filter in the cleaner (e.g., Corsi et al. 2008; Lewis et al. 2018). Older models typically used cloth bags that were very inefficient in collecting smaller particle size. Now many models have moved to HEPA filters with 99.97% efficiency that substantially reduced the suspended PM mass and particle number concentrations (Vicente et al. 2020).

Lifestyle

People do a number of things that introduce particles indoors including smoking, vaping, burning candles or incense, and using consumer spray products. Tobacco smoke and its airborne residuals (environmental tobacco smoke or ETS) were covered in detail by Samet and Wang (2001). However, since then there has been an exponential rise in vaping where a person uses a system to vaporize a solution of vegetable glycerin and polyethylene glycol (PEG) containing nicotine and typically some kind of flavoring agent. There is a chapter in this handbook devoted to vaping and its effects on indoor air quality. "Electronic" cigarettes were introduced in 2002, nominally as an aid to tobacco combustion smoking (Bhatnagar et al. 2014) and have grown exponentially in popularity (Rom et al. 2014) particularly among young people. They are most highly used in the United States and Europe (Rahman et al. 2014) and in China (Cai and Wang 2017) and are rising elsewhere as use of combustion cigarettes is stable or declining. Although the presence of the glycerin and PEG produce a visible plume, it largely evaporates and leaves a limited particulate residue.

Combustion in the form of candles and incense can produce high concentrations of particles and in some cases, PM. Candles can also include scents that add volatile and semi-volatile organic compounds in the air in addition to particles. Rasmussen et al. (2021) measured the emissions from candles made of five different materials, animal stearin, palm stearin, paraffin, including mixtures. Burning a candle also involves burning the wick and they examined several wick materials. They found modes in the particle size distributions in the range of 5.4–7.1 nm. Many candles have cored wicks made from cotton wrapped around a metal support. This design keeps the wick from falling into the wax and is especially useful for scented candles since the fragrant oils soften the wax resulting in noncored wicks to fall over. However, these wicks can then potentially add metallic particles to the indoor aerosol.

Several groups have characterized the emissions from burning incense (Jetter et al. 2002; Chang et al. 2007; Ji et al. 2010). The lower temperature of combustion produces a much larger diameter distribution with a peak size around 136 nm (Ji et al. 2010). The sizes measured in this study were comparable to similar measurements by Chang et al. (2007) on other types of incense. In many Asian countries, large quantities of incense are burned in various temples as part of the worship rituals (Lung and Kao 2003; Goel et al. 2017) resulting in PM concentrations ranging from 100s to 1000s of $\mu\text{g}/\text{m}^3$. Temples can represent a large enough source to affect ambient air quality. The impact of the Temple of the Tooth in Kandy Sri Lanka was observed by Seneviratne et al. (2017).

Various consumer products including air fresheners, spray cleaners, and personal care products aerosolize liquids or solids to provide their ingredients to serve their purpose. However, there is the likelihood of some of the material escaping into the indoor air. For example, there are spray oils to lubricate pans for cooking. Not all of the particle sprayed at the pan will stick to it. In cases where the active product is in solution, the particle is formed after the solvent has evaporated. Kim et al. (2020) showed that propellant-type products generated more particles than hand generated pressure. They found most of the particles were in sizes < 100 nm although some products produced an aerosol with a supermicron mode. More details are provided in ► Chap. 5, “Fragranced Consumer Products as Sources.”

Infiltration of Ambient Aerosol

Transport of ambient particles into indoor environment is a major long-term source. It occurs as a consequence of air exchange of indoor environment with outdoors. The exchange can occur deliberately, through ventilation (Liu and Zhang 2019), or by infiltration through gaps in the building envelope. Its intensity is determined by outdoor concentrations, air exchange rate, and any controls in the ventilation system if present. Buildings are ventilated via three modes: mechanical ventilation, natural ventilation, and infiltration. Mechanical ventilation uses mechanical equipment such as fans, while natural ventilation mainly occurs through open windows. Both modes are intentional ventilation. In contrast, infiltration is entry of outdoor air through unintentional openings in a building envelop such as window cracks. These ventilation methods can bring outdoor particle indoors. Its strength (in unit of mass/time)

is usually lower than the indoor sources described above. However, infiltration of ambient particles constantly occurs via any or all of the three ventilation modes while indoor sources are generally of limited durations. Thus, particles of ambient origin generally dominate the long-term exposure to indoor particles. The details of the infiltration mechanisms are described in ► Chap. 10, “Impact of Outdoor Particles on Indoor Air.”

Secondary

In addition to direct injection of particles into the indoor atmosphere from the sources summarized in the previous section, particles can also form indoors through chemical reactions. Indoor chemistry is described in the section devoted to this topic. Typically, light intensities indoors are insufficient to drive the same types of photochemical reactions observed in the ambient environment, there can be reactions between infiltrated ozone and reactive hydrocarbon compounds emitted into the indoor air. The presence of ozone in indoor air was reviewed by Weschler (2000) and many studies have been made on the reactions of olefinic compounds with ozone with the subsequent formation of hydroxyl radicals with its additional oxidizing capabilities. Another important aspect of the indoor environment is the presence of surfaces on which heterogeneous reactions can occur. The oxidation of hydrocarbon compounds adds oxygen to the molecule resulting in forming compounds that have lower vapor pressures. These compounds can then either condense on the existing particulate surface or nucleate to form new particles. Unlike the ambient atmosphere, the condensation sink, available surface area on which the material can condense, is typically low, thereby allowing new particle formation (McMurtry and Friedlander 1979). Thus, infiltrated ozone can react with the terpenes and terpenoids that are used as fragrances in cleaning and personal care products, air fresheners, and other products that produce a notable odor. These reactions can produce particles at concentrations observed in indoor air (Chen et al. 2011). This freshly formed secondary organic aerosol (SOA) also contains reactive oxygen species (ROS) (Chen et al. 2011) that can have direct human health effects (Hopke 2015).

Particle Compositions

Particulate matter (PM) is a complex mixture of chemical constituents. Chemical composition has been suggested to play a key role in health impacts with recent results showing differential effects from exposure to PM emitted by different sources (Rich et al. 2019; Croft et al. 2020; Hopke et al. 2020). Recently, an increasing body of evidence has suggested that oxidative stress induced by particle exposure is responsible for health risk, and attention should be paid to relevant species such as transition metals and organics (Hopke 2015). However, further work is needed to fully ascertain which compositions are more detrimental to health.

Particle composition is traditionally divided into three broad categories driven by measurement techniques: water-soluble ions, carbonaceous species, and elements other than carbon. Sampling and measurement methods are described in detail in Measuring Particle Concentration and Compositions in Indoor Air. Regarding their indoor fate, categorization based on volatility can be more useful to understand the outdoor-to-indoor transport and fate on particles from indoor sources. Then nonvolatile and semi-volatile species will be discussed. Semi-volatile species partition in both gas- and particle-phase, while nonvolatile species stay in particle-phase only.

Nonvolatile Species

Nonvolatile species in particles include sulfate, elemental carbon, and all the elements. They are in the condensed-phase and do not have gas-phase counterparts. Their movement follows bulk particles in transport processes. Knowledge about dynamics of indoor particles such as penetration and deposition is usually considered applicable for these species. Sulfate has been suggested as a useful surrogate to track ambient particles and other nonvolatile species in outdoor-to-indoor transport (Sarnat et al. 2002; Liu and Zhang 2019). Sulfate has negligible indoor sources, is chemically stable, typically has sufficient concentration to be accurately measured, and behaves similarly to particles composed of other nonvolatile species. The indoor/outdoor concentration ratio of sulfate can represent contribution of outdoor-origin particles/species to indoor concentrations.

Semi-Volatile Species

Semi-volatile species includes water-soluble ammonium nitrate, and a large fraction of organic carbon (OC) compounds. They establish partitioning relationships with their gaseous counterparts, i.e., ammonium nitrate-nitric acid and ammonia, and OC-semi-volatile organic compounds. Concentrations of these gaseous species differ between outdoors and indoors. Once semi-volatile species enter indoors as constituents of ambient particles, these partitioning relationships will be disturbed. These species will establish new relationships with their gaseous precursors indoors via re-partitioning. The new relationship will not necessarily reach equilibrium since there will also be differential deposition onto surfaces. This process has been called a phase change (Lunden et al. 2008) or volatilization effect (Sangiorgi et al. 2013). This phase shift makes indoor/outdoor relationship of the semi-volatile species more complex than the nonvolatile species. Efforts have been made to quantify this re-partitioning process for nitrate and ammonium (Liu et al. 2019).

OC is the most complex constituent of particles, since it represents multiple classes of compounds, instead of a single one with well-defined physical chemical properties. OC includes numerous compounds with largely unknown identities and a wide range of thermodynamic properties (Seinfeld and Pankow 2003). Outdoor SVOCs are mainly formed by oxidation of volatile organic compounds, and then

partition to particles as OC (Kroll and Seinfeld 2008; Glasius and Goldstein 2016). Once indoors, these semi-volatile particulate OC species volatilize (Johnson et al. 2016; Salthammer et al. 2018). Meanwhile, indoor SVOCs are emitted from chemical items such as plastics, electronics, and personal care products (Liu et al. 2013, 2015; Liu and Zhang 2016) and from cooking. They partition to the existing particles by adsorption and absorption (Pankow 1994, 2003). Based on mass transfer theory, the OC-SVOCs partition occurs on a compound-by-compound level, and gas-particle partitioning of OC is therefore bidirectional indoors. It is difficult to accurately describe and predict indoor OC of outdoor origin. Current analytical methods cannot characterize OC on a compound-by-compound level. Explicitly modeling indoor-outdoor transport of all individual organic compounds is not practical (Liu and Cao 2018). Hodas and Turpin (2014) applied a volatility basis set approach (Donahue et al. 2006) to examine shifts in partitioning of ambient OC when it transports from outdoors to indoors. They found that both temperature and indoor organic aerosol loading are important to describe this process. This behavior is presented in the section on Source/Sink Characteristics and the chapter in this section on Interaction of Gas Phase Pollutants and Particles.

Indoor Particle Dynamics

When the particles are suspended in the air, any force applied to them will be resisted by the air as they move with respect to it. Characterization of these applied and resistive forces is essential to understand particle movement on the macroscopic scale, termed as indoor particle dynamics. Because particles exhibit a wide range of particle sizes, particle dynamics cover issues from the continuum regime to transition regime to the molecular regime based on how air is considered as a fluid. In the continuum range, air is considered as a continuous fluid while in the molecular regime, the gas is considered in terms of the motion of individual molecules with the transition regime in between. Macroscopically, there are three major dynamic processes in an indoor environment of interest: infiltration, deposition, and resuspension. Basics about indoor particle dynamics are introduced in ► Chap. 9, “Introduction to Aerosol Dynamics.” Each of the three specific dynamic processes is detailed in the chapters that follow in this section.

Infiltration

Although we think of the outer shell of a building as a boundary separating the ambient atmosphere from the indoor air, particles and gases in the ambient air can penetrate through the walls into the interior of a building and contribute to the indoor air pollution. For particles, penetration is strongly dependent on particle size. For large particles, inertial behavior such as not being able to follow airflow streamlines when they are forced to deviate in direction leads to their impaction on the obstacle to the flow. Thus, as wind blows particles at a wall or window and air

flows into cracks, the larger particles ($> 1 \mu\text{m}$) can be removed by impaction onto the obstacle. Within the crack, flow rates are typically reduced and gravitational settling can occur leading to limitations in the penetrability of larger particle sizes. For smaller sized particle ($< 0.1 \mu\text{m}$), the diffusion coefficient increases with decreasing size so smaller particles can diffuse the surfaces of the cracks and be kept from the building interior. However, for sizes in between these limits, only gravitational settling is important and it is very slow so these particles have the greatest ability to penetrate into indoor spaces. Composition also matters since semi-volatile material may change phase given differences in temperature between the ambient and the interior environments. The details of these mechanisms are presented in ► Chap. 10, “Impact of Outdoor Particles on Indoor Air,” by Chen and Zhao.

Deposition

An important difference between indoor and outdoor air are the deposition rates given the much higher available surface area in indoor spaces due to walls and furniture. Particles settle to horizontal surfaces through gravitational setting depending on particle size. Deposition on other surfaces needs to be conceptualized in terms of multiple segment transport. The particles are transported to the boundary layer of a solid object like a wall through turbulent diffusion. The extent of the turbulence depends on the kinetic energy being deposited into the indoor air ranging from low values with just natural ventilation in a closed room to high when fans or forced air flow is used to move the air in a space. Typically, rooms will have dead spaces in places like corners or where air flows are blocked by furniture or other obstacles resulting in increased local deposition. Once the particle gets to the boundary layer, it must diffuse through it to the surface and stick to it. The thickness of the boundary layer also depends on the degree of turbulence in the room. The details of deposition are provided in ► Chap. 11, “Deposition,” by Benes and Holub.

Resuspension

Personal exposure studies like the PTEAM study (Wallace 1996) identified the effect of human activities like walking or sitting on furniture in terms of resuspending particulate matter (dust) and that such activities contribute to peoples’ “personal cloud” (Özkaynak et al. 1996). A few initial studies (Thatcher and Layton 1995; Brauer et al. 1999; Ferro et al. 1999; Long et al. 2000) examined the effects of a variety of specific activities on indoor PM concentrations and increases in the concentrations in the personal cloud of those involved in the activities. Subsequently, more detailed studies have been made on the effects of specific levels of activity on and the mechanisms of particle resuspension as described in ► Chap. 12, “Resuspension,” by Ferro.

Conclusions

At this time, much has been learned regarding particles in the indoor environment including sources, dynamics, transport within structures, control methods, and the effects of ambient concentrations. However, as lifestyles including furnishings, cleaning and personal care products, cooking styles, etc., energy usage, building construction, and related items continue to change, there will be a need for further study to elucidate what these changes will mean on the size, composition, concentrations, and resulting exposures resulting from particles in indoor air. This section provides an introduction to the basics of particle dynamic and many of the direct sources. Details of indoor air chemistry that can also form particles are presented in the Indoor Air Chemistry section. Thus, within this handbook, there is a broad introduction to the issues associated with the indoor aerosol.

Abstract

Aerosols play a substantial role in determining the quality and potential health impacts of indoor air. However, understanding how they are measured, monitored, and mitigated starts with a basic understanding of how they behave. The term “aerosol” refers to a collection of liquid and/or solid particles suspended in a gas. Aerosol behavior is determined by the physics of the suspending gas and the suspended particles and interactions between them. Starting from kinetic theory, this chapter develops an understanding of basic properties of gas behavior and how this is connected to aerosol behavior. Properties of gases from molecular mean free path and viscosity to boundary layers, Reynolds number, laminar and turbulent flow, and flow stagnation are described. Building on these, the chapter explores how interactions between particles and a surrounding gas affect behavior under different conditions. Concepts that are relevant to understanding aerosol behavior within indoor environments are addressed, including definitions of diameter (including aerodynamic diameter), linear and curvilinear motion, particle mobility, relaxation time, stopping distance, and diffusion. The chapter is designed to provide an introduction to aerosol dynamics that will be helpful in addressing the behavior and potential impacts of aerosols within indoor environments.

Keywords

Aerosol dynamics · Particles · Motion · Impaction · Diffusion · Inertia

Introduction

The purpose of this chapter is to provide an introduction to a number of physical processes that affect the behavior of particles in indoor environments. It is deliberately written at a level that allows people new to the field to get a grounding in the basics. It is not possible to provide a comprehensive and detailed introduction to aerosol dynamics here. For more information on the aerosol properties addressed in the chapter, the reader is referred to Hinds and Zhu (2022). For an advanced discussion of aerosol science topics, the reader is referred to Friedlander (2000).

Basics of Gas Behavior**Background**

Particles in the air move under a variety of forces. This chapter provides a basic understanding of the physical processes that govern the motion of particles and important behaviors such as settling, deposition, and resuspension. To begin, it is necessary to define the critical basic term: aerosol.

An aerosol is a collection of solid or liquid particles suspended in a gas. Here, it is important to recognize that the term “aerosol” refers to the two-phase system consisting of the particles and the gas, and not the suspended particles alone. The

term aerosol was coined around the 1920s as an analogy of hydrosols – suspensions of solid particles in a liquid. Aerosols are also referred to as suspended particulate matter, aero-colloidal systems, and disperse systems. However, particles and droplets are *not* aerosols. Rather, they are components of aerosols. Thus, in any given indoor space there is one and only one aerosol.

An aerosol may occur in many systems, either as a naturally occurring phenomenon or as man-made (anthropogenic) products. They are responsible for influencing processes and phenomena as diverse as cloud formation, global warming and cooling, visibility, rainbows, microchip fabrication, pigment formation, nanoscale material production, global material transport, the application of pesticides, asthma attacks, plant propagation, drug delivery, and various pulmonary, cardiovascular, and systemic diseases. Particle sizes range from the sub-nanometer (molecular clusters) to larger than several 100 μm . They may consist of biological material, including viruses and bacteria, solids, or liquids, and may be found in simple geometric forms such as spheres or highly complex morphologies. Each particle may consist of a single substance or may be a complex mixture of a number of substances. As a result, the study of aerosols is not only vital to the understanding of the environment in which we live and work, but it is a highly complex field that overlaps many other disciplines.

The first step to understanding the association between an aerosol and its effects on health (or its behavior in other systems) is to be able to appropriately characterize it. Likewise, the interpretation of aerosol measurements is dependent on an understanding of the assumptions and simplifications being made in the measurement process. This chapter is aimed at developing a sufficient comprehension of aerosol behavior to understand the basis of measurement methods, allow the correct methods to be selected for specific needs, and to allow a clear comprehension of the limitations and simplifications associated with any method used.

Properties of Gases

Since an aerosol is a two-phase system consisting of particles/droplets and gas, to fully understand aerosol behavior, it is also necessary to have a good understanding of how gases behave. Here, it is worth noting that with most aerosol concentrations encountered in indoor environments, the aerosol mass is sufficiently low to make the assumption that the presence of the particulate phase does not unduly influence the gas behavior. However, at high mass concentrations (typically where the aerosol density is greater than 1% different from the density of the gas alone), the presence of particles has a significant influence on gas properties.

Kinetic Theory of Gases

A good understanding of how gases behave can be gained from a very simple physical model that treats individual molecules as rigid spheres analogous to billiard balls (Fig. 1). This is referred to as the kinetic theory of gases (Loeb 1961), as it is

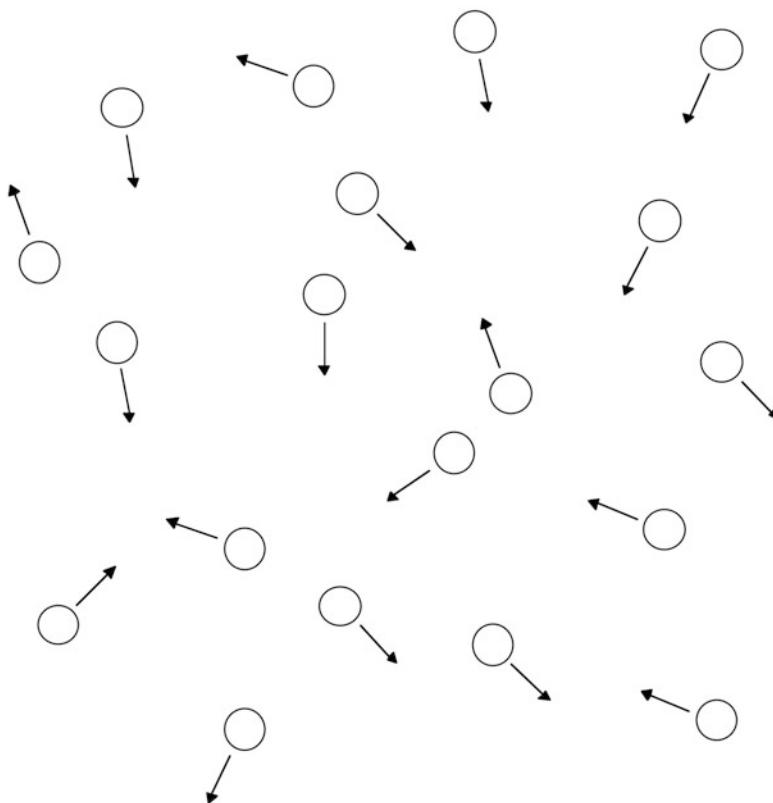

Fig. 1 Kinetic model of an ideal gas

based on the exchange of kinetic energy between molecules during collisions. Qualitatively understanding gas behavior using this model, while imperfect, provides a good foundation to understanding aerosol particle motion later on.

This model relies on a number of assumptions that, despite their simplicity, lead to a sophisticated understanding of gas behavior. These include:

- The gas consists of a great number of identical molecules.
- The physical dimensions of the molecules are much smaller than the distances between them.
- The molecules are rigid. Collisions between molecules are elastic (no energy is lost), and they travel in straight lines between collisions.

Starting from these assumptions, it is possible to describe properties such as temperature, pressure, viscosity, mean free path, diffusion, and thermal conductivity in terms of the number of molecules per unit volume N , the mass of individual molecules m , molecular diameter d_m , and mean molecule velocity c .

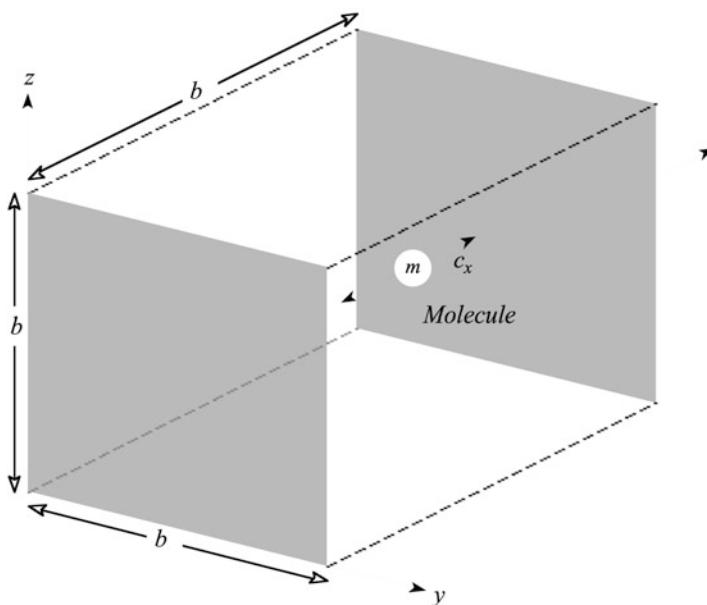

Fig. 2 Basis of describing pressure using kinetic gas theory

Pressure

Imagine a kinetic gas molecule enclosed in a cubic box. Each time the molecule collides with a wall of the box, it “pushes” the box away from it as it rebounds. As no energy is lost to the box wall, the molecule bounces back and forth between opposite walls indefinitely, giving the walls a little push with each collision. “Pressure” simply describes how much of the molecule’s effort goes into pushing the walls each second (i.e., the force) for each unit area of wall (Fig. 2).

The impulse of the molecule pushing against the wall is equal to the change in its momentum. Momentum is given by mass times velocity. We can assume that as the box is much more massive than the molecule, the molecule rebounds with an equal but opposite velocity to that with which it hit the wall. Thus, if the mean molecule velocity is c_x , the change in momentum is $2mc_x$. Here, the c_x notation denotes the molecule is bouncing back and forth in just one direction at any given moment.

The force applied to the box wall is simply the rate of change of momentum with time (Newton’s second law), which is given by the change in momentum for one collision, divided by the time between collisions. In our one-molecule-in-a-box model, the molecule has to travel from one side of the box to the other between collisions (remembering that we are looking at collisions with both of the end walls). Thus, if the length of the box is b , the time between collisions is simply distance divided by velocity or b/c . Therefore, the force exerted per collision is:

$$F = \frac{2mc}{b/c_x} = \frac{2mc^2}{b} \quad (1)$$

The force per unit area, or pressure, is simply F divided by the area of the box wall of interest. At this point, the molecule is just bouncing back and forth between two opposite walls, and so the area is the area of these two walls, or $2b^2$. And so pressure P is given by:

$$P = \frac{F}{2b^2} = \frac{c_x^2 m}{b^3} = \frac{c_x^2 m}{V} \quad (2)$$

where V is the volume of the box.

Equation (2) gives the pressure resulting from just 1 mol in a box. To extend this analysis to a box containing N molecules, we must do two things. First, if we assume that collisions between molecules within the box do not affect this analysis, then Eq. (2) can be multiplied by the total number of molecules (N) to derive the pressure from all molecules. However, these molecules will now be traveling in all directions, not just back and forth between the two opposite walls of the box.

In the more general case of molecules traveling in all directions, it can be shown that the mean square molecule velocity (c_x^2) in each direction (x , y , and z) is the same and that the overall mean square velocity of the particles is given by:

$$c^2 = c_x^2 + c_y^2 + c_z^2 \quad (3)$$

Thus, c_x^2 in Eq. (2) can be replaced by $c^2/3$.

From a set of simple assumptions based on a solid molecule trapped in a box, we therefore end up with pressure being defined as:

$$P = \frac{mNc^2}{3V} \quad (4)$$

or

$$PV = \frac{mNc^2}{3} \quad (5)$$

This equation is a statement of Boyle's law, which states that for an ideal gas $PV = \text{constant}$ for a fixed amount of gas at constant temperature.

Equation (5) is the microscopic form of the ideal gas law. It is more usually used in its macroscopic form of:

$$PV = nRT \quad (6)$$

where n is the number of moles of gas, R is the gas constant, and T is the gas temperature in Kelvin. For pressure in Newtons per square meter, or Pascals, and volume in m^3 (SI units), $R = 8.31 \text{ Pa m}^3/\text{K mol}$.

Mean Velocity

As can be seen from the above analysis, kinetic theory is powerful in that starting from very simple assumptions, a sophisticated understanding of gas behavior can be reached. For instance, Eqs. (5) and (6) can be used without much further work to derive an expression for the mean square velocity of particles in a gas. For 1 mole of gas, $PV = RT$ and $N = N_a$ (Avogadro's number, or the number of molecules in 1 mole of a substance [$N_a = 6.022 \times 10^{23}$ mol/mole]). Substituting these in Eq. (5),

$$c^2 = \frac{3RT}{mN_a} \quad (7)$$

A more useful quantity is the root of the mean square velocity or c_{rms} :

$$c_{rms} = \sqrt{c^2} = \sqrt{\frac{3RT}{mN_a}} \quad (8)$$

The root mean square velocity is the average velocity of molecules in a gas at temperature T . As the molecule velocity rises, so does the gas temperature, and vice versa. Remembering that the kinetic energy of the molecules is a function of their velocity, Eq. (8) shows us that the temperature of the gas is related to the kinetic energy of the individual molecules.

In practice, molecules in a gas will have a broad range of velocities. As a result, a number of different ways of calculating mean velocity exist, each leading to a slightly different result. The root mean square velocity is one such approach. A commonly used alternative is to calculate the arithmetic mean of particle velocity denoted by \bar{c} and calculated as:

$$\bar{c} = \sqrt{\frac{8RT}{\pi mN_a}} = \sqrt{\frac{8RT}{\pi M}} \quad (9)$$

where M is the molecular weight of the gas.

Mean Free Path

A key assumption in the analysis above is that molecules travel in straight lines between collisions. The distance between these collisions is important as it indicates whether assumptions about the molecule diameter being small compared to the distance between collisions are correct. It is even more important when particles are present in the gas. A particle that is much smaller than this collision distance will behave differently within the gas to one that is much larger than the mean collision distance. Here, the distance between collisions is referred to as the *free path*, and as there will be some variation in these distances in a gas, the quantity most usually used is the mean free path.

The mean free path of a molecule, λ , is calculated by dividing the mean velocity by the average number of collisions encountered per second (n_c):

$$\lambda = \frac{\bar{c}}{n_c} \quad (10)$$

n_c is calculated by making assumptions on the area that each molecule presents to others (the collision cross section) and the number of molecules per unit volume in the gas N . This leads to:

$$n_c = \sqrt{2N\pi d_m^2 \bar{c}} \quad (11)$$

where d_m is defined as the collision diameter of the molecule, usually considered to be the distance between molecule centers at the point of collision. For air, the approximate collision diameter is 3.7×10^{-10} m.

Combining Eqs. (10) and (11) yields:

$$\lambda = \frac{1}{\sqrt{2N\pi d_m^2}} \quad (12)$$

The mean free path for air at 101 kPa [1 atm] and 293 K is 0.066 μm.

Diffusion

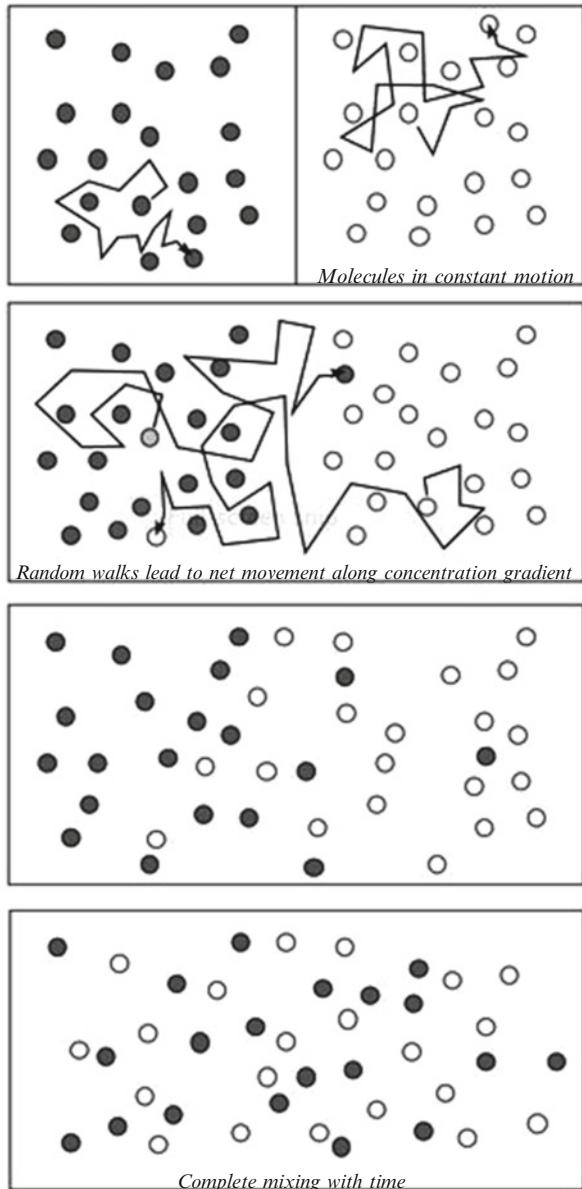

As the molecules in a gas are in constant motion, they will move from one place to another (migrate) within an enclosed space, even in the absence of a net flow of gas. If you were able to tag a single molecule and watch its progress with time, you would see it follow a series of jumps in random directions (associated with collisions with other molecules), gradually taking it further and further away from its original position. The molecules are said to take “random walks.” If all the molecules in an enclosure are identical, as one molecule moves away from its starting position, another one, indistinguishable from the first, takes its place. Thus, it is not apparent that there is continual movement within the gas. However, if you started with an enclosed volume with, say, red molecules on one side and white on the other, the red molecules would follow random walks that would take some of them over to the white side, and likewise, the white ones would follow random walks resulting in some ending up on the red side. The end result would be a uniform mixture of red and white molecules. This process of molecule migration is referred to as diffusion and is seen wherever there is a concentration gradient of a particular molecule type (Fig. 3).

The derivation of the equations determining diffusion is beyond this chapter. However, it is useful to be aware of the expression describing the quantity of a material diffusing per unit time through a unit area perpendicular to the direction of diffusion, J (Fick’s first law of diffusion):

$$J = -D \frac{dC}{dx} \quad (13)$$

J is the flux of material moving along the concentration gradient dC/dx . D is a constant of proportionality referred to as the diffusion coefficient.

Fig. 3 A simple model of molecular diffusion

Viscosity

The final gas property that it is useful to conceptualize in terms of kinetic theory is dynamic viscosity (usually simply referred to as viscosity). If two parallel plates with a gas between them move relative to each other, there will be a resisting force resulting from the intervening gas. From Newton's law of viscosity, the force that

must be applied to overcome this resisting force is proportional to the plate area A and the relative velocity U , and inversely proportional to the separation distance y . The constant of proportionality is the viscosity, η , giving

$$F = \frac{\eta A U}{y} \quad (14)$$

On a microscopic scale, molecules at the surface of either plate will have a net velocity in the same direction as the plate. A molecule traveling from one plate to the other through thermal motion will effectively remove a small amount of energy from the first plate and impart it to the other. The tendency in the absence of an external force will therefore be to reduce the relative motion between the plates. This is the source of the gas' viscosity. Using kinetic theory, it can be shown that η is a function of gas constants and temperature alone and that it increases with increasing temperature. It is independent of pressure.

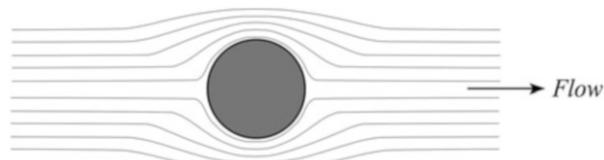

Macroscopic Properties of Gases

While kinetic theory provides a simple basis for understanding gas behavior, understanding the bulk motion and behavior of gases is not so straightforward. There are however fundamental properties of gas flow that need to be appreciated for an understanding of how aerosols behave. Bulk gas motion can be described using basic equations of motion and conservation known collectively as the Navier Stokes equations. While the underlying bases of these equations are relatively straightforward, solutions to the equations themselves are not. For simplicity, therefore, the main concepts and properties of gas flow will be introduced with little derivation of the underlying physics.

Streamlines

One important set of solutions to the Navier Stokes equations results in streamlines or patterns that graphically characterize flow. In simple terms, streamlines show the path that a tagged parcel of gas would take through a flow system. Introducing a thin stream of smoke into a flow is one common method of visualizing streamlines. The more densely packed the streamlines, the higher the gas velocity (Fig. 4).

Fig. 4 Illustration of flow streamlines around an object

Boundary Layers

One physical constraint applicable to real fluids (including gases) is that the velocity of the fluid must be zero at every point where the fluid connects with a solid boundary. This constraint means that there must exist a steep velocity gradient next to a surface across which a gas is moving. The boundary layer defines the layer within which the gas velocity differs significantly from the bulk gas velocity. Figure 5 illustrates the nature of typical boundary layers across a flat sheet and between a pair of plates. As can be seen, the boundary layer takes some time to fully develop. When the boundary layer is fully formed in a tube, the flow velocity has a parabolic profile across the tube diameter, with the velocity on the center-line being twice the average flow velocity (“Poiseuille flow”). A common rule of thumb is that it takes approximately 10 diameters for this equilibrium flow to be fully established.

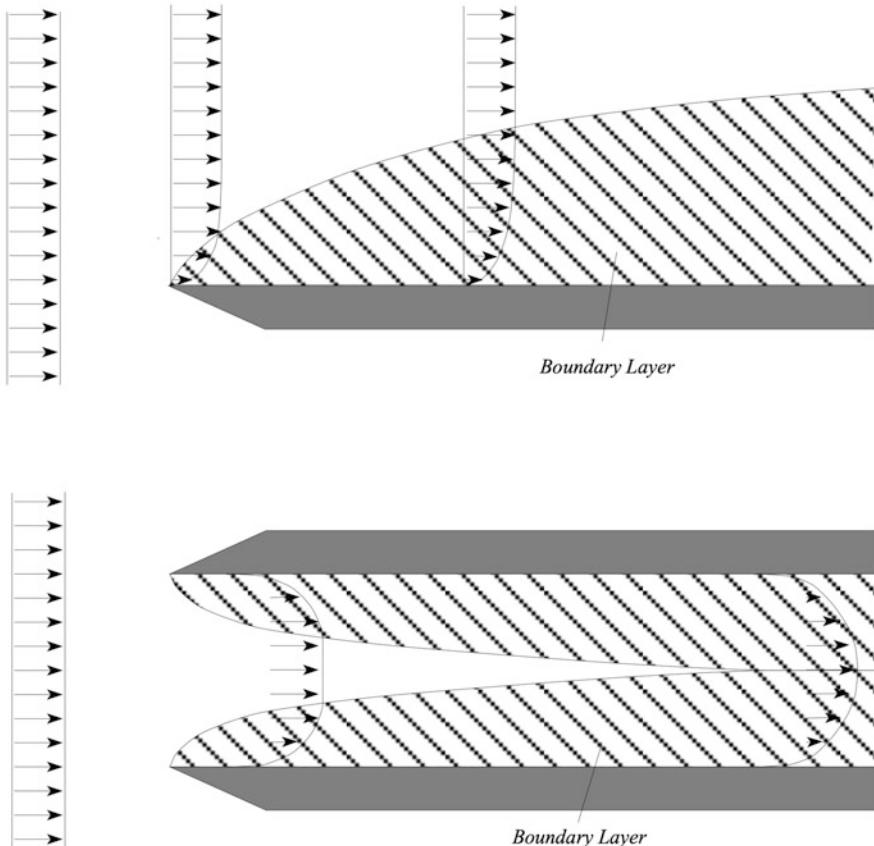

Fig. 5 Schematic of boundary layer formation on a surface and in a tube

Gas Flow Through a Tube

Two other characteristics of flow through a tube are worth noting as they are influential in how particles are transported. A constriction in the flow will force the gas to increase in velocity and be focused toward the center of the tube, leading to an effective tube diameter that is *smaller* than the actual diameter (Fig. 6). The contraction region is termed the “vena contracta.” Established tube flow round a bend in the tubing will result in secondary flow circulation within the tube (Fig. 7). In each case, the ten-diameters rule is a good rule of thumb for estimating the distance required to regain equilibrium flow after the disturbance.

Fig. 6 Flow in a *vena contracta*

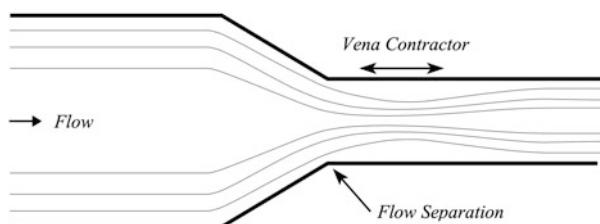

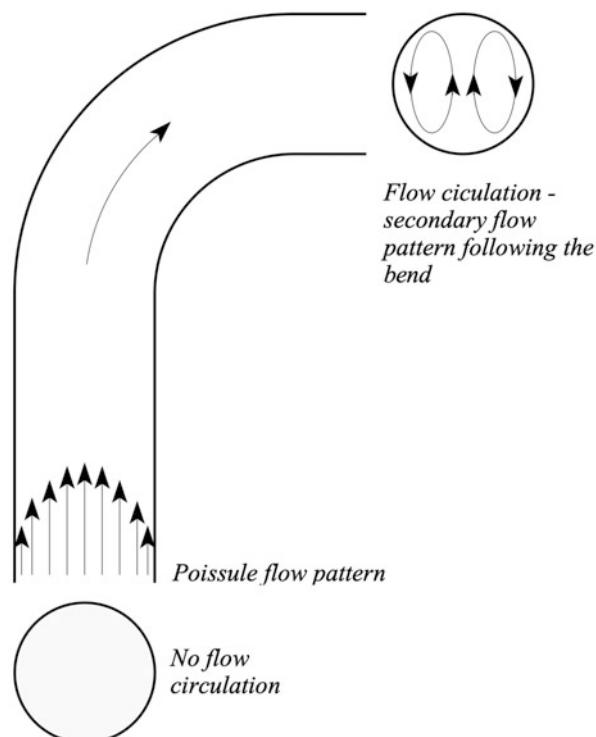

Fig. 7 Flow circulation around a 90° bend

Reynolds Number

An important aspect of understanding the flow of gases and the aerodynamic properties of aerosol particles is the Reynolds number (Re), a dimensionless number that characterizes fluid flow through a pipe or around an object. Dimensionless numbers are independent of scale and units and are widely used in engineering to characterize systems that exhibit similar properties at different scales. Aspect ratio is perhaps the simplest dimensionless number to understand. It has no dimension of its own and may be used to describe similarly shaped objects of any physical size. The Reynolds number has the following properties:

- It provides a benchmark to determine whether the flow is laminar or turbulent.
- It is proportional to the ratio of inertial forces to frictional forces acting on each element of the fluid.
- Geometrically similar flow will occur around geometrically similar objects at the same Reynolds number. Thus, for a given Re , the streamlines will be the same around objects of different size or flow of different fluids (or gas).

The Reynolds Number is defined as:

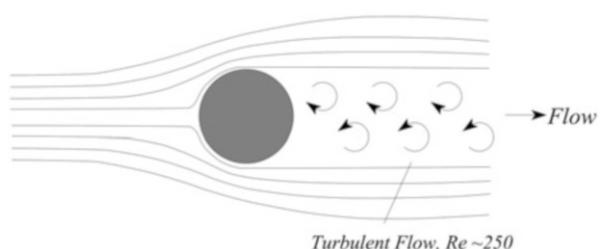

$$Re = \frac{\rho VL}{\eta} \quad (15)$$

where ρ is the gas density, V is the gas velocity, η is the gas viscosity, and L is a characteristic dimension. For instance, for flow through a tube, L is the tube diameter, and for flow around a particle, L is particle diameter. Re is dimensionless in any unit system, but obviously, all quantities need to be in the same system of units. Re depends only on the relative velocity between an object and the gas flow. It is aerodynamically equivalent for air to flow past a stationary object or for the object to move in stationary air.

Laminar and Turbulent Flow

Laminar flow around a particle occurs when $Re < 1$. Within this region, viscous forces are much greater than inertial forces. This type of flow is characterized by a smooth pattern of streamlines that are symmetrical on the upstream and downstream sides of the object (Fig. 8). At $Re \gg 1$ eddies form in the flow downstream of the

Fig. 8 Turbulent flow

object, breaking the smooth pattern of the streamlines and leading to random fluctuations in flow and velocity for small packets of gas. Flow within this regime is classed as turbulent flow. Turbulence is a complete topic in itself, and perhaps one of the least understood aspects of fluid flow. However, its influence on flow systems is highly significant. Generally, turbulence occurs when an obstruction or change in flow system leads to high localized flow velocities, and inertial forces dominating viscous forces. The result is randomly fluctuating gas motion superimposed on the mean flow. Two consequences are an increase in apparent viscosity and a sharp rise in the mixing properties of the gas. Flow through pipes is laminar for $Re < 2000$, and turbulent for $Re > 4000$. Whether the flow around a particle or through a flow channel is laminar or turbulent has a significant influence on particle motion and behavior within the flow.

Flow Stagnation

Where a streamline intercepts an object, the flow velocity falls to zero, resulting in a stagnation point. Stagnation points are particularly important when considering aerosol particle transportation, as particles approaching such a point run the risk of being trapped in a zone of very little air movement (Fig. 9).

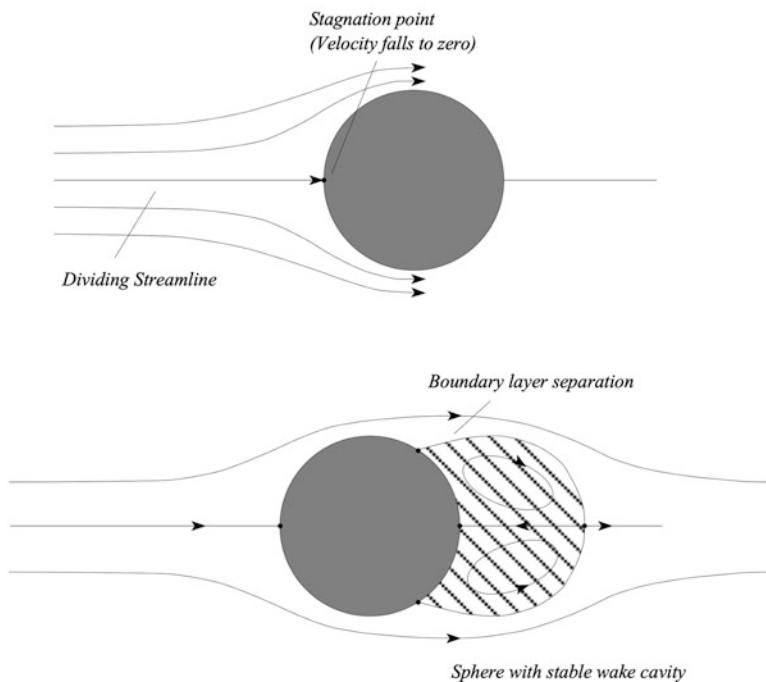

Fig. 9 Flow stagnation and separation

Flow Separation

For idealized inviscid frictionless flow, all streamlines impinging on an object would move around the object and continue in the object's wake. However, in the real world, where there is friction due to viscosity, some streamlines will lose sufficient energy to be "lost." The result is boundary layer separation – the fluid in the boundary layer close to the surface of the downstream side of the body comes to rest prematurely. When and where this occurs, the flow breaks away from the body, enclosing a negative-pressure recirculating region (this may or may not be turbulent). Formation of the vena contracta (Fig. 6) at a sharp change in flow channel is an example of flow separation. In a rapidly expanding flow channel, flow will separate from the channel walls. In general, the angle between the wall and the flow axis needs to be less than 7° to prevent separation. As in the case of stagnation points, aerosol particles run the risk of being trapped in regions of separated flow (Fig. 9). The mechanisms that determine whether a particle will enter such regions or not will be covered below.

Particle Motion in Air

Background

An understanding of how aerosol particles react in response to an applied force is fundamental to understanding many of the factors affecting their sampling, measurement, and characterization. As the particles are suspended in a gas, any external force applied to them will be resisted as they move with respect to the gas. A steady state will eventually be reached where the resistive forces equal the applied forces, leading to particles moving at a constant velocity (with respect to the gas). The resulting steady-state motion is often attained very rapidly, and an understanding of the relationship between an applied force (such as gravity, or an electrical field) and the resulting steady-state motion is a very useful tool in making sense of aerosol behavior. Once there is an understanding of the steady-state motion of aerosol particles, the basic concepts of motion under an applied force can be developed for the case where particles are under acceleration. *An understanding of both states is needed to understand many of the mechanisms leading to particle deposition and particle sampling.*

Drag

Drag is a force that opposes particle motion relative to the surrounding gas. It results from a number of mechanisms including gas viscosity (friction) and the energy required by the particle to displace gas as it moves (inertia). The applied force leading to particle motion with respect to the gas can be any force that acts differentially on the particles and the gas in an aerosol. For instance, an electrostatic

field will lead to a resultant force on charged particles but not on the carrier gas. And gravity will lead to a net force on suspended.

Newtonian Drag

Intuitively, drag is proportional to the projected area of a particle, and its velocity with respect to the gas. Newton derived the general equation for the drag force on a sphere while considering the motion of cannonballs through the air. He reasoned that the drag experienced by a cannonball results from the force required to remove the air from its path as it travels. The mass of air that has to be pushed aside each second by a sphere of diameter d is simply the projected area ($\pi d^2/4$) times the sphere's relative velocity (V) and the air's density (ρ_g). The force required to achieve this equals the change in momentum of the gas per unit time, which is simply equal to the mass of gas displaced times the relative velocity between the sphere and the gas.

This leads to the drag force F_D being given by:

$$F_D = \frac{\text{change of momentum}}{\text{unit time}} \propto \rho_g \frac{\pi}{4} d^2 V^2$$

$$F_D = \frac{C_D}{2} \rho_g \frac{\pi}{4} d^2 V^2 \quad (16)$$

where C_D is the drag coefficient. This is the general form of Newton's resistance equation and is valid for all sub-sonic particle motion, including that of aerosol particles. For situations where inertial forces dominate ($Re > 1000$), C_D is constant and is ~ 0.44 (for spheres). However, as viscous forces become significant at lower Re , C_D no longer remains constant but becomes dependent on Re . Below $Re \approx 1$, $C_D = 24/Re$, and in the transition region C_D can be approximated by an empirical expression:

$$C_D = \frac{24}{Re} (1 + 0.15 Re^{0.687}) \quad (17)$$

Stokes' Law

For aerosol particle motion, the particle Re is less than 1 in most cases and drag forces are dominated by viscous forces. The expression for the drag force on a particle in this regime was derived by George Stokes in 1851 and is given by:

$$F_D = 3\pi\eta Vd \quad (18)$$

where η is the gas viscosity, V the particle's relative motion, and d the particle diameter (spherical particles). In this regime, F_D is proportional to d and *not* d^2 . Comparing Stokes' law to Newton's law gives:

$$C_D = \frac{24\eta}{\rho_g V d} = \frac{24}{Re} \quad (19)$$

Particle Mobility

The drag on a particle is a function of its velocity. As a result, if a constant force is applied to a particle, it will eventually reach a velocity where the applied force matches the drag force. This is the maximum velocity attainable with the applied force and is referred to as the terminal velocity (or settling velocity when the force is gravity). Particles traveling at their terminal velocity are said to be in steady-state motion.

A useful concept when considering the steady-state motion of particles is their mobility. Mobility (usually denoted by the symbol B) is a measure of the relative ease of producing steady-state motion for an aerosol particle and is defined for spherical particles as:

$$B = \frac{V}{F_D} = \frac{1}{3\pi\eta d} \quad (20)$$

Using particle mobility, the terminal velocity of a particle, V_T , is expressed by:

$$V_T = FB \quad (21)$$

where F is the applied force.

An important application of Stokes' law is the derivation of the terminal velocity under gravity (particle settling velocity, V_{TS}). The gravitational force on a particle is given by mg where particle mass $m = \pi d^3 \rho / 6$. Thus, from Eq. (21), V_{TS} is given by:

$$V_{TS} = \frac{\pi d^3 \rho_p g}{6} \times \frac{1}{3\pi\eta d} = \frac{\pi d^2 \rho_p g}{18\eta} \quad (22)$$

This expression is valid for spherical particles $d > 1 \mu\text{m}$ and $Re < 1.0$.

Slip Correction

The derivation of Stokes' law assumes that particles are in the continuum regime (i.e., that the particle diameter is much larger than the gas mean free path and that the gas velocity at the particle's surface is zero). However, as particle diameter approaches and goes below the gas molecule mean free path, these assumptions begin to break down. The gas can no longer be treated as a continuous medium, and the assumption that gas velocity at the particle surface is zero becomes meaningless.

This phenomenon is sometimes visualized as the gas flow “slipping” across the particle surface. At the extreme, particles will behave like massive molecules, “slipping” between the gas molecules until a random collision takes place. For Stokes’ law to be used in this region – typically at particle diameters $< 1 \mu\text{m}$, a correction needs to be applied. This correction is usually referred to as the Slip Correction.

The first derivation of the correction factor was proposed by Cunningham (1910) and incorporated into the equation for the drag force on a particle as the Cunningham Slip Correction Factor C_C :

$$F_D = \frac{3\pi\eta Vd}{C_C} \quad (23)$$

where

$$C_C = 1 + \frac{2.52\lambda}{d} \quad (24)$$

Use of the Cunningham slip correction factor extends the applicable range of Stokes’ law to particles of diameter $0.1 \mu\text{m}$. A more generally applicable empirical form of the slip correction factor (developed by Davies 1945) is given by:

$$C_S = 1 + \frac{\lambda}{d} \left(2.34 + 1.05e^{-0.39\frac{d}{\lambda}} \right) \quad (25)$$

which is applicable for all particles smaller than $1 \mu\text{m}$ down to around 2 nm. A further extension to molecular sizes was presented by Ramamurthi and Hopke (1989).

Particle settling velocity for all particle sizes with $Re < 1$ becomes:

$$V_{TS} = \frac{\rho_p d^2 g C_S}{18\eta} \quad (26)$$

Particle Shape

The above expressions all assume that spherical particles are involved. If a particle is non-spherical, it will generally experience a different drag to a similarly sized sphere (Fig. 10). Generally, it is unusual to find spherical solid aerosol particles (unless they are manufactured specifically to be spheres), and so is particularly useful to know how particle shape affects drag, and therefore mobility and terminal velocity.

A correction factor, the Dynamic Shape Factor, is applied to Stokes’ law to account for the effect of shape on moving particles. The dynamic shape factor (χ) is defined by the ratio of the actual drag experienced by the particle to that experienced by an equivalent spherical particle. χ is given by:

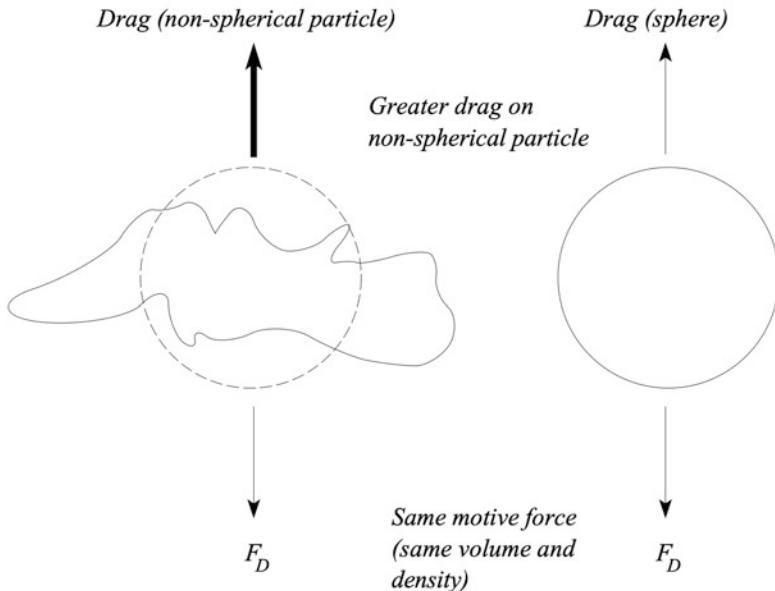

Fig. 10 Dynamic shape factor

$$\chi = \frac{F_D}{3\pi\eta V d_e} \quad (27)$$

where d_e is the equivalent volume diameter of the particle (i.e., the diameter of a spherical particle having the same volume). For a spherical particle, χ is 1.

Stokes' law including particle shape is given by:

$$F_D = \frac{3\pi\eta V d \chi}{C_S} \quad (28)$$

and particle terminal settling velocity becomes:

$$V_{TS} = \frac{\rho_p d^2 g C_S}{18\eta\chi} \quad (29)$$

Calculation of χ is complex, and for all but the simplest geometries, it must be measured experimentally. χ is always greater than 1. Compilations of shape factors are provided in Hinds and Zhu (2022).

Tranquil and Stirred Settling

Knowing V_{TS} allows an estimate to be made of how long it will take for a particle to settle from the air in an enclosed space. If there is no air motion within a room of

height h , it will simply take a time of $V_{TS} \times h$ for all particles to settle out. If the aerosol concentration N at a given point was measured, it would remain constant to a point and then abruptly fall to zero as the last particle settles past the reference point. However, air movement and activities in the room lead to different behaviors as described in ► Chaps. 11, “Deposition,” and ► 12, “Resuspension.”.

Definition of Particle Diameter: Aerodynamic Diameter

It is now possible to examine the concept of particle diameter. Previously in this chapter, it has been assumed that diameter d refers to a particle’s physical diameter, for instance, what might be seen and measured if examined under a microscope. However, the “diameter” of a particle depends strongly on the shape and composition of the particle and on the measurement method. Measuring particle diameter using microscopy, settling velocity, and light scattering, for instance, will all give different answers in many cases.

Here, there is a need for a measure of diameter that determines how a particle will behave in any given situation, and this may or may not be the same as its physical diameter. Differences in how particle diameter is characterized are particularly pertinent for non-spherical particles, where expressing particle size by a single parameter alone will always be an approximation. And here, understanding that the measured diameter of a particle is dependent on the way it is measured is particularly important when interpreting aerosol measurements (Fig. 11).

To a first approximation, particles being measured, characterized, or separated by inertial forces such as gravity or “centrifugal” force, are characterized by their settling velocity. Under inertial forces, two particles with the same settling velocity will behave in the same manner and be measured as being identical – even though they may have very different physical characteristics. It is common to define particles under these conditions by their aerodynamic diameter. Aerodynamic diameter is defined as the diameter of a sphere of density 1000 kg/m^3 with the same settling velocity as the particle of interest. A similar definition, used occasionally, is the Stokes’ diameter (d_s), which is the diameter of a sphere with the same density as the particle in question, and the same settling velocity. Re-arranging Eq. (29) and ignoring slip correction gives aerodynamic diameter (d_{ae}) as:

$$d_{ae} = d_e \left(\frac{\rho_p}{\rho_0 \chi} \right)^{\frac{1}{2}} = d_s \left(\frac{\rho_p}{\rho_0} \right)^{\frac{1}{2}} \quad (30)$$

where ρ_0 is 1000 kg/m^3 (“unit” density). For spheres, d_{ae} is simply

$$d_{ae} = d_p \left(\frac{\rho_p}{\rho_0} \right)^{\frac{1}{2}} \quad (31)$$

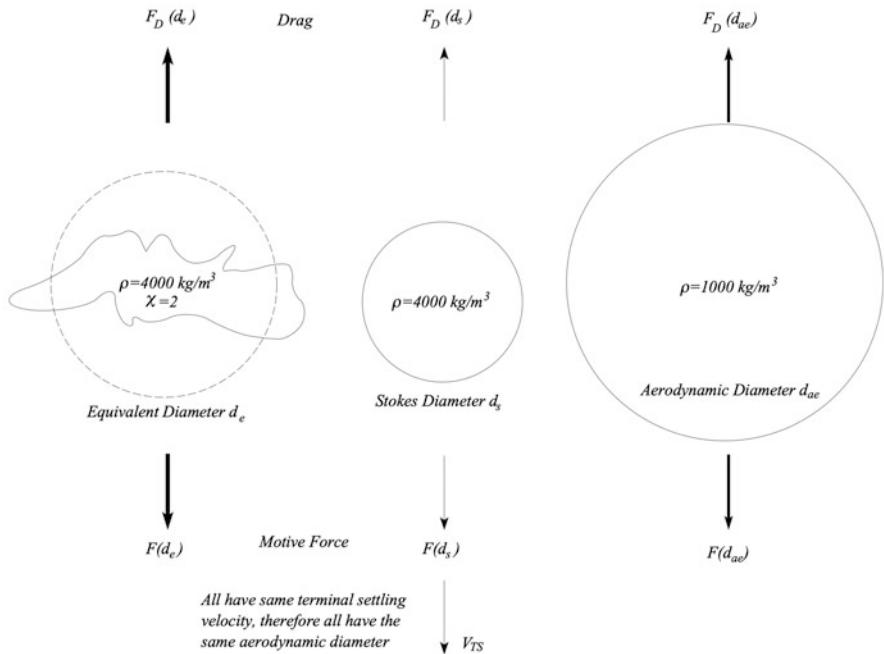

Fig. 11 Aerodynamic diameter. Despite variations in size and shape, all of these particles have the same aerodynamic diameter

For smaller particles where slip correction is important, Eqs. (30) and (31) need to be modified to include C_s for both d_p and d_e .

In general terms, it is common to speak of a particle's mobility diameter. Aerodynamic diameter is a special case where mechanical mobility is being considered. However, a similar approach is used for electrical mobility, diffusional mobility, thermophoretic mobility, etc. The important point to realize is that there is no absolute particle diameter. The diameter is defined by the method used to measure it.

Particle Motion Under Acceleration

A number of particle collection and measurement methods depend on the motion of particles under an accelerating force either leading to straight line acceleration or curvilinear motion (motion along a curved path). Here, three quantities are useful in understanding particles undergoing acceleration: particle relaxation time, stopping distance, and Stokes number. The concepts behind each quantity are described below, along with the necessary expressions to calculate them. However, a detailed derivation is beyond the scope of this chapter but can be found in Hinds and Zhu (2022).

Relaxation Time

We have already established that if you apply a steady force to a particle, it will eventually reach a steady velocity as the drag force matches the applied force. The assumption was made earlier that this steady state is reached relatively rapidly. However, knowing something about how long a particle takes to respond and “adjust” to a change in applied force is a useful tool for determining behavior under conditions of change.

Recall that under gravity, the terminal settling velocity is given by the mobility B multiplied by the applied force: in this case gravity (where $F = mg$). V_{TS} is written as:

$$V_{TS} = Bmg = \tau g \quad (32)$$

where τ has the units of time and is referred to the relaxation time. Relaxation time is a measure of how rapidly a particle will respond or “relax” to any changes in applied force. τ occurs in many instances within aerosol dynamics where a particle’s motion is governed by mechanical mobility. It is useful for understanding how rapidly different particles will respond to an applied force – for instance, if a group of particles with different diameters are moving under the influence of an electric field, it indicates which particles will continue to move for an appreciable amount of time when the field is switched off, and which will stop almost immediately. Re-arranging Eq. (32) and using the expression for mechanical mobility B gives:

$$\tau = \frac{\rho_p d^2 C_s}{18\eta} = \frac{\rho_0 d_a^2 C_s}{18\eta} \quad (33)$$

It takes 3τ for a particle to reach 95% of its new terminal velocity following a change in the applied force.

Stopping Distance

While relaxation time gives an indication of the time taken for a particle to adjust to a new set of forces, stopping distance is a measure of how far a particle will travel until it reaches a new steady state velocity under these forces. For instance, stopping distance S of a particle traveling at velocity V_0 will give the distance the particle will continue to travel after the applied force has been removed. Stopping distance is particularly important when it comes to determining the likelihood of particle deposition due to inertia.

Stopping distance for the situation where the motive force in the direction of travel is removed is given by:

$$S = V_0 \tau = Bm V_0 \quad (34)$$

where V_0 is the initial velocity. While τ gives the time taken to travel distance S , the actual time will be much longer since, as the particle slows down, the drag force will become smaller and the particle’s rate of deceleration will decrease, leading to the

distance traveled exponentially approaching the stopping distance S . In the absence of other forces, a particle will travel 95% of the distance toward S in a time of 3τ .

Curvilinear Motion

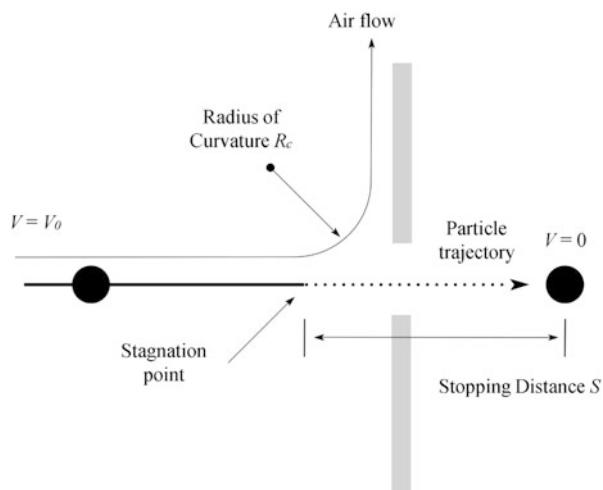

Curvilinear particle motion is an extension of straight-line motion and occurs when a particle experiences forces that are changing with respect to time and/or position. A good example is of particles in an aerosol flowing around an obstruction, or through a series of constrictions. The gas streamlines depicting flow in these situations will curve in response to the flow conditions. Particles entrained in the flow will also attempt to follow the streamlines as the varying flow direction exerts a force upon them. The degree to which particles will remain in the streamlines, or diverge from them, is characterized by the Stokes number Stk . Stk is the ratio of particle stopping distance to some measure of the size of the object causing the flow to diverge. In the illustrated example in Fig. 12, where R_C is the radius of curvature of the airflow as it deviates through a 90° bend, Stk is given by:

$$Stk = \frac{S}{R_C} = \frac{\tau V_0}{R_C}, Re_0 \leq 1 \quad (35)$$

Another example, if the particles are flowing in streamlines around a cylinder with its long axis oriented perpendicular to the flow, the characteristic dimension will be the cylinder's diameter, and Re_0 will be the initial particle Reynolds number ($V = V_0$).

Like Reynolds number, Stokes number is dimensionless. Stokes number can be understood as the “persistence” of a particle divided by the size of an obstruction. As Stk approaches zero, particles will follow the streamlines perfectly. As Stk increases,

Fig. 12 Illustration of stopping distance

a particle's resistance to any changes in direction will increase, resulting in increasingly more streamlines being crossed by the particle in regions of rapid flow direction change.

If a particle has the same values of Re and Stk for similar geometric conditions, the particle's motion will be the same. Equal Re ensures that the flow conditions are similar, while equality of Stk ensures that the particles motion in the flow fields are similar.

Brownian Motion

In 1827 the botanist Robert Brown first observed the random motion of pollen grains in water that is now called Brownian motion. Around 50 years later, similar behavior was noticed with smoke particles, and the connection was made between gas molecule motion and random particle motion. Molecules in a gas are in a continuous state of motion. Clearly, any aerosol particles present will be constantly bombarded by these molecules. If the particles are of similar mass to the gas molecules, they will move around in a similar way, and follow a similar random walk (Fig. 12). For particles very much larger than the gas mean free path, the collision rate with air molecules on all sides will be approximately equal, and there will be no net force leading to motion. However, in the transition region between these extremes, there is a finite probability of more collisions from one direction than the opposite direction, leading to a net force in that direction. The net direction, magnitude, and persistence of the force is itself random, leading to the random particle motions seen in Brownian motion. The motion is analogous to molecular motion, although it is important to remember that the particle motion is a result of many collisions with molecules and not in single collisions (Fig. 13).

Particle Brownian motion leads to three characteristics of particle behavior that are analogous or similar to molecular behavior in an ideal gas: diffusion, mean velocity, and mean free path.

Diffusion

The Brownian motion of aerosol particles leads to the bulk movement of particles through diffusion. As in the case of molecules, the flux of aerosol particles moving from a high to low concentration region through diffusion is given by Fick's first law of diffusion (Eq. 13). The diffusion coefficient D can be derived from equating the Stokes' drag force experienced by particles to the net force arising from molecular collisions. It is given by:

$$D = \frac{kTC_S}{3\pi\eta d} \quad (36)$$

k is the Boltzmann constant ($1.38 \times 10^{-23} \text{ J K}^{-1}$) and T the temperature of the gas in degrees Kelvin. The diffusion coefficient can be expressed in terms of particle mobility B :

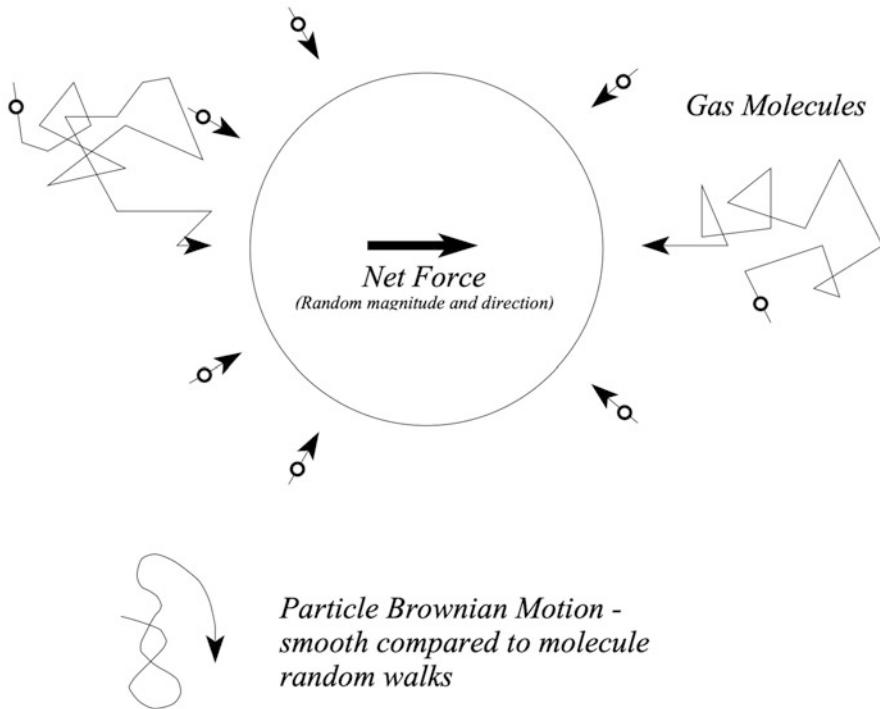

Fig. 13 Particle Brownian motion

$$D = kTB \quad (37)$$

D is proportional to temperature but inversely proportional to particle diameter. For small particles with high values of C_s , D is approximately proportional to $1/d^2$ since d^2 represents the cross-sectional area of a particle as it collides with gas molecules. However, the diffusion coefficient of a $0.01\text{ }\mu\text{m}$ particle is still three orders of magnitude smaller than that of a typical gas molecule.

The average distance a particle will travel from its starting position in a given time through diffusion is given by its displacement over time t . Brownian displacement is represented by the root mean square distance traveled, x_{rms} , and is given by:

$$x_{rms} = \sqrt{2Dt} \quad (38)$$

Mean Particle Velocity

As aerosol particles are constantly exchanging energy with the surrounding gas molecules, they have the same kinetic energy as these molecules. Therefore, in the same way that the root mean square and arithmetic mean velocities for gas molecules were derived, the same quantities can be derived for aerosol particles:

$$c_{rms} = \left(\frac{3kT}{m} \right)^{\frac{1}{2}} = \left(\frac{18kT}{\pi\rho_p d^3} \right)^{\frac{1}{2}} \quad (39)$$

$$\bar{c} = \left(\frac{8kT}{\pi m} \right)^{\frac{1}{2}} = \left(\frac{48kT}{\pi^2 \rho_p d^3} \right)^{\frac{1}{2}} \quad (40)$$

Mean Free Path

Particle mean free is not directly analogous to molecule mean free path. Since most aerosol particles are much more massive than gas molecules, it takes many collisions to lead to a change in direction of particle motion. However, the concepts are similar. Particle mean free path is defined as the distance traveled before molecular collisions have led to a complete (i.e., 90°) change in direction. This quantity is essentially the stopping distance of the particles under the influence of Brownian motion and is given by:

$$\lambda = \tau \bar{c} \quad (41)$$

The diffusion coefficient of an aerosol particle can be expressed in terms of particle mean free path and mean velocity:

$$D = \frac{\pi}{8} \lambda_p \bar{c} \quad (42)$$

Relative Deposition Velocities

In general, different deposition forces become dominant at different particle sizes. For large particles, gravitational deposition (or inertial deposition) is important. Electrostatic deposition becomes more important at smaller particle diameters, but for most aerosols the Boltzmann charge equilibrium (the distribution of positive and negative charges on a collection of aerosol particles at equilibrium) inhibits very small particles having sufficient charge for electrostatic deposition to be significant. In this region, diffusion rapidly becomes the dominant deposition mechanism.

Conclusions

This chapter provided an introduction to many of the concepts related to aerosol dynamics that will be helpful in understanding the other chapters in this section, such as deposition and resuspension. It is not meant to be comprehensive in covering all of the related topics, such as charged particle behavior in the presence of external electric fields or how to represent particle size distributions. Details on particle measurement methods are provided in the chapter on indoor particle concentrations, size distributions, and exposures. A comprehensive introduction to aerosol dynamics

is provided in a number of textbooks, including Hinds and Zhu (2022) and Friedlander (2000).

Nomenclature (Note that in some cases a symbol may be used to denote different values in different contexts. All equations listed should be evaluated using SI units (kg, m, s). SI units for the values below are listed where appropriate)

A	Area [m^2]
B	Particle mechanical mobility [$\text{m N}^{-1} \text{ s}^{-1}$]
c	Velocity [m/s]
c_x	Velocity in the x-direction [m]
c_{rms}	Root mean square velocity [m/s]
\bar{c}	Mean velocity [m/s]
C	Concentration (e.g., gas concentration) [concentration units/ m^3]
C_c	Cunningham slip correction [dimensionless]
C_s	Slip correction [dimensionless]
C_D	Drag coefficient [dimensionless]
D	Diffusion coefficient [m^2/s]
d	Particle diameter [m]
d_m	Collision diameter [m]
d_{ae}	Aerodynamic diameter [m]
d_e	Equivalent diameter (diameter of sphere with same volume) [m]
d_s	Stokes diameter [m]
F	Force [kg m/s^2 or N]
F_D	Drag force [kg m/s^2 or N]
g	Gravity [9.81 m/s^2]
J	Flux. Particles [$\#/ \text{m}^2/\text{s}$]
k	Boltzmann constant [$1.38 \times 10^{-23} \text{ J/K}$]
m	Mass. Often of a single particle or molecule. [kg]
N	Number of molecules per unit volume (gas kinetics) [$\#/ \text{m}^3$]
n	Number of moles of gas (gas kinetics) [mol]
N_a	Avogadro's number [$6.022 \times 10^{23} \text{ mol}^{-1}$]
n_c	Molecule collisions per second [$\#/ \text{s}$]
P	Pressure [N/m^2 or Pa]
R	Gas constant [$8.31 \text{ Pa m}^3/\text{K mol}$]
Re	Reynolds number [dimensionless]
R_c	Radius of curvature
S	Stopping distance [m]
Stk	Stokes number [dimensionless]
t	Time [s]
τ	Relaxation time [s]
T	Temperature [K]

U	Velocity. Usually free stream gas
V	Volume [m^3]
V_0	Initial velocity [m/s]
V_T	Terminal velocity [m/s]
V_{TS}	Settling velocity [m/s]
V_{th}	Thermophoretic deposition velocity [m]
x_{rms}	Root mean square distance traveled [m]
η	Viscosity [$\text{kg m}^{-1} \text{s}^{-1}$]
λ	Mean free path [m]
λ_p	Particle mean free path [m]
λ_g	Gas mean free path [m]
ρ	Density [kg/m^3]
ρ_g	Gas density [kg/m^3]
ρ_p	Particle density [kg/m^3]
ρ_0	Unit density [1000 kg/m ³]
χ	Dynamic shape correction factor

Abstract

Even people mostly stay indoors, they are constantly exposed to outdoor-originated particles. Outdoor particles can penetrate into indoor environments via the building envelope through ventilation and air infiltration. Penetration factor is the ratio of outdoor particles entering the indoor environments through the building's envelope, and infiltration factor is the equilibrium fraction of ambient particles that enter and remain suspended indoors. The penetration factor and infiltration factor are important parameters to understand the transport of particles from outdoors to indoors. Penetration factors can be measured according to regression approach, equilibrium concentration approach, or error analysis approach. The penetration factors are

0.78 ± 0.17 for accumulation-mode particles ($0.1\text{--}1\text{ }\mu\text{m}$ diameter). They decreased due to Brownian diffusion for smaller particles, or due to stronger gravitational settling and impaction for larger particles. In addition to particle sizes, penetration factors are determined by pressure differences, geometry and surface roughness of cracks, etc. Infiltration factors can be measured by regression approach, equilibrium concentration approach, or tracer element approach, and can also be simulated based on the air change rate, penetration factor and deposition rate. The infiltration factors of $\text{PM}_{2.5}$ are approximately 0.50, which are lower than ultrafine particles and higher than PM_{10} under the same conditions. Infiltration factors are also influenced by air change rates, window opening behaviors, ventilation systems, etc.

Particulate matter · Indoor air · Penetration factor · Infiltration factor

Introduction

People spend 85–90% of their time indoors (Buonanno et al. 2014; Duan 2013; Klepeis et al. 2001; Lee and Lee 2017; Leech et al. 2002; Matz et al. 2014; Spalt et al. 2016). There are various sources of indoor particles. Ambient particles penetrate into indoor environments via the building envelope through ventilation and air infiltration (Chen and Zhao 2011; Nazaroff 2004). Indoor activities, for example, including cooking and smoking also lead to the generation of indoor particles (Chen et al. 2018a, b; Morawska et al. 2017; Nazaroff 2004). Besides, the indoor particle concentration is also determined by the deposition, coagulation and resuspension of particles. Assuming that air is well mixed indoors and the ambient concentration is steady, and the mass balance equation for particles can be expressed as (Rim et al. 2016; Thatcher and Layton 1995; Vu et al. 2017):

$$\frac{dC_{in}(d_p, t)}{dt} = aPC_{out}(d_p) - (a + k_d + k_c)C_{in}(d_p, t) + \frac{RL_f A_f}{V} + \frac{S(d_p, t)}{V} \quad (1)$$

$$k_d = \frac{A}{V} v_d \quad (2)$$

$$k_c = -\frac{\frac{1}{2} \sum_n \sum_m K_{m,n} C_{in}(m, t) C_{in}(n, t) - C_{in}(d_p, t) \sum_n K_{dp,n} C_{in}(n, t)}{C_{in}(d_p, t)} \quad (3)$$

where $C_{in}(d_p, t)$, $C_{in}(m, t)$, and $C_{in}(n, t)$ are the real-time indoor particle concentrations with diameter d_p , m , and n , respectively, at the measuring moment t , a is the air change rate, P is the penetration factor of outdoor particles entering the indoor environments through the building's envelope, k_d is the deposition rate, R is the particle resuspension rate, L_f is the mass loading of particles on accessible floor surfaces, A_f is the surface area of floors, S is the emission rate of particles generated from indoor sources, V is the volume of the room, k_c is the net rate of loss due to coagulation, and $K_{m,n}$ and $K_{dp,n}$ are the coagulation coefficients between particles

with diameter m and n , d_p and n , respectively. The numerator of equation for k_c represents the net loss of indoor concentration of particles with diameter d_p due to coagulation, which depends on the generation when particles with diameter m coagulate with particles with diameter n , and the reduction of the concentration when particles with diameter d_p coagulate with particles in all other size categories.

Ambient air pollution is still severe in a lot of areas, including India and China, which account for more than 30% of the world's population (Huang et al. 2018; Pant et al. 2016). Environmental events, such as Camp Fire (Li et al. 2020; Reid et al. 2015; Rooney et al. 2020), also increased ambient particle concentrations in those areas where ambient air pollution was well controlled before. Thus, assessing indoor exposure to outdoor-originated particles is important. **Penetration factor (P)** in Eq. (1) is one of important parameters to understand the transport of particles from outdoors to indoors. Besides, **infiltration factor (F_{inf})**, another important parameter, is defined as the **equilibrium** fraction of ambient particles that enter and remain suspended indoors (Ozkaynak et al. 1996; Wilson and Suh 1997). F_{inf} can be expressed as:

$$F_{\text{inf}} = \frac{C_{\text{in},os}(d_p, t_\infty)}{C_{\text{out}}(d_p, t_\infty)} \quad (4)$$

where $C_{\text{in},os}(d_p, t_\infty)$ is the indoor concentration of particle with diameter d_p originating from outdoor sources at steady state, and $C_{\text{out}}(d_p, t_\infty)$ is the outdoor concentration of particle with diameter d_p at steady state.

As outdoor particles contribute significantly to indoor aerosols, penetration factor and infiltration factor are discussed in this chapter as one of the most important indoor aerosol dynamics. And deposition, resuspension, and sources of particles will be explained in detail in next chapters of this section.

Penetration Factor

There are several experiments for penetration factors conducted in real buildings or laboratory. Nearly all studies neglected the effects of coagulation and resuspension based on mass balance equation as:

$$\frac{dC_{\text{in}}(d_p, t)}{dt} = aPC_{\text{out}}(d_p) - (a + k_d)C_{\text{in}}(d_p, t) + \frac{S(d_p, t)}{V} \quad (5)$$

Measurement

Methods in Real Buildings

Regression Approach

Koutrakis et al. (1992) sampled indoor and outdoor PM_{2.5} (fine particles whose aerodynamic diameters are not greater than 2.5 μm) in 187 residences and determined

the concentrations of elements in PM_{2.5}. Then, linear regression models between average indoor and outdoor concentration of PM_{2.5} and elements were developed as Eq. (6), which is the equilibrium solution. The penetration factor can be determined based on the slope of regression model, measured a and V , and estimated A/V and v_d .

$$C_{in} = \frac{aP}{a + \frac{A}{V}v_d} C_{out} + \frac{S}{V(a + \frac{A}{V}v_d)} \equiv \text{slope} \times C_{out} + \text{intercept} \quad (6)$$

Ozkaynak et al. (1994) modified this model as:

$$C_{in} = \frac{aPC_{out}}{a + k_d} + \frac{N_s S_s + T_c S_c}{(a + k_d)Vt} + \frac{Q_{other}}{(a + k_d)V} \quad (7)$$

where N_s is the number of cigarettes smoked, T_c is the duration of cooking, S_s and S_c are the mass of PM_{2.5}, PM₁₀ (coarse particles whose aerodynamic diameters are not greater than 10 μm), or elements generated per cigarette smoked and per hour of cooking, respectively, and Q_{other} is the mass flux of PM_{2.5}, PM₁₀ or elements from all other indoor sources. The C_{in} , C_{out} , N_s , T_c , V , and a were all measured or recorded in 293 residences. The penetration factor of PM_{2.5}, PM₁₀ and elements in PM_{2.5} and PM₁₀ can be determined using a nonlinear model as well as k_d , S_s , S_c , and Q_{other} (Ozkaynak et al. 1994, 1996).

Long et al. (2001) developed regression models of C_{out}/C_{in} as a function of $1/a$ based on nightly average data in 9 residences when the indoor sources can be neglected:

$$\frac{C_{out}}{C_{in}} = \frac{k_d}{P} \left(\frac{1}{a} \right) + \frac{1}{P} \equiv \text{slope} \times \left(\frac{1}{a} \right) + \text{intercept} \quad (8)$$

The values of P and K can be estimated from the intercept and slope.

This method is simple but the regression would be poor due to high variance of temporal contribution from specific indoor particle sources (Fonseca et al. 2014).

Equilibrium Concentration Approach

Tung et al. (1999) estimated the penetration factor of PM₁₀ in an office by measuring the equilibrium concentration as:

$$P = \frac{(a + k_d)C_{inf}}{aC_{out}} \quad (9)$$

where a and k_d were measured based on the natural decay curve of CO₂ and PM₁₀, respectively; C_{inf} was estimated as:

$$C_{in} - C_{inf} = \frac{1}{2} \left(C_{in,T_{1/2}} - C_{inf} \right) \quad (10)$$

where $C_{in,T_{1/2}}$ was the indoor concentration measured at the half-life, $T_{1/2}$; $T_{1/2}$ can be estimated as:

$$T_{1/2} = \frac{\ln 2}{a + k_d} \quad (11)$$

Numerous studies measured the equilibrium concentration for the penetration factor similarly (Chao et al. 2003; Chen et al. 2012b; Tran et al. 2017; Vette et al. 2001; Xie et al. 2020; Zhao et al. 2020). The decay curve of particle concentrations was monitored for 2–10 h until the steady state conditions were most likely achieved.

Zhou et al. (2019) turned off the ceiling cassette fan-coil unit in an office and monitored the indoor concentration of PM_{0.3–10} until it reached the equilibrium status. The penetration factor was calculated following Eq. (9) with the measured air change rate and the estimated deposition rate referring to previous studies. Vu et al. (2017) evaluated the penetration factor as the ratio of the downstream to upstream concentration through the mechanical ventilation system.

Peng et al. (2020) developed a method based on indoor PM_{2.5} removal by an air cleaner as Eq. (12). The average penetration factor is:

$$P = \left[\frac{1}{aC_{\text{out}}(d_p, t)} \frac{dC_{\text{in}}(d_p, t)}{dt} + \frac{(a + k_d + CAER)C_{\text{in}}(d_p, t)}{aC_{\text{out}}} \right] \quad (12)$$

where CAER is the ratio of the clean air delivery rate to the room volume.

Error Analysis Approach

Thatcher et al. (2003) developed a decay and rebound approach by measuring indoor and outdoor PM_{0.1–10} concentrations in two residences including three factors: (1) the particle loss rate following artificial elevation of indoor particle concentrations, (2) rapid reduction in particle concentration through induced ventilation by pressurization with HEPA-filtered air, and (3) the particle concentration rebound after house pressurization stopped. In such an experimental design, the indoor concentration varied over a wide range and the transient model in Eq. (13) was used to determine the combination of penetration factor and deposition rate that best fits the observed data, in other words, minimizes the sum of the square of differences between the measured and the modeled indoor concentration at each time step.

$$C_{\text{in}}(d_p, t + \Delta t) = C_{\text{in}}(d_p, t) + a(t)PC_{\text{out}}(d_p, t)\Delta t - [a(t) + k_d]C_{\text{in}}(d_p, t)\Delta t \quad (13)$$

where the time-varying air change rate, $a(t)$, is calculated using a transient mass balance of tracer gas (SF₆) approach that accounts for the injection rate and the time-dependent infiltration losses. Many studies monitored indoor and outdoor particle concentrations for hours or even days without invention and used such least-squares estimation for the penetration factor (Chatoutsidou et al. 2015; Mleczkowska et al. 2016; Rim et al. 2010, 2013). Bennett and Koutrakis (2006) simulated the indoor

concentration and employ least-squares estimation for the penetration factor as Eq. (14) similarly, which is also applied by Huang et al. (2017) and Wang et al. (2019):

$$C_{\text{in}}(d_p, t + \Delta t) = C_{\text{in}}(d_p, t) e^{-(a+k_d)\Delta t} + \frac{aPC_{\text{out}}(d_p, t)}{a + k_d} \left[1 - e^{-(a+k_d)\Delta t} \right] \quad (14)$$

Zhu et al. (2005) measured continuous concentrations of indoor and outdoor PM_{0.06-0.22} in four residences. The $\Delta C_{\text{in}}/\Delta t$ was used as a dependent variable in a linear regression while C_{in} and C_{out} were two independent variables in Eq. (15). Least-squares estimation was used to produce the best linear unbiased estimates for the penetration factor and deposition rate.

$$\frac{\Delta C_{\text{in}}(d_p, t)}{\Delta t} = aPC_{\text{out}}(d_p, t) - (a + k_d)C_{\text{in}}(d_p, t) \quad (15)$$

Stephens and Siegel (2012) and Zhao and Stephens (2017) modified the two-parameter error analysis approach. They measured the deposition rate by using a log-linear regression solution to the initial indoor decay portion of the data. With the earlier estimates of a and k_d , the penetration factor was then estimated using a one-parameter nonlinear least-squares regression following Eq. (13). The entire test period only lasted about 2–4 h, typically yielding relatively low uncertainties and high fitness for estimates of both P and k_d . Maskova et al. (2016, 2020) used the same approach for the penetration factor in historic buildings.

Hussein et al. (2006) and Chen et al. (2020b) modified the two-parameter error analysis approach in a different way. The three key parameters (the penetration factor, deposition rate and air change rate) were all estimated following Eq. (13) or Eq. (14) with the limitation of reasonable ranges.

Laboratory Methods

Different from measurements in real buildings, the pressure differences between inlet and outlet of the cracks can be maintained in laboratories to understand the factors influencing particle penetration.

Mosley et al. (2001) monitored particle concentrations in two compartments of a chamber as the particles are transported from the first compartment to the second one by advective flow via rectangular slits, simulating leakage paths. The penetration factor can be calculated based on the linear regression as following:

$$\frac{C_{\text{outlet}}(t)}{C_{\text{inlet}}(t)} \approx \frac{PQ}{V} t \equiv \text{slope} \times t \quad (16)$$

The penetration factor was also evaluated as the ratio of the downstream to upstream concentration through cracks or ventilation systems in many previous laboratory-based experiments (Jeng et al. 2006, 2007; Lai et al. 2012; Liu and

Nazaroff 2003; Lv et al. 2018; Stratigou et al. 2020; Wang et al. 2010; Xu et al. 2010).

Wang et al. (2020a, 2010) also applied the equilibrium concentration approach to their laboratory-based experiments. Lai et al. (2020) used the error analysis approach and developed a blower-door method giving higher precision. The penetration factor was measured based on the mass balance model of depressurization as Eq. (15) with the deposition rate estimated under pressurization.

Data Analysis

The penetration factor of UFPs (ultrafine particles, whose mobility diameters are not greater than $0.1 \mu\text{m}$), $\text{PM}_{2.5}$ and PM_{10} is in the range of 0.59–0.78, 0.72–1, and 0.69–0.86, respectively (Koutrakis et al. 1992; Ozkaynak et al. 1996; Tung et al. 1999; Williams et al. 2003; Zhao and Stephens 2017), which is consistent with the size-dependent results presented in Figs. 1 and 2. The size-dependent measured results in residences (A) and other real buildings (B) are presented in Fig. 1 (Chao et al. 2003; Chatoutsidou et al. 2015; Chen et al. 2020b; Hussein et al. 2006; Long et al. 2001; Maskova et al. 2016; Rim et al. 2010, 2013; Thatcher et al. 2003; Tran et al. 2017; Vette et al. 2001; Vu et al. 2017; Xie et al. 2020; Zhao and Stephens 2017; Zhao et al. 2020; Zhou et al. 2019; Zhu et al. 2005). The penetration factors are 0.78 ± 0.17 for accumulation-mode particles ($0.1\text{--}1 \mu\text{m}$ diameter). The penetration factors for UFPs

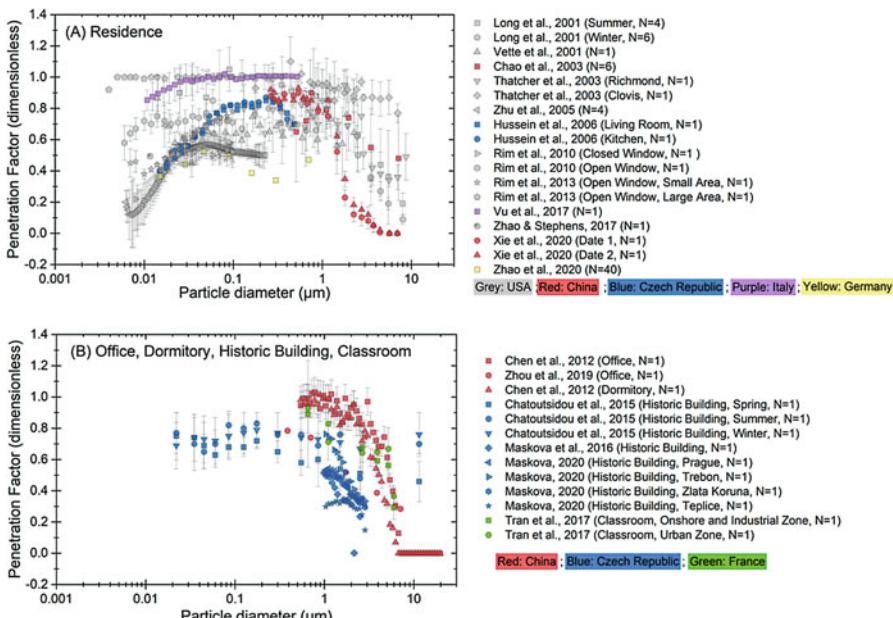

Fig. 1 Penetration factors measured in residences (a) and other buildings (b, including office, dormitory, historic building and classroom). Error bars represent standard errors

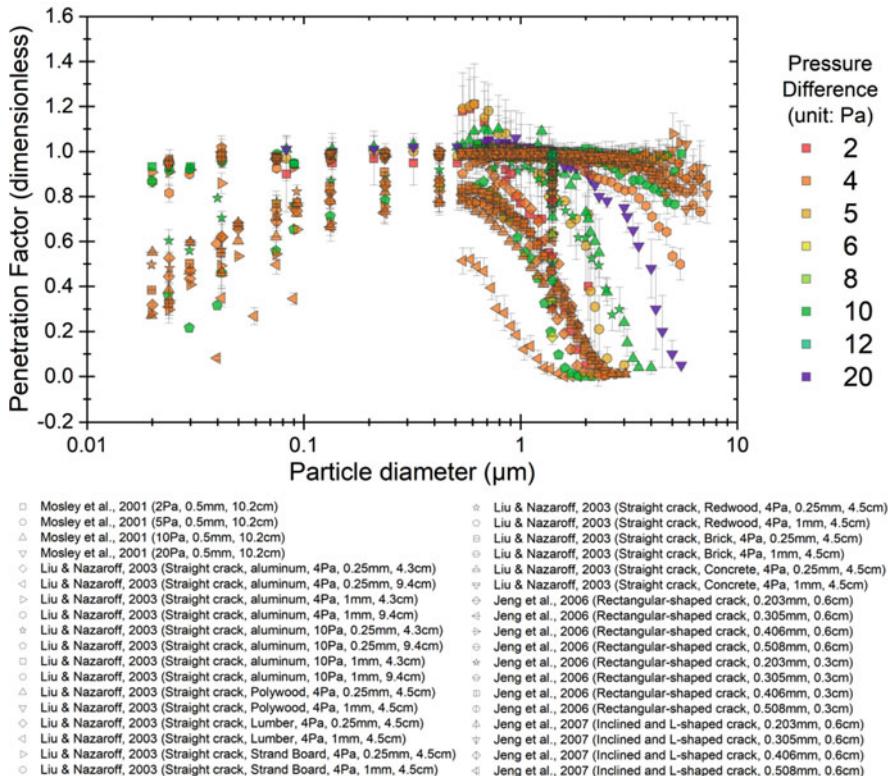

Fig. 2 Penetration factors measured in laboratories. Error bars represent standard errors (Adapted from Chen and Zhao (2011), Figure 7, with permission from Elsevier)

decreased to 0.61 ± 0.23 due to Brownian diffusion. The penetration factors for larger particles also decrease due to stronger gravitational settling and impaction with values of 0.48 ± 0.31 for particles greater than $1 \mu\text{m}$.

The penetration factors are influenced by air change rates and airtightness levels of building envelopes, which are determined by building types, seasons, window opening behaviors, years of construction, etc. (Chatoutsidou et al. 2015; Chen et al. 2020b; Long et al. 2001; Rim et al. 2010, 2013; Wang et al. 2019; Zhao and Stephens 2017). The measured results varied from building to building. Stephens and Siegel (2012) found that the penetration factor of PM_1 was significantly and negatively correlated with the years of construction of residences. In other words, higher fraction of outdoor PM_1 can enter leakier and older homes than those in tighter and newer homes. Stephens (2015) reanalyzed these results by Stephens and Siegel (2012) and the outdoor particle infiltration rates (aP) tended to be log-normally distributed with a geometric mean value of 0.16 h^{-1} and a geometric standard deviation of 2.33. Shi et al. (2017) collected measured data in real

buildings from previous studies (Chao et al. 2003; Chen et al. 2012b; Long et al. 2001; Thatcher et al. 2003; Vette et al. 2001; Zhu et al. 2005) and developed an empirical equation to estimate the penetration factors depending on particle diameter.

The measured data in laboratories in Fig. 2 showed the functions of penetration factors influencing by particle size, pressure differences, geometry and surface roughness of cracks (Jeng et al. 2006, 2007; Liu and Nazaroff 2003; Mosley et al. 2001). Penetration factors increase with larger pressure differences, larger crack height and smaller flow-path lengths (Jeng et al. 2006, 2007; Liu and Nazaroff 2003; Mosley et al. 2001). The effects of impaction and gravitation settling on large particles and Brownian diffusion on UFPs are similar to those in real buildings. Roughness appears to be relatively important for smaller particles because impaction and gravity begin to control deposition of larger particles in cracks. The roughness elements may be immersed within the particle concentration boundary layer for UFPs but extend well into the boundary layer for the case of 0.1–0.4 μm particles leading to a greater role in enhancing deposition for 0.1–0.4 μm particles than for UFPs (Liu and Nazaroff 2003). Based on the results of L-shape crack, Brownian diffusion is found to be the dominant particle deposition mechanism for a vertical crack while the gravitational sedimentation is the dominant deposition mechanism for a horizontal crack (Jeng et al. 2007). The penetration factors measured in laboratories are close to those measured in real buildings (Fig. 3).

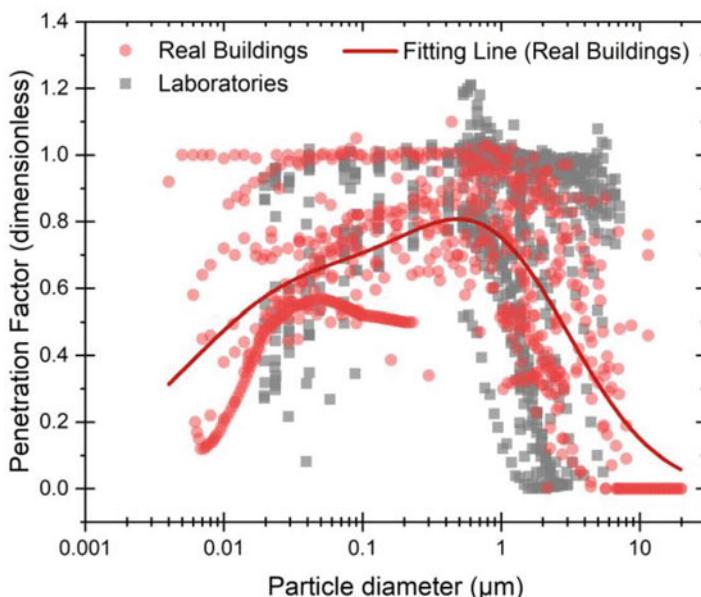

Fig. 3 Comparison of penetration factors measured in real buildings and laboratories

Modeling

Liu and Nazaroff (2001) developed a mathematical model to estimate the particle penetration factor through building cracks by considering the effects of three major particle deposition mechanisms: Brownian diffusion, gravitational settling, and impaction. Super-micron and ultrafine particles are significantly removed due to gravitational settling and Brownian diffusion, respectively. The penetration of accumulation-mode particles is also predicted to be approximately one when the crack height is larger than 0.25 mm, consistent with measurement results. The overall penetration is found to be influenced more by the largest cracks than by the smallest cracks in a building since airflow rates increase strongly as crack height increases. Especially, the modeled size-dependent penetration factors by Liu and Nazaroff (2001) when the crack is 1 mm high by 10 cm long at a fixed pressure drop of 4 Pa were summarized by Nazaroff (2004) and applied to further studies. For example, Ji and Zhao (2015) measured the size-dependent outdoor particle concentration and calculated the penetration factors of PM_{2.5} based on these modeled results and 69 groups of measured concentrations. The penetration factors of PM_{2.5} were found to be in the range of 0.90–0.97 with the mean value of 0.95.

Chen et al. (2012b) developed a methodology for predicting the penetration factor for actual engineering application. The geometries of the cracks in a building can be estimated according to the American Society of Heating, Refrigeration, American Society of Heating, Refrigeration, Air-Conditioning Engineers (ASHRAE) Handbook (ASHRAE 2001). The penetration of horizontal cracks can be calculated considering three major particle deposition mechanisms mentioned above, while the gravitational settling of particles in vertical cracks is negligible. The air change rate and effective air leakage area were found to be important factors influencing particle penetration through cracks in real buildings. The effect of inertial impaction cannot be neglected for coarse particles, especially when the air change rates are relatively large ($\sim 1 \text{ h}^{-1}$). However, the effect of the ratio of horizontal to vertical crack areas is negligible with such large air change rate.

Tian et al. (2009) and Lai et al. (2012) developed mathematical models to calculate particle penetration factor incorporating the influence of surface roughness. The penetration factor was found to be insensitive to roughness scales. The penetration factors through rough cracks are smaller than smooth crack at low pressure.

Zhao et al. (2010) developed and compared three models to model particle penetration factor through a single straight crack, including a mathematical model, an Eulerian model, and a Lagrangian model. It was found that the mathematical and the Eulerian model predicted the penetration factor reasonably while the Eulerian model showed the best agreement (Fig. 4). The Lagrangian model are less satisfied for UFPs and Chen and Zhao (2017) improved the accuracy by modifying the Brownian force in the model (Fig. 4).

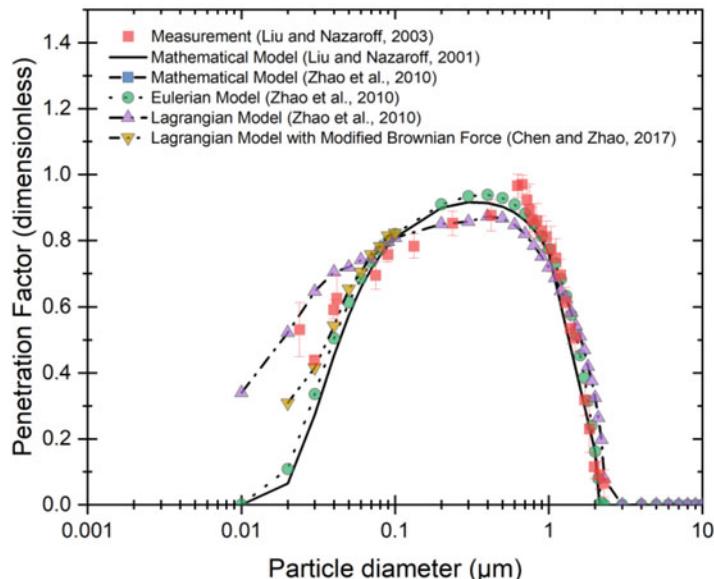

Fig. 4 Comparison of model predictions with experimental data for aluminum cracks when the crack is 0.25 mm high by 4.3 cm long at a fixed pressure drop of 4 Pa (Adapted from Chen and Zhao (2011), Figure 9, with permission from Elsevier)

Infiltration Factor

Measurement Methods

Regression Approach

After measuring the indoor and outdoor particle concentrations, the infiltration factor can be estimated the slope in Eq. (17), another form of Eq. (6):

$$C_{\text{in}} = F_{\text{inf}} C_{\text{out}} + C_{\text{is}} \equiv \text{slope} \times C_{\text{out}} + \text{intercept} \quad (17)$$

This approach was used in many previous studies (Barraza et al. 2014; Hoek et al. 2008; Hu et al. 2018; Lachenmyer and Hidy 2000; Landis et al. 2001; Meng et al. 2005, 2007; Ott et al. 2000; Rivas et al. 2015; Wallace et al. 2003; Williams et al. 2003; Wu et al. 2012).

According to section “[Methods in Real Buildings](#)”, the penetration factor and deposition rate can be determined by the nonlinear regression of Eq. (13) or (14). Then, the infiltration factor can be calculated based on their results as following (Allen et al. 2003; Chatoutsidou et al. 2015; Kearney et al. 2011; Rim et al. 2010, 2013):

$$F_{inf} = \frac{aP}{a + k_d} \quad (18)$$

The Eq. (14) can be expressed as the function of the changes of indoor concentrations in the indoor and outdoor concentrations as following:

$$\begin{aligned} \Delta C_{in}(d_p, t + \Delta t) &= \left[e^{-(a+k_d)\Delta t} - 1 \right] C_{in}(d_p, t) \\ &\quad + F_{inf} \left[1 - e^{-(a+k_d)\Delta t} \right] C_{out}(d_p, t) \\ &\equiv slope_1 C_{in}(d_p, t) + slope_2 C_{out}(d_p, t) \end{aligned} \quad (19)$$

The $slope_1$ and $slope_2$ can be solved using a linear regression forcing the intercept to zero. Thus, the infiltration factor can be calculated based on the regression results (Allen et al. 2003; Polidori et al. 2007).

Equilibrium Approach

The infiltration factors were calculated as the ratio of indoor to outdoor concentration with the absence of indoor sources, which were always measured during the overnight (Bhangar et al. 2011; Chen et al. 2011; Kearney et al. 2011, 2014; Long et al. 2001; MacNeill et al. 2012; Mullen et al. 2011a, b; Polidori et al. 2007; Rim et al. 2010, 2013; Sarnat et al. 2006; Wallace and Ott 2011; Wang et al. 2010; Zauli-Sajani et al. 2018; Zhao and Stephens 2017).

Tracer Element Approach

The tracer element should be selected based on the assumptions that (1) The tracer element must be present in both indoor and outdoor particle in sufficient quantities; (2) The tracer element should be primarily of outdoor origin, in other words, the indoor sources of the tracer element should be insignificant and the ratio of the indoor to outdoor tracer element concentrations shouldn't be larger than one; (3) The physical behaviors of the tracer element should be similar to those of outdoor particles, including deposition, penetration, and chemical stability (Ji et al. 2018; Long and Sarnat 2004; Sarnat et al. 2002).

Sulfur was always used as a tracer of outdoor PM_{2.5} (Allen et al. 2003; Chen et al. 2017, 2019; Cohen et al. 2009; Li et al. 2019; Meng et al. 2005; Miller et al. 2019; Sarnat et al. 2002; Wallace and Williams 2005; Zhou et al. 2018). Long and Sarnat (2004) found that nickel can serve as a strong tracer for total outdoor PM_{2.5}, especially particles with diameter of 0.04–0.5 μm, in the residences in the United State. However, Ji et al. (2018) found that there were indoor sources of sulfur in Chinese residences related to the sulfur-containing substances added to Chinese natural gas, and the indoor and outdoor concentrations of nickel were below the detection limit. Instead, iron is found to be more suitable as a tracer for outdoor PM_{2.5} in Beijing, China. The iron tracer approach was applied to the estimation of infiltration factor in Beijing to separate PM_{2.5} of outdoor and indoor origin (Chi et al. 2019). Wang et al. (2020b) confirmed the more stable effects of iron than sulfur on tracking outdoor PM_{2.5} in temporal and spatial scales in Nanjing, China.

The infiltration factors of PM_{2.5} can be calculated in the previous studies mentioned above as following:

$$F_{\text{inf}} = \frac{C_{\text{in,tracer}}}{C_{\text{out,tracer}}} \quad (20)$$

where $C_{\text{in,tracer}}$ and $C_{\text{out,tracer}}$ are the indoor and outdoor concentrations of the tracer elements in PM_{2.5}, respectively.

Hanninen et al. (2004) modified Eq. (20) and calculated the infiltration factors of PM_{2.5} as following:

$$F_{\text{inf}} = \frac{\text{slope}_{PM2.5}}{\text{slope}_{\text{tracer}}} \frac{C_{\text{in,tracer}}}{C_{\text{out,tracer}}} \quad (21)$$

where $\text{slope}_{PM2.5}$ and $\text{slope}_{\text{tracer}}$ are the indoor-outdoor regression slopes for PM_{2.5} and the tracer elements, respectively. The ratios of $\text{slope}_{PM2.5}$ to $\text{slope}_{\text{tracer}}$ are roughly equal to 1, with the range of 0.79 to 0.86.

Modeling Methods

Long-term or largescale measurements are challenging and costly to conduct. Thus, the infiltration factors can be predicted based on the mechanism shown in Eq. (18) considering the influence of the ventilation, particle penetration and deposition.

For instance, Chen et al. (2012a) calculated the seasonal infiltration factors of PM₁₀ for 83 cities in the United States and assessed their influence on the relationship between PM₁₀ and short-term mortality. El Orch et al. (2014) predicted statistical distribution of long-term size-resolved infiltration factors for typical single-family residential building stock in the United States. Shi et al. (2017) developed a Monte Carlo simulation model to simulated the probabilistic distributions of the PM_{2.5} and PM₁₀ infiltration factors for residences in Beijing, China. Xiang et al. (2019) estimated the infiltration factors of PM_{2.5} for 339 cities from 31 provinces in mainland China and Hu et al. (2020) comprehensively estimated the distribution of infiltration factors of PM_{2.5} and PM₁₀ across seasons, genders, and ages in 333 Chinese cities from 31 provinces.

Data Analysis

As Fig. 5 shown, the infiltration factors changed with particle diameters according to the measured results (Abt et al. 2000; Bennett and Koutrakis 2006; Chatoutsidou et al. 2015; Chen et al. 2011; Hu et al. 2018; Hussein et al. 2004, 2006; Lazaridis et al. 2017; Long et al. 2001; McAuley et al. 2010; Rim et al. 2010, 2013; Sarnat et al. 2006; Talbot et al. 2016; Wallace and Ott 2011; Zauli-Sajani et al. 2018; Zhao and Stephens 2017; Zhao et al. 2020; Zhu et al. 2005). Compared with penetration factor, the ranges of infiltration factors are larger. The infiltration factors are ranged from 0.20 to 1 with the mean value of 0.66 for accumulation-mode particles and

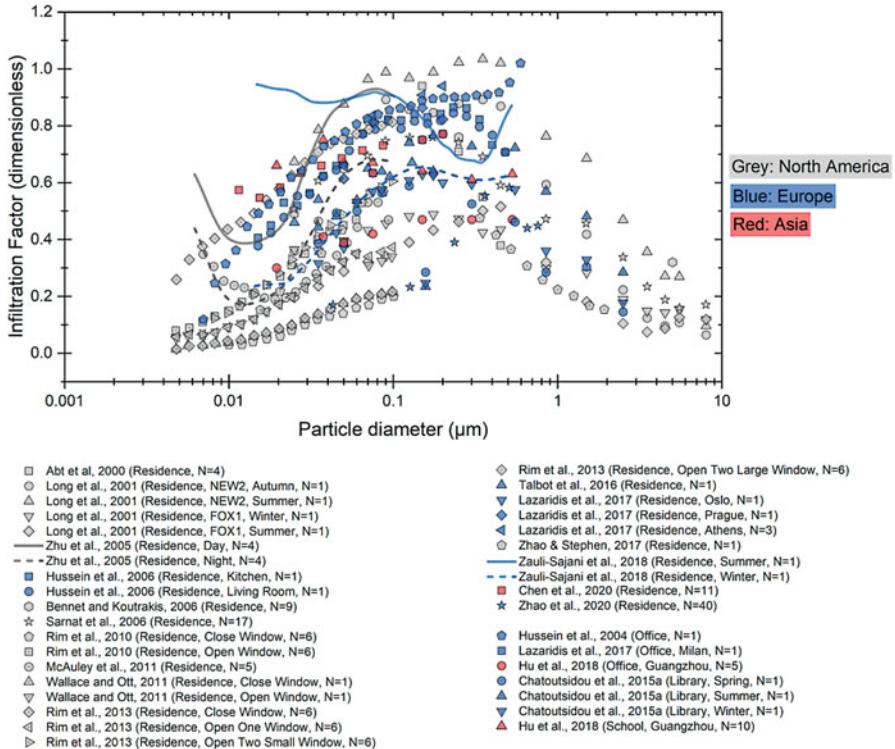

Fig. 5 Infiltration factors measured in residences and other buildings (including office, library and school)

standard deviation of 0.22. The infiltration factors of smaller and larger particles are less than accumulation-mode particles, which ranged from 0.40 ± 0.25 to 0.23 ± 0.14 , respectively. It's caused by the relatively high penetration and low deposition of accumulation-mode particles. Combining the effects of particle size distributions, the infiltration factors of UFPs, $\text{PM}_{2.5}$ and PM_{10} are shown in Fig. 6, which are 0.45 ± 0.19 (0.15 to 0.80), 0.51 ± 0.16 (0.16 to 0.78), and 0.40 ± 0.19 (0.17 to 0.70), respectively.

The large variation of infiltration factors is determined by air change rates (Zhao and Stephens 2017), window opening behaviors (Meier et al. 2015; Mullen et al. 2011b; Rim et al. 2010, 2013; Wallace and Ott 2011), ventilation systems (Bhangar et al. 2011; Meng et al. 2007, 2009; Mullen et al. 2011a; Quang et al. 2013; Saraga et al. 2017; Zhang and Zhu 2012), etc. Zhao and Stephens (2017) found that infiltration factors of UFPs generally increased with air change rate, but the infiltration factors for $\text{PM}_{2.5}$ were mostly influenced by deposition loss rate constants and/or envelope penetration factors.

The infiltration factors of UFPs are about 0.63 under window opening conditions and 0.32 under window closed conditions according to the measurements by Meier

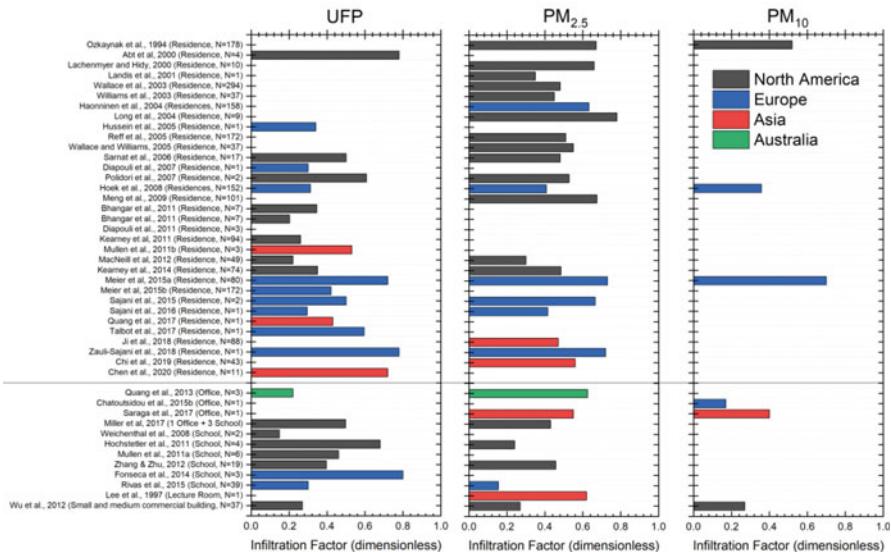

Fig. 6 Infiltration factors of UFP, PM_{2.5} and PM₁₀ measured in residences and other buildings (including office, school, lecture room and commercial building)

et al. (2015) and Mullen et al. (2011b). The infiltration factors of UFPs and PM_{2.5}, PM₁₀ are 0.26, 0.71 and 0.70 with mechanical ventilation systems on, respectively, and 0.29, 0.53 and 0.10 with mechanical ventilation systems off (Bhangar et al. 2011; Meng et al. 2009; Mullen et al. 2011a; Quang et al. 2013; Saraga et al. 2017). Zhang and Zhu (2012) compared five kinds of ventilation systems (old single duct system, new single duct system with one filter, new single duct system with two filters, window-mounted AC/fan and split system) and observed that the infiltration factors were lowest for UFPs (0.12) using old single duct system and for PM_{2.5} (0.35) using new single duct system with two filter, and largest for UFPs (0.66) and PM_{2.5} (0.59) using window-mounted AC/fan.

Different from PM_{2.5} and PM₁₀, the loss rates due to coagulation effects influenced the infiltration factors of UFPs (Chen et al. 2011; Franck et al. 2006; Vu et al. 2017). Chen et al. (2020) found the impacts of the factors on UFP infiltration factors exhibited the following ranking: a (air change rate) > A/V (ratio of the total deposition area to the room volume) > C_{out} (outdoor UFP concentration) > μ (geometric mean diameter of outdoor UFPs) > σ (geometric standard deviation of outdoor UFP diameters) > indoor temperature > indoor relative humidity > indoor ozone concentration. The effects of outdoor UFP concentrations due to coagulation were considerable. The infiltration factors of UFPs could be calculated as:

$$F_{inf} = 1.92 + 0.184 \ln a + 0.00178\mu - 0.0688\sigma - 0.273(A/V) - 0.0618 \ln C_{out} \quad (22)$$

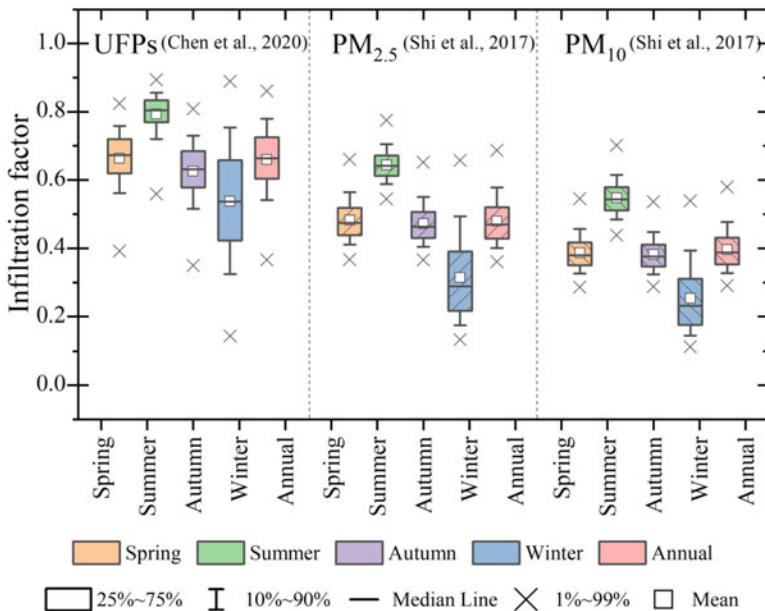

Fig. 7 The box-plots of seasonally-averaged and annually-averaged F_{inf} for residences in Beijing, China (Adapted from Chen et al. (2020a), Figure 3, with permission from Elsevier)

The simulated results are shown in Fig. 7 based on Eq. (22) for UFPs and Eq. (18) for $\text{PM}_{2.5}$ and PM_{10} using a Monte Carlo simulation model (Chen et al. 2011; Shi et al. 2017). The mean values of season-averaged infiltration factors of UFPs (annual-averaged value: 0.66 ± 0.10) were larger than those of $\text{PM}_{2.5}$ (annual-averaged value: 0.48 ± 0.07) and PM_{10} (annual-averaged value: 0.40 ± 0.06) in Beijing, China, indicating that residents would be exposed to higher fractions of outdoor-originated UFPs than $\text{PM}_{2.5}$ and PM_{10} . The simulated results of $\text{PM}_{2.5}$ showed good agreements with the measured results using tracer elements in Beijing (mean value: 0.49) by Ji et al. (2018), indicating the reasonability of results. The results using a Monte Carlo simulation model by Hu et al. (2020) showed that the annual average infiltration factors were higher in southern than in northern China. Hainan province had the highest infiltration factors, whereas Jilin had the lowest (Jilin–Hainan, annual average infiltration factor: PM_{10} , 0.19–0.45; $\text{PM}_{2.5}$, 0.49–0.76).

Conclusion

Measuring penetration factors or infiltration factors according to regression models is simple but the regression would be poor due to high variance of temporal contribution from specific indoor particle sources. Numerous studies obtained the penetration factors based on measured equilibrium concentrations and other known parameters, and obtained the infiltration factors directly. Such measurements always

require enough long time to reach the equilibrium status. The penetration factors can also be obtained by employing least-squares estimation to simulate indoor concentrations or their change rates. The infiltration factors can be also obtained according to tracer element approach. The tracer element is mainly from outdoor sources and shows similar physical behaviors as the focused particles. The ratio of indoor to outdoor tracer element concentrations is equal to the infiltration factor.

The penetration factor of UFPs, PM_{2.5} and PM₁₀ is in the range of 0.59–0.78, 0.72–1, and 0.69–0.86, respectively. The penetration factors are 0.78 ± 0.17 for accumulation-mode particles (0.1–1 μm diameter). They decreased due to Brownian diffusion for smaller particles, or due to stronger gravitational settling and impaction for larger particles. Penetration factors are determined by particle size, pressure differences, geometry and surface roughness of cracks, etc.

The infiltration factors of PM_{2.5} are approximately 0.50 according to measured and simulated results, which would be lower than ultrafine particles and higher than PM₁₀ under the same conditions. Infiltration factors are also influenced by air change rates, window opening behaviors, ventilation systems, etc. Additionally, the loss rates due to coagulation effects influenced the infiltration factors of UFPs, which is different from PM_{2.5} and PM₁₀.

Abstract

Deposition of particles present in the air environment of enclosures and transported by its motion is a process that is important for the removal of particles from the enclosure volume. It can serve in cleaning the indoor air from unwanted impurities or, to the contrary, it can bring pollution to the surface that is the target of the deposition. The wall deposition (plateout), in particular, is the deposition applied to the surfaces surrounding the enclosure, a volume of a room, vessel, chamber, reactor, mine, or similar space. This process is at the end of the aerosol particle transport. It usually is a consequence of the interaction of the turbulent bulk motion with the diffusion near the wall and the wall attachment via van der Waals forces. Plateout has been widely studied experimentally and analytically using a variety of approaches and with many achievements. The aerosol chamber with an accurately controlled condensation nuclei, air flow and thermal properties together with a radioactive aerosol belong to the most advanced tools in deposition research. Despite advances in deposition research, the details of this process are not yet fully understood. This chapter aims to survey the achievements and formulate challenges motivating further research into aerosol particle deposition.

Wall deposition · Plateout · Enclosed spaces · Fractal boundary · Turbulence

Introduction

Within the complexity of aerosol transport, deposition on surfaces is one of terminal phenomena contributing to the removal of aerosol particles from the bulk volume. It occurs whenever the aerosol particles lose their movement inside the volume because of a lack of forces exerted by the carrying gas phase. According to the literature, it may be due to lack of momentum in the proximity of a stagnant layer, due to gravitational forces, electrical field, thermal effects, etc. (see Fuchs 1964; Friedlander 2000; Seinfeld and Pandis 2016; Williams and Loyalka 1991 and others). The obvious importance of this phenomenon is underlined by the environmental concerns with industry, e.g., in mining, dusty fabrication procedures, nuclear industry, with the environment of urban and traffic areas as well as indoor building ventilation issues, air inhalation processes, or by the scientific applications such as cloud chambers in nuclear particle research.

Particle deposition in most situations is mostly a consequence of the interaction of the air flow with turbulent features with the Brownian diffusion. Both processes, being stochastic by their intrinsic nature, can be measured and described by deterministic models of fluid dynamics. However, bridging the experiments to models creates the need for using constitutive relations with unknown factors to be determined by processing the experimental data. Improvements in this area is subject of current research.

Wall deposition (plateout) is a removal process of particles to surfaces (of walls, ceilings and floors of rooms, vessels, propeller blades, and reactors). It differs from plateout in pipes, where there is a prevailing flow in one direction. Overall agreement

is that it depends on eddy diffusion and on the Brownian diffusion of the particles. The bottleneck is the diffusion through the stagnant layer on surfaces. The stagnant layer's thickness depends on the turbulence nature. The higher the turbulence, the thinner the layer the particles have to diffuse through, and therefore the higher the plateout. Brownian diffusion is dependent on the size of aerosols. Literature indicates various dependence of the eddy diffusivity on the power of distance from the wall allowing for the adjustment of the power exponent by the experiment but leaving the dimensionality of such modification mostly unresolved. This issue is addressed in this chapter as well.

The conventional treatment of wall deposition assumes that once particle hits the surface it sticks. However, it has been shown that VVOC, VOC, and SVOC (high/semi volatile compounds) can evaporate/sublimate from surfaces, and react with reactive oxygen species, or radiation to form new particles, starting from monomers, dimers, etc. It voids the assumption there is no source from the surfaces. Experimentally, it is very difficult to observe – unless one has a chamber that can attain an initial aerosol-free atmosphere.

Particle plateout can be studied using both inert and radioactive aerosols. The advantage of the latter is many orders of magnitude greater sensitivity. If radioactive aerosols from radon or thoron are used in an aerosol-free chamber, one gets monodispersed $\sim 1 \text{ nm}$ size aerosols. Unfortunately, very few people are taking advantage of this technique. What would be even more advantageous is to use standard radioactive isotope labeling techniques.

Recently, approaches based in the analytical treatment of simplified models of turbulent aerosol deposition were complemented by results of detailed numerical solution of equations of transport and fluid dynamics. It is shown later in this chapter that these results mutually agree and reproduce the experimental data. Such a robustness in modeling particle deposition allows consideration of even extreme situations such as experimental configurations when the air is not put into motion by propeller and its velocity becomes unmeasurable. On the other hand, intrinsic thermal oscillations and fluctuations give reason to believe that state of air still exhibits nature of turbulence.

Addressing these aspects of the aerosol transport toward surfaces, the chapter contains a summary of conservation laws governing the transport with an emphasis on the bulk-interface interaction. Due to the influence of the turbulent nature of the air flow and turbulent energy dissipation in enclosures, the corresponding models are complex. Simplifications that are useful for understanding the reported experimental results are summarized. This chapter also addresses issues arising in the research of aerosol wall deposition related both to the fundamental understanding of the processes involved as well as to the technical details of the underlying experimental work.

Bulk Airflow and Interaction with Surfaces

Essentially, deposition is a phenomenon of mass transfer from the bulk fluid consisting of the main carrier phase (air) and at least one dilute species (aerosol particles) in it. Respecting the experimental framework through which the models of aerosol

dynamics are validated, deposition is studied at medium scales (~ 1 m). Therefore, the aerosol as a collection of individual particles can be studied as part of continuum and represented by continuum quantities such as concentration, velocity, and temperature, and by size distribution if needed. Correspondingly, the dynamic model of deposition in a limited volume at least partially surrounded by solid boundary (wall) can be obtained by exploring the conservation laws for mass, momentum, and energy.

Assume that the indoor particle transport occurs in a spatial volume Ω over the time interval $(0, T)$. Respecting the purpose of the model, behavior of the indoor aerosol particles in bulk and on surfaces, and their volumic and mass contents and nature of interactions, we formulate the conservation laws of mass, momentum, and energy for the carrying main gaseous phase, aerosol particles, and additional passive components such as water vapor and condensation nuclei. We proceed in accordance with Slattery (1999), Kolev (2011), Gidaspow (1994), or Bauer et al. (2015) and Beneš et al. (2021).

The **mass balance** considers the air as the main gaseous component with density ρ_g [$\text{kg} \cdot \text{m}^{-3}$], \mathbf{v}_g the bulk velocity [$\text{m} \cdot \text{s}^{-1}$], and the volume fraction ε_g [1]. The aerosol particles essentially are condensed-phase small objects with the density ρ_a [$\text{kg} \cdot \text{m}^{-3}$], \mathbf{v}_a their bulk (macroscopic) velocity [$\text{m} \cdot \text{s}^{-1}$], and the volume fraction ε_a [1]. The solid condensation particles have the density ρ_s [$\text{kg} \cdot \text{m}^{-3}$], \mathbf{v}_s the bulk velocity [$\text{m} \cdot \text{s}^{-1}$], and the volume fraction ε_s [1]. The water vapor mass fraction is Y_w [1]. If no other phase or component is considered, the mass fraction filling the volume is

$$\varepsilon_g + \varepsilon_a + \varepsilon_s = 1. \quad (1)$$

Then the mass balances hold for gaseous phase without any volumetric source

$$\frac{\partial(\varepsilon_g \rho_g)}{\partial t} + \operatorname{div}(\varepsilon_g \rho_g \mathbf{v}_g) = 0, \quad (2)$$

the aerosol particles with the growth term $Q_a = Q_a(\varepsilon_a, \varepsilon_s, Y_w)$

$$\frac{\partial(\varepsilon_a \rho_a)}{\partial t} + \operatorname{div}(\varepsilon_a \rho_a \mathbf{v}_a) = Q_a(\varepsilon_a, \varepsilon_s, Y_w), \quad (3)$$

for the water vapor as a passive component of gas phase with the sink term

$$\frac{\partial(\varepsilon_g \rho_g Y_w)}{\partial t} + \operatorname{div}(\varepsilon_g \rho_g Y_w \mathbf{v}_g) = -Q_a(\varepsilon_g, \varepsilon_s, Y_w), \quad (4)$$

and for condensation nuclei with the source term $Q_s = Q_s(t, x)$

$$\frac{\partial(\varepsilon_s \rho_s)}{\partial t} + \operatorname{div}(\varepsilon_s \rho_s \mathbf{v}_s) = Q_s(t, x). \quad (5)$$

In what follows, we assume the proportion of particular components of the indoor particle transport, the solid and condensed phase densities are constant ($\rho_a = \text{const.}$, $\rho_s = \text{const.}$), the solid phase fraction negligible ($\varepsilon_g + \varepsilon_a \approx 1$), and the solid phase fully advected by the air flow ($\mathbf{v}_s \approx \mathbf{v}_g$). The mass balances then simplify to

$$\frac{\partial(\varepsilon_g \rho_g)}{\partial t} + \operatorname{div}(\varepsilon_g \rho_g \mathbf{v}_g) = 0, \quad (6)$$

$$\frac{\partial(\varepsilon_a)}{\partial t} + \operatorname{div}(\varepsilon_a \mathbf{v}_a) = \frac{1}{\rho_a} Q_a(\varepsilon_a, \varepsilon_s, Y_w), \quad (7)$$

$$\frac{\partial(\varepsilon_g \rho_g Y_w)}{\partial t} + \operatorname{div}(\varepsilon_g \rho_g Y_w \mathbf{v}_g) = -Q_a(\varepsilon_g, \varepsilon_s, Y_w), \quad (8)$$

and the condensation nuclei are decoupled having the gas velocity

$$\frac{\partial(\varepsilon_s)}{\partial t} + \operatorname{div}(\varepsilon_s \mathbf{v}_g) = \frac{1}{\rho_s} Q_s(t, x). \quad (9)$$

Within this framework, we formulate the **momentum conservation laws** for the gas phase

$$\frac{\partial(\varepsilon_g \rho_g \mathbf{v}_g)}{\partial t} + \operatorname{div}(\varepsilon_g \rho_g \mathbf{v}_g \mathbf{v}_g) = -\nabla P_g + \nabla \cdot (\varepsilon_g \mathbf{T}_g) + \beta(\mathbf{v}_a - \mathbf{v}_g) + \rho_g \mathbf{g}, \quad (10)$$

and for the aerosol particles

$$\begin{aligned} \frac{\partial(\varepsilon_a \rho_a \mathbf{v}_a)}{\partial t} + \operatorname{div}(\varepsilon_a \rho_a \mathbf{v}_a \mathbf{v}_a) &= -\nabla P_a + \nabla \cdot (\varepsilon_a \mathbf{T}_a) + \beta(\mathbf{v}_g - \mathbf{v}_a) \\ &\quad + (\rho_a - \rho_g) \varepsilon_a \mathbf{g}, \end{aligned} \quad (11)$$

where P_g , P_a are the pressures of gas and aerosol particles as phases, \mathbf{T}_g , \mathbf{T}_a the stress tensors of the gas and particles, and P_g is the drag coefficient between the gas and the particles. Due to nature of particles, we may further assume that the pressures are balanced through the interface conditions and there is no stress or friction between the aerosol particles themselves ($\mathbf{T}_a = 0$). The momentum balances then become

$$\frac{\partial(\varepsilon_g \rho_g \mathbf{v}_g)}{\partial t} + \operatorname{div}(\varepsilon_g \rho_g \mathbf{v}_g \mathbf{v}_g) = -\nabla P_g + \nabla \cdot (\varepsilon_g \mathbf{T}_g) + \beta(\mathbf{v}_a - \mathbf{v}_g) + \rho_g \mathbf{g}, \quad (12)$$

$$\frac{\partial(\varepsilon_a \rho_a \mathbf{v}_a)}{\partial t} + \operatorname{div}(\varepsilon_a \rho_a \mathbf{v}_a \mathbf{v}_a) = -\nabla P_g + \beta(\mathbf{v}_g - \mathbf{v}_a) + (\rho_a - \rho_g) \varepsilon_a \mathbf{g}. \quad (13)$$

The stress tensor for air as a Newtonian fluid is expressed as

$$\begin{aligned} \mathbf{T}_g &= -\lambda \operatorname{div} \mathbf{v} \mathbf{I} + 2\mu \mathbf{D}, \\ \mathbf{D} &= \frac{1}{2} \left(\nabla \mathbf{v} + (\nabla \mathbf{v})^T \right), \end{aligned} \quad (14)$$

where μ is the shear viscosity, λ is the bulk viscosity, and \mathbf{D} is the rate-of-deformation tensor.

The **energy conservation laws** in terms of internal energies U_g of the gas phase and U_a of the particles are

$$\frac{\partial(\varepsilon_g \rho_g U_g)}{\partial t} + \operatorname{div}(\varepsilon_g \rho_g U_g \mathbf{v}_g) = -P_g \nabla \cdot \mathbf{v}_g + \varepsilon_g \nabla \cdot (\mathbf{q}_g) + \rho_g \mathbf{g} \cdot \mathbf{v}_g, \quad (15)$$

$$\frac{\partial(\varepsilon_a \rho_a U_a)}{\partial t} + \operatorname{div}(\varepsilon_a \rho_a U_a \mathbf{v}_a) = -P_g \nabla \cdot \mathbf{v}_a + \varepsilon_a \nabla \cdot (\mathbf{q}_a) + (\rho_a - \rho_g) \mathbf{g} \cdot \mathbf{v}_a, \quad (16)$$

where \mathbf{q}_g , \mathbf{q}_a are the energy fluxes for the gas and the particles.

The system of eqs. (1–16) is closed by the state equation for the gas pressure,

$$P_g = P_g(\varepsilon_g, \varepsilon_a, \mathbf{v}_g, \mathbf{v}_a, \rho_g, \rho_a, U_g, U_a, Y_w), \quad (17)$$

by the initial conditions and the boundary conditions, among which, at the enclosure walls, the no-slip conditions for velocities

$$\mathbf{v}_g|_{\text{wall}} = 0, \mathbf{v}_a|_{\text{wall}} = 0 \quad (18)$$

and the zero volume fractions are set

$$\varepsilon_g|_{\text{wall}} = 0, \varepsilon_a|_{\text{wall}} = 0, \quad (19)$$

The inlet conditions (compare with Fig. 1) are crucial as they deliver both energy and mass into the enclosure.

$$\mathbf{v}_g|_{\text{inlet}} = \mathbf{v}_{\text{in}}, \varepsilon_g|_{\text{inlet}} = \varepsilon_{g,\text{in}}, \varepsilon_a|_{\text{inlet}} = \varepsilon_{a,\text{in}} \quad (20)$$

which eventually are dispersed into the volume by friction and lost by wall deposition.

Once this system of equations is resolved or approximated, the quantity of interest describing the wall loss of aerosol particles by the deposition is described by the **deposition rate** defined as

$$\beta_a = \frac{\int_{\text{wall}} \mathbf{j}_a \cdot \mathbf{n}_{\text{wall}}(x) dS}{\int_{\Omega} dx}, \quad (21)$$

where \mathbf{j}_a is the mass flux of the aerosol particles and \mathbf{n}_{wall} is the outward normal vector to the wall – the boundary of the domain Ω .

The deposition rate (Eq. 21) can be used to understand the process of removing aerosol particles from the entire volume of the enclosure described as

$$\frac{dN}{dt} = -\beta_a N, \quad (22)$$

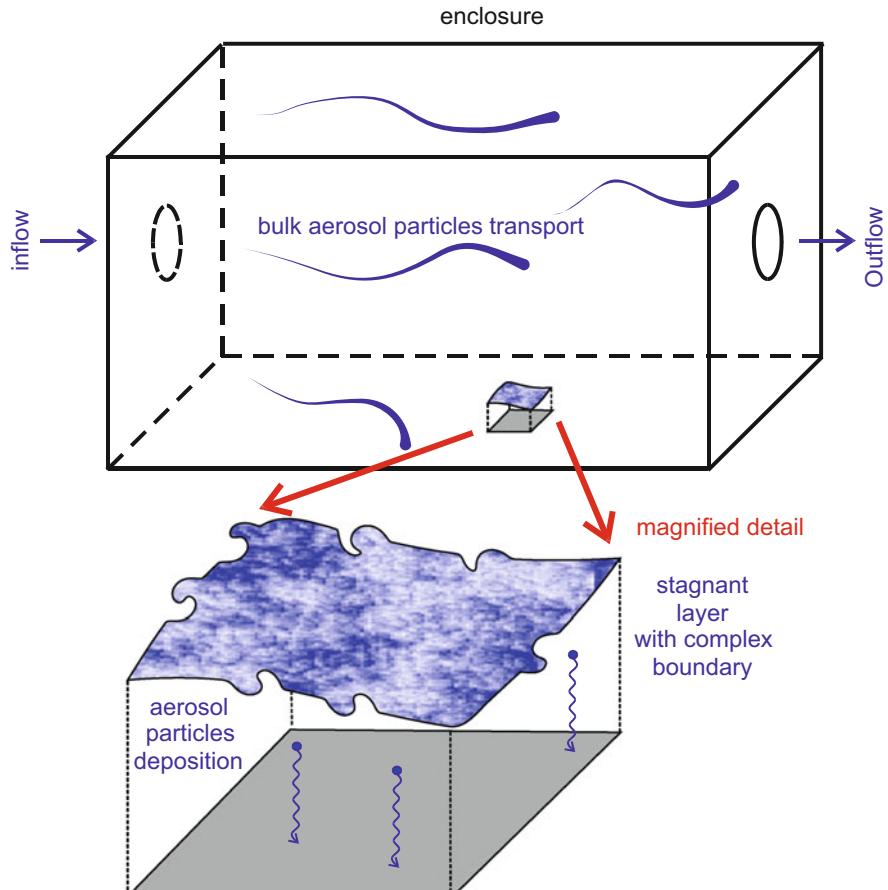

Fig. 1 Flow and transport of aerosol particles in an enclosure

where $N = N(t)$ is the number of aerosol particles in the enclosure, or its density, provided there is no additional source of particles in the volume.

We may further assume that the volume fraction of the aerosol particles is negligible ($\varepsilon_a \approx 0$), and therefore has no momentum contribution to the force balances. We rather work with the aerosol mass concentration c_a and replace corresponding quantities in Eq. (7) which makes the right side of the equation equal to Q_a (c_a, Y_w).

In the case that the aerosol bulk velocity is modified by the volumetric Brownian diffusion flux, the velocity is represented by:

$$\mathbf{v}_a = \mathbf{v}_g - \frac{1}{c_a} D_B \nabla c_a, \quad (23)$$

where $D_B = D_B(d_p)$ is the Brownian diffusion coefficient that depends on the particle diameter d_p . Eq. (7) becomes the advection-diffusion equation for the aerosol particle concentration

$$\frac{\partial c_a}{\partial t} + \operatorname{div}(c_a \mathbf{v}_g) = \nabla \cdot (D_B \nabla c_a) + Q_a(c_a, Y_w). \quad (24)$$

At the thermal equilibrium when the internal energies U_g , U_a do not change and no condensation or evaporation occurs ($Q_a(c_a, Y_w) = 0$), we have the following system of equations:

$$\frac{\partial \rho_g}{\partial t} + \operatorname{div}(\rho_g \mathbf{v}_g) = 0, \quad (25)$$

$$\frac{\partial(\rho_g \mathbf{v}_g)}{\partial t} + \operatorname{div}(\rho_g \mathbf{v}_g \mathbf{v}_g) = -\nabla P_g + \nabla \cdot \mathbf{T}_g + \rho_g \mathbf{g}, \quad (26)$$

$$\frac{\partial c_a}{\partial t} + \operatorname{div}(c_a \mathbf{v}_g) = \nabla \cdot (D_B \nabla c_a), \quad (27)$$

$$P_g = P_g(c_a, \mathbf{v}_g, \rho_g). \quad (28)$$

These equations are solved incorporating the boundary and initial conditions.

As indicated in Fig. 2, nature of such a convective diffusion process leads to stratification of the volume. The aerosol is being transported through the bulk volume inside the enclosure where shearless turbulence prevails. At the diffusion (laminar or stagnant) boundary layer close to the wall (boundary) of the enclosure, the Brownian diffusion competes with the eddy diffusion, prevails at the very proximity of surface and brings the particles to the wall.

Turbulent Nature of Indoor Air Flow

The motion of air and particles in an enclosure under usual conditions corresponding to living or commercial work spaces typically have moderate velocities and temperatures unlike the flow under industrial or transport conditions in turbines or around airplanes. However, when evaluating the Reynolds number for such flows, it might rise to values qualifying as being in the turbulent regime (see, e.g., Corner and Pendelbury 1951; Holub 1984; Holub et al. 1988; Cheng 1997, and others). Additionally, experimental evidence accompanying measurement of wall deposition in experimental chambers (Drouillard et al. 1984; Holub et al. 1991; Holub and Drouillard 1992; Nomura et al. 1997; Lahti-de Bruyne 1997; Cheng 1997; Okuyama et al. 1986; Linden et al. 2007; El Hamdani et al. 2008; Mishra and Mayya 2008; Mishra et al. 2009; De-Ling 2009) supports the understanding of this phenomenon as the one influenced by chaotic irregular motion of air. Therefore, it is useful to address aspects of turbulence description and describe quantities entering the evaluation of the deposition rate (Eq. 21)).

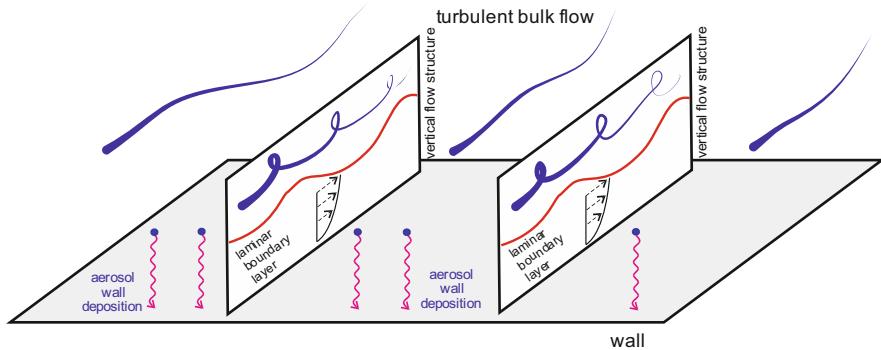

Fig. 2 Stratification of the deposition process

The computational complexity of the governing equations introduced in “Bulk Airflow and Interaction with Surfaces” section can be handled by accurate numerical methods used in the direct numerical simulation of the turbulent flow using contemporary high-performance computational tools (compare with, e.g., Parker et al. 2010, Liu et al. 2019), or a simplification of the model can be derived to obtain easily solvable model equations. The latter path has been explored in the past by variety of mathematical tools as described in Landau and Lifschitz (1959), Hinze (1975), Schlichting (1979), Bradshaw (1976), Monin and Yaglom (1975), Nelkin (1992), and summarized in modern textbooks (e.g., Pope 2000).

The derivation of the equations approximating turbulent flow at coarser spatial and temporal reference frames is based on averaging. Each quantity is decomposed to its mean value and associated fluctuations, e.g., gas density, gas volume fraction, gas velocity, and gas energy are expressed as

$$\begin{aligned} \varepsilon_g &= \bar{\varepsilon}_g + \varepsilon'_g, \\ \rho_g &= \bar{\rho}_g + \rho'_g, \\ \mathbf{v}_g &= \bar{\mathbf{v}}_g + \mathbf{v}'_g, \\ U_g &= \bar{U}_g + U'_g. \end{aligned} \quad (29)$$

Similarly, other quantities are treated in model (25–28). For example, Eq. (25) becomes

$$\begin{aligned} \frac{\partial \left(\bar{\varepsilon}_g \bar{\rho}_g + \bar{\varepsilon}_g \rho'_g + \varepsilon'_g \bar{\rho}_g + \varepsilon'_g \rho'_g \right)}{\partial t} \\ + \operatorname{div} \left(\bar{\varepsilon}_g \bar{\rho}_g \bar{\mathbf{v}}_g + \bar{\varepsilon}_g \bar{\rho}_g \mathbf{v}'_g + \bar{\varepsilon}_g \rho'_g \bar{\mathbf{v}}_g + \bar{\varepsilon}_g \rho'_g \mathbf{v}'_g + \varepsilon'_g \bar{\rho}_g \bar{\mathbf{v}}_g + \varepsilon'_g \bar{\rho}_g \mathbf{v}'_g + \varepsilon'_g \rho'_g \bar{\mathbf{v}}_g + \varepsilon'_g \rho'_g \mathbf{v}'_g \right) = 0 \end{aligned} \quad (30)$$

Repeated averaging removes terms linear in fluctuations and leaves others for further treatment

$$\frac{\partial \left(\bar{e}_g \bar{\rho}_g + \bar{e}'_g \bar{\rho}'_g \right)}{\partial t} + \text{div} \left(\bar{e}_g \bar{\rho}_g \bar{\mathbf{v}}_g + \bar{e}_g \bar{\rho}'_g \bar{\mathbf{v}}'_g + \bar{\rho}_g \bar{e}'_g \bar{\mathbf{v}}'_g + \bar{e}'_g \bar{\rho}'_g \bar{\mathbf{v}}_g + \bar{e}'_g \bar{\rho}'_g \bar{\mathbf{v}}'_g \right) = 0. \quad (31)$$

The terms such as $\bar{e}'_g \bar{\rho}'_g$, $\bar{\rho}'_g \bar{\mathbf{v}}'_g$, $\bar{e}'_g \bar{\mathbf{v}}'_g$, $\bar{e}'_g \bar{\mathbf{v}}'_g$ must be expressed by the averaged quantities in order to close the system of equations. For this purpose, various models of turbulence have been derived (e.g., algebraic or differential). For details, see Monin and Yaglom (1975), Pope (2000), or Graebel (2007).

With specific focus on the advection diffusion Eq. (27), the abovementioned decomposition is performed to obtain

$$\frac{\partial \bar{c}_a}{\partial t} + \nabla \cdot \left(\bar{c}_a \bar{\mathbf{v}}_g + \bar{c}'_a \bar{\mathbf{v}}'_g \right) = \nabla \cdot (D_B \nabla \bar{c}_a). \quad (32)$$

As described in Monin and Yaglom (1975), the term $\bar{c}'_a \bar{\mathbf{v}}'_g$ is expressed in terms of the mean quantity as

$$\bar{c}'_a \bar{\mathbf{v}}'_g = -\mathbf{K}_{\text{eddy}} \nabla \bar{c}_a, \quad (33)$$

where \mathbf{K}_{eddy} is the eddy diffusion tensor. This term is responsible for the diffusion transport produced the turbulent nature of the flow. Various attempts to express the tensor are discussed further in the text.

Recent Advances in Understanding Turbulence

The initial approach to describing the interaction of a turbulent flow with walls as boundaries of the flow region was based on the boundary layer theory (e.g., Schlichting 1979, Monin and Yaglom 1975). This layer was assumed to be flat and parallel to the surface having a predefined thickness usually entering important formulas evaluating the turbulent boundary layer flow. Some more recent advances in the research of turbulent flow showed that the eddy structures have very complex geometrical structures (see, e.g., Lesieur et al. 2002 or Gaißinski and Rovenski 2018 for reviews; Meneveau and Sreenivasan 1990, Evov et al. 1998, Kurien et al. 2000, Foias et al. 2001, and Biferale and Procaccia 2005 for related articles).

Comparison of Brownian and Turbulent Diffusion by Means of Particle Approach

The impact of the turbulent nature of the aerosol particles can be clearly seen in the experimental and theoretical analysis of the wall deposition. The turbulence term in transport Eq. (32) can be expressed using approximate formulas given by various turbulence models (see, e.g., von Kármán 1930; Monin and Yaglom 1975). Such models apply for the fully developed flow in external or internal aerodynamics (see, e.g., Anderson 2007). Their use for aerosol transport with small average velocities and nondeveloped turbulence deserves further investigation and comparison (for

more details and context, see Spiegel 1962; McCready and Hanratty 1984; Fotou and Pratsinis 1993; Jähne and Haußecker 1998; Nielsen 1998; Schimpf et al. 2000; Turney and Banerjee 2008; Li et al. 2012; and Goda 2014). This investigation can be done either by comparing various CFD strategies or using the particle approach following each aerosol element separately.

This particle or Lagrangian approach is presented by Ounis and Ahmadi (1990) and Ounis et al. (1991a, 1991b). The Brownian diffusion and the turbulent diffusion in the fully developed part of the turbulent flow far from the wall is compared. For this purpose, the Basset-Boussinesq-Oseen equation of motion in turbulent flow

$$m_p \frac{d\mathbf{v}^p}{dt} + \frac{3\pi\mu d_p}{C_c} (\mathbf{v}^p - \mathbf{v}^f) = \mathbf{N}(t) \quad (34)$$

is studied. Here m_p , \mathbf{v}^p , d_p is the particle mass, velocity, and diameter, μ is the viscosity, C_c the Cunningham correction to Stokes drag, $\mathbf{N}(t)$ the Brownian force, and \mathbf{v}^f the fluid velocity. The spectral method for stochastic linear systems is used to obtain a relationship for the total particle diffusivity depending on the turbulent diffusivity D_{eddy} as

$$D_{\text{eddy}} + \frac{1}{S_c Re_f}, \quad (35)$$

where $S_c = \frac{\nu}{D_B}$ is the Schmidt number, $Re_f = \frac{\rho_f V_0 l}{\mu}$ the Reynolds number of the fluid flow, ν the kinematic viscosity, ρ_f the fluid density, V_0 the fluid velocity scale, and l is the length scale. This comparison shows that for large Re_f , and/or for large S_c , the Brownian diffusion effect diminishes.

Analytic Solution of the Turbulent Wall Deposition

The aerosol deposition in the controlled experimental chambers has been studied in the past. For example, Langstroth and Gillespie (1947) experimentally analyzed the change in particle numbers in an enclosure due to coagulation and wall deposition. A theoretical basis for their results was established by Corner and Pendelbury (1951) who find the decay constants for the particle loss due to the both coagulation and wall deposition in the stirred and nonstirred environments in a chamber of rectangular geometry. For the case of the turbulent flow they have expressed the eddy diffusion flux as in Eq. (32) and used the following quadratic dependence of the eddy diffusion tensor on the distance from the wall denoted as ξ

$$\mathbf{K}_{\text{eddy}} = k_e \xi^2. \quad (36)$$

The coefficient k_e is in this relationship to describe the turbulent properties of the flow and is discussed later in this chapter.

A generalization of this approach and evaluation of Eq. (21) for the deposition rate has been presented in Crump and Seinfeld (1981) and used in subsequent papers

such as Crump and Seinfeld (1981). Similar to Corner and Pendelbury (1951), the stationary advection-diffusion problem is treated in a stagnant boundary layer within rotationally symmetric geometry. For this purpose, the equation

$$\frac{\partial \bar{c}_a}{\partial t} + \nabla \cdot (\bar{c}_a \bar{\mathbf{v}}_g + \bar{c}'_a \bar{\mathbf{v}}'_g) = \nabla \cdot (D_B \nabla \bar{c}_a), \quad (37)$$

is considered for the case of the incompressible advective medium ($\nabla \cdot \bar{\mathbf{v}}_g = 0$), the stationary solution ($\bar{c}_a = \bar{c}_a(x)$), and gravitational sedimentation ($\bar{\mathbf{v}}_g = V_s \mathbf{e}_{\text{vert}}$, V_s is the settling velocity, \mathbf{e}_{vert} the vertical direction). Using \mathbf{I} as the identity tensor, the equation becomes

$$\nabla \cdot ((D_B \mathbf{I} + \mathbf{K}_{\text{eddy}}) \nabla \bar{c}_a) + V_s \mathbf{e}_{\text{vert}} \cdot \nabla \bar{c}_a = 0, \quad (38)$$

and has the boundary conditions:

$$\bar{c}_a|_{\text{wall}} = 0, \bar{c}_a|_{r=\delta} = c_{\text{out}}, \quad (39)$$

where δ is the thickness of the boundary layer and c_{out} is the bulk aerosol concentration. Such a boundary condition is justified by Friedlander (2000), see Figs. 3 and 4.

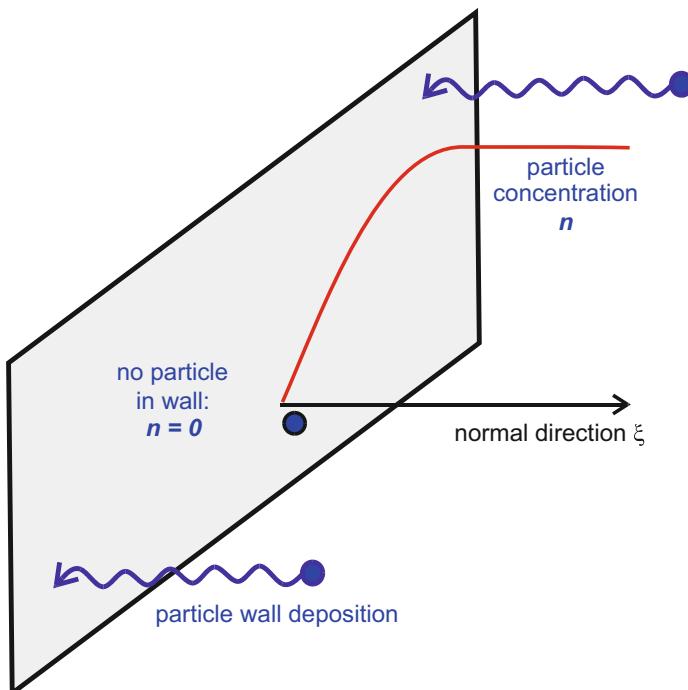

Fig. 3 Dirichlet boundary condition for the particle concentration at the wall as in Friedlander (2000)

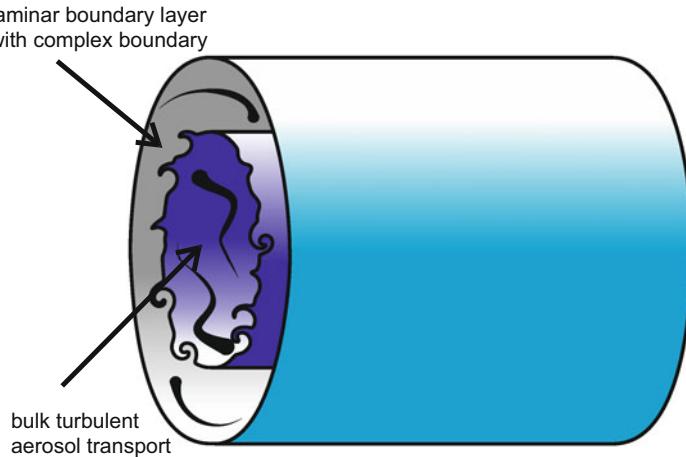

Fig. 4 Transport layers in a cylindrical enclosure

Crump and Seinfeld (1981) provide Eq. (21) for the combined turbulent and sedimentation wall deposition as

$$\beta_a = \frac{1}{\int dx} \int_{\text{wall}} \frac{V_s \mathbf{e}_{\text{vert}} \cdot \mathbf{n}_{\text{wall}}(x)}{\exp\left(\frac{\pi V_s \mathbf{e}_{\text{vert}} \cdot \mathbf{n}_{\text{wall}}(x)}{2\sqrt{k_e D_B}}\right) - 1} dS, \quad (40)$$

Equation (10) used for the cylindrical volume of radius R and area without bases gives

$$\beta_a = \frac{6\sqrt{k_e D_B}}{\pi R} F\left(\frac{\pi V_s}{2\sqrt{k_e D_B}}\right) + \frac{V_s}{\frac{4}{3}R}, \quad (41)$$

where $F(s) = \frac{1}{s} \int_0^s \frac{t}{e^t - 1} dt$.

For the cubic chamber it provides

$$\beta_a = \frac{1}{L} \left\{ \frac{8\sqrt{k_e D_B}}{\pi} + V_s \coth\left(\frac{\pi V_s}{4\sqrt{k_e D_B}}\right) \right\}, \quad (42)$$

in agreement with Corner and Pendelbury (1951).

According to Friedlander (2000), the settling velocity is expressed as

$$V_s = \frac{1}{18} \frac{(\rho_a - \rho_g)}{\mu} g d_p C_c, \quad (43)$$

where d_p is the particle diameter.

Crump and Seinfeld (1981) also extends the mentioned solution to the case when the eddy diffusivity has a general power-law form

$$\mathbf{K}_{\text{eddy}} = k_e \xi^n \quad (44)$$

with $n \geq 2$ is arbitrary. However, dimensionality of the quantity k_e fails to have its original meaning. The deposition rate becomes

$$\beta_a = \frac{1}{\int_{\Omega} dx} \int_{\text{wall}} \frac{v_s \mathbf{e}_{\text{vert}} \cdot \mathbf{n}_{\text{wall}}(x)}{\exp \left(\frac{\pi v_s \mathbf{e}_{\text{vert}} \cdot \mathbf{n}_{\text{wall}}(x)}{n \sin \left(\frac{\pi}{n} \right) \sqrt[n]{k_e D_B^{n-1}}} \right) - 1} dS. \quad (45)$$

This equation is also motivated by an alternative approach to the eddy diffusivity by Friedlander (2000) (originating in Lin et al. 1953) where $n = 3$.

$$\mathbf{K}_{\text{eddy}} = \nu \left(\frac{\xi^+}{14.5} \right)^3 \text{ with } \xi^+ = \frac{\xi V_0 (0.5f)^{0.5}}{\nu}, \quad (46)$$

where f is the Fanning friction factor.

Generalization to other values of n offers better fits to the experimental data as shown in Crump et al. (1982), Holub et al. (1988), Cheng (1997), and Lai and Nazaroff (2000). However, it creates problems with the dimensional analysis as indicated in Beneš and Holub (1996). This issue is addressed in the subsequent section.

Improvements in the Wall Deposition Model

Model adjustment motivated by experiments. The continuing experimental investigations of aerosol wall deposition in the context of the fine powder production in chemical reactors, radioactive aerosols in nuclear reactor safety, and atmospheric aerosol behavior led to the need of adjusting the model parameters according to the experimental data.

Okuyama et al. (1977) first studied the influence of turbulence on the bulk and surficial aerosol dynamics in a stirred tank, namely turbulent coagulation and deposition. In terms of the particle number concentration N , the aerosol stirred in a tank behaves according to equation

$$\frac{dN}{dt} = -K_a N^2 - \beta_a N, \quad (47)$$

where $K_a > 0$, $[m^3 s^{-1}]$ is the coagulation constant. Exploring the results of Corner and Pendelbury (1951) and Takahashi and Kasahara (1967), the deposition rate is evaluated for the vessel of cylindrical geometry (with diameter d_s and height h_s) as

$$\beta_a = \frac{8}{\pi d_s} \sqrt{k_e D_B} + \frac{V_s}{h_s} \coth \left(\frac{\pi V_s}{4\sqrt{k_e D_B}} \right). \quad (48)$$

where V_s is the settling velocity as in the section on turbulent wall deposition.

The particle deposition for aerosols up to 2 μm in turbulent chamber environment is analyzed in Okuyama et al. (1986). Here Eq. (44) is considered for the turbulent diffusion term. The best fit of particular experimental data suggested the value of the exponential factor $n = 2.7$ in deposition rate Eq. (45). This value has been used in the study of particle deposition onto rough surfaces by Shimada et al. (1987) that was based on Eq. (45) for the deposition rate applied to the regular geometry of rough surface.

The investigation of the rough surface deposition in the turbulent environment has been performed in various contexts as in Chamberlain (1967), Hahn et al. (1985), Hopke and Stukel (1993), Fan and Ahmadi (1993), (1995), Adhiwidjaja et al. (2000), Airaksinen et al. (2004), Hussein et al. (2009, 2012), and others.

Dimensional Analysis in Deposition Rate Formulas

The series of experimental results for ultrafine stirred aerosols deposited in an enclosure showed that Eq. (45) could have been used, provided the exponent n of the eddy diffusivity had values between 2 and 3. This fact is mentioned in Okuyama et al. (1986), Holub et al. (1988), and Van Dingenen (1989). Then, the eddy diffusivity is $D_{\text{eddy}} = k_e \xi^n [m^2 s^{-1}]$ while $\xi [m]$ that contradicts the dimensionality of k_e for arbitrary n . This discrepancy obviously propagates into Eq. (45) in the section on turbulent wall deposition.

$$\beta_a = \frac{1}{\int_{\Omega} dx} \int_{\text{wall}} \frac{V_s \mathbf{e}_{\text{vert}} \cdot \mathbf{n}_{\text{wall}}(x)}{\exp \left(\frac{\pi V_s \mathbf{e}_{\text{vert}} \cdot \mathbf{n}_{\text{wall}}(x)}{n \sin \left(\frac{\pi}{n} \right) \sqrt[n]{k_e D_B^{n-1}}} \right) - 1} dS. \quad (49)$$

This equation suddenly becomes questionable with unresolved dimensionality. This discrepancy can be removed as shown in Beneš and Holub (1996) by considering a dimensionally correct expression for the eddy diffusivity

$$D_{\text{eddy}} = k_e l_D^2 \left(\frac{\xi}{l_D} \right)^n, \quad (50)$$

where l_D is the turbulent diffusion layer thickness defined by Schlichting (1979) using the characteristic length L_{CH} of the flow (e.g., the enclosure dimension) as

$$l_D = \frac{L_{\text{CH}}}{\sqrt{\text{Re}}} \quad (51)$$

and $\xi \in [0, l_D]$ is the distance from the wall. Then, Eq. (45) becomes

$$\beta_a = \frac{1}{\int_{\Omega} dx} \int_{\text{wall}} \frac{V_s \mathbf{e}_{\text{vert}} \cdot \mathbf{n}_{\text{wall}}(x)}{\exp \left(\frac{\pi V_s \mathbf{e}_{\text{vert}} \cdot \mathbf{n}_{\text{wall}}(x)}{n \sin \left(\frac{\pi}{n} \right) \sqrt[n]{k_e l_D^{2-n} D_B^{n-1}}} \right) - 1} dS. \quad (52)$$

The deposition rate of the ultrafine particles in a chamber with the volume V and the wall area S , where the settling velocity can be neglected and after an asymptotic expansion, has the form

$$\beta_a = \frac{S}{V} \frac{n}{\pi} \sin \frac{\pi}{n} \sqrt[n]{k_e l_D^{2-n} D_B^{n-1}}, \quad (53)$$

and can be used for analyzing the experimental results as shown in Beneš and Holub (1996).

Fractal Nature of Turbulence

The agreement of Eq. (53) with experiments on ultrafine particle wall deposition given by the choice of $n \approx 2.7$ is not supported by any first principles analysis. An explanation supported by the nature of the flow occurring in enclosures can be sought in the geometric nature of turbulent air flow which can be explored. Geometric analyses of turbulent flow are provided by Schlichting (1960), Monin and Yaglom (1975), Meneveau and Sreenivasan (1990, 1991), and later by Lvov et al. (1998), Kurien (2000), Lesieur et al. (2002), Biferale and Procaccia (2005), and others. The complexity of turbulence implies that the turbulent diffusion boundary layer has a geometrically complex interface with the bulk of the flow. Geometric complexity can be described by fractal geometry (for a survey, see Peitgen et al. (2004), for mathematical background, see Edgar (2007)). As a consequence, the interface between the diffusion boundary layer and the turbulent bulk has an increased area allowing for greater mass transfer toward the wall. One may imagine such an increase from a two-dimensional projection where the length of this interface is increased. This expansion is shown schematically in Fig. 5. As shown by Beneš and Holub (1996), this approach led to agreement with the experimental data while keeping the original dimensionality of all quantities involved.

In particular, choosing a bounded domain Ω as a part of the boundary layer, we can consider the diffusion problem with Brownian and the turbulent terms as follows:

$$\nabla \cdot ((D_B \mathbf{I} + \mathbf{K}_{\text{eddy}}) \nabla \bar{c}_a) = 0, \quad (54)$$

with the boundary conditions.

$$\bar{c}_a|_{\partial\Omega_{\text{left}}} = \bar{c}_a|_{\partial\Omega_{\text{right}}}, \bar{c}_a|_{\partial\Omega_{\text{bottom}}} = 0, \bar{c}_a|_{\partial\Omega_{\text{top}}} = \bar{c}_{a,\text{bulk}}, \quad (55)$$

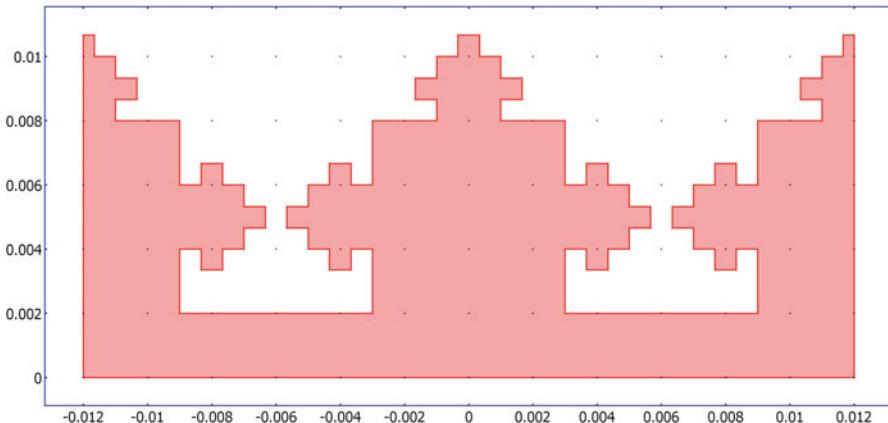

Fig. 5 Sketch of two-dimensional cross-section of the turbulent boundary layer with fractal-like interface with the bulk air volume

where c_{out} is the bulk aerosol concentration. Here, the eddy diffusion coefficient has quadratic dependence on the distance ξ from the wall

$$\mathbf{K}_{\text{eddy}} = k_e \xi^2. \quad (56)$$

The deposition rate is calculated by the formula

$$\beta_a = \frac{\int \mathbf{j}_a \cdot \mathbf{n}_{\text{wall}}(x) dS}{\int dx}, \quad (57)$$

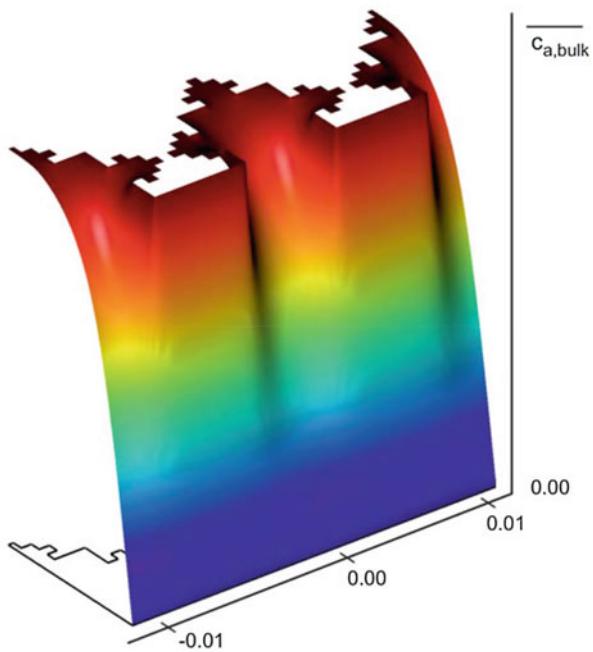

provided the solution of Eq. (54) is available (e.g., numerically, as indicated in Fig. 6). According to Beneš and Holub (1996), the agreement with the experimental data is achieved by this approach and has a similar effect as in Eq. (53).

This approach has been used and commented in a series of subsequent publications such as Cheng (1997), Nomura et al. (1997), Lai and Nazaroff (2000), Park and Lee (2002), Godoy et al. (2002), Wu et al. (2006), Schwarzenegger (2008), Rim et al. (2013), Wallace (2019), and others.

Applications

The description of the aerosol particle deposition on surfaces of an enclosure incorporates parameters of the flow, spatial environment, and particle properties. Such parameters are not always straightforward to obtain. This section is devoted to summarizing such parameters and some ways they can be determined. We also compare various experimental data presented in literature to the analytical modeling.

Fig. 6 Numerical solution of Eq. (54) in the turbulent boundary layer with geometrically complex interface to the bulk obtained by the finite element method

Boundary Layer Thickness

The flow of the gaseous phase carrying the aerosol particles under usual circumstances can always be understood as turbulent. The flow near surfaces forms several layers across which the flow conditions change from the bulk turbulence to the laminar flow and the boundary conditions at the surface (Monin and Yaglom 1975). One of these layers, the diffusion boundary layer, is important for the distribution of the aerosol particles near the wall that by its gradient determines the flux of particles toward the surface. As in Beneš and Holub (1996), the thickness of this layer l_D is determined as

$$l_D = \frac{L_{\text{CH}}}{\sqrt{\text{Re}}}, \quad (58)$$

where L_{CH} [m] is the characteristic length scale (for example, the chamber diameter, the distance an object perturbing the flow. Etc.) and Re [−] is the Reynolds number.

The value of l_D is of the order of centimeters in the experiments. The Reynolds number has its usual definition,

$$\text{Re} = \frac{\rho_g V_0 L_{\text{CH}}}{\mu_g}, \quad (59)$$

with ρ_g [$\text{kg} \cdot \text{m}^{-3}$] as the fluid density, V_0 [$\text{m} \cdot \text{s}^{-1}$] as the characteristic fluid velocity, and μ_g [$\text{kg} \cdot \text{m}^{-1} \cdot \text{s}^{-1}$] as the fluid viscosity that usually provides the information on its order of magnitude, not a precise value.

Using the parameters that are experimentally more accessible, one may, as in Cheng (1997), use:

$$\text{Re} = \frac{\rho_g \omega L_{\text{CH}}^2}{\mu_g}, \quad (60)$$

where ω [s^{-1}] is the fan rotational velocity. The value of Re is about 20000–30000 for experimental chambers. This approach, however, does not provide the information on the surface-to-volume ratio.

Eddy Diffusivity

The turbulent diffusion term described by Eq. (50) contains the coefficient k_e [s^{-1}] that according to Corner and Pendelbury (1951), Saffman and Turner (1956), and others is determined by:

$$k_e = \kappa_0^2 \left(\frac{2\varepsilon}{15\nu} \right)^{\frac{1}{2}}, \quad (61)$$

where ε [$\text{m}^2 \cdot \text{s}^{-3}$] is the average rate of energy dissipation per unit mass, $\nu = \frac{\mu_g}{\rho_g}$ is the kinematic viscosity, and κ_0 [–] is the von Kármán constant whose value is usually 0.4 but can range from 0.2 (Corner and Pendelbury 1951) to 7.9 (Okuyama et al. 1986). In some references, Eq. (62) has only the first power of κ_0 . This approach contains the energy dissipation, a phenomenon occurring near the wall whereas the bulk motion is essentially frictionless. The energy dissipation can be expressed in measurable quantities as well.

Energy Dissipation

The specific configuration of particle wall deposition in experimental chambers where the air flow is induced by a fan allows the consideration of the energy delivered by the fan to be fully dissipated by the friction of air at the chamber walls due to molecular viscosity.

Several formulas estimating the energy dissipation rate have been used in literature. In Friedlander (2000), p. 209, the equation for ε [$\text{m}^2 \cdot \text{s}^{-3}$] is

$$\varepsilon \approx \left(\frac{f}{2} \right)^{\frac{3}{2}} V_0^3 \frac{4}{L_{\text{CH}}}, \quad (62)$$

where f is the Fanning friction factor ($= 0.0025$).

Instrumentation for measurements of the pressure drop along the flow in a corridor or pipe has been greatly improved so that small portable instruments can measure as low-pressure differences as 0.1 Pa . (SETRA, Inc). Realizing that the energy dissipated must be proportional to the pressure loss due to wall friction, one can write

$$\varepsilon = \frac{\Delta P U}{\rho L} = \frac{\Delta P Q}{\rho V}, \quad (63)$$

where we provide example of experimental values observed while measuring the pressure drop along a corridor of an experimental mine as

ΔP = measured pressure drop along the pipe or adit [5 Pa]

Q = flow rate in pipe [$47.2 \text{ m}^3 \cdot \text{s}^{-1}$]

V = volume of the pipe ($= A_e L$) [m^3]

A = cross-section of the pipe [9.6 m^3]

$U = Q/A$ = air velocity [$0.6 \text{ m} \cdot \text{s}^{-1}$]

L = corridor length [314 m]

The eddy diffusivity coefficient in Eq. (62) then becomes

$$k_e = \kappa_0^2 \left(\frac{2\varepsilon}{15\nu} \right)^{1/2} = \kappa_0^2 \left(\frac{2\Delta P U}{15\rho L \nu} \right)^{1/2} = 1.53 \text{ s}^{-1}. \quad (64)$$

Comparison of Measured Data

In Fig. 7, the data presented in Holub and Drouillard (1992) (denoted as U and D), in Liu et al. (2019) (denoted as L), in Okuyama et al. (1986) (denoted as O), and in Holub et al. (1988) (denoted as G) are depicted. The data L have been obtained from computational studies presented in Liu et al. (2019) for two specific particle sizes.

To make these comparisons, it is assumed that most of the supplied kinetic energy is depleted along the walls in the stagnant layer. The rate of plateout is controlled by the diffusion across the stagnant layer. The thickness of the stagnant layer depends on the degree of turbulence. The kinetic energy removed at the outlet of the vessel is negligible and is not included in the subsequent calculation.

The inflowing air (F) is pumped into a chamber of volume V_{CH} through tubing of radius R , and length . Assuming that the kinetic energy injected into the system is the kinetic energy of the air in the inlet tubing, the equation for the energy dissipation can be written as:

$$\varepsilon = \frac{1}{2} \rho_g V_t U_t^2 \frac{1}{\rho_g V_{\text{ch}} \Delta t} \quad [\text{m}^2 \cdot \text{s}^{-3}], \quad (65)$$

where

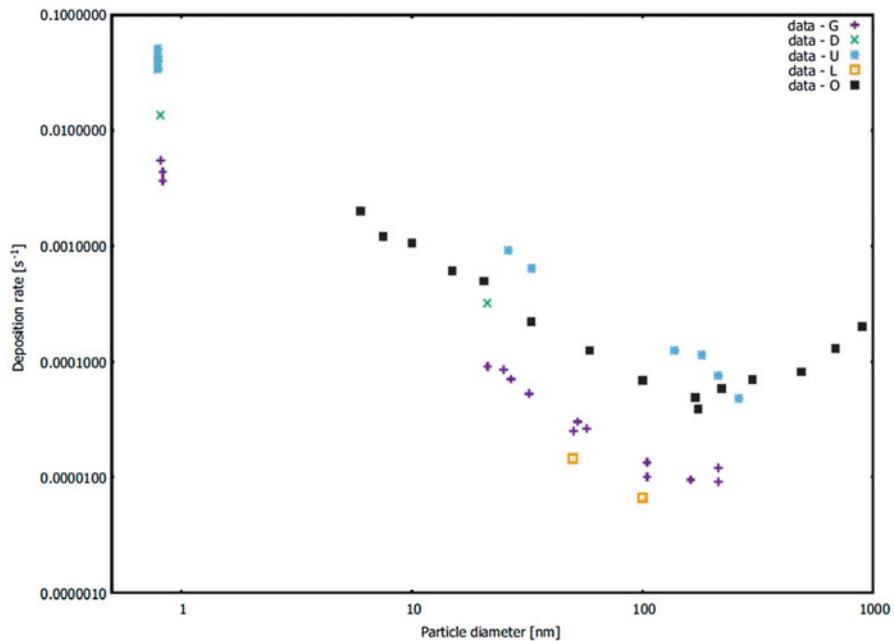

Fig. 7 Comparison of data from different aerosol chambers. (Data from Holub and Drouillard (1992) are denoted as U and D, from Liu et al. (2019) as L, from Okuyama et al. (1986) as O, from Holub et al. (1988) as G)

ρ_g is the air density [$\text{kg} \cdot \text{m}^{-3}$],
 $V_t = \pi R^2 L$ is the tubing volume [m^3],
 $U_t = \frac{F}{\pi R^2}$ is the air velocity [$\text{m} \cdot \text{s}^{-1}$],
 $\Delta t = \frac{L}{U_t}$ is the time it takes to empty the air from the tubing [s],

Consequently, the energy dissipation becomes

$$\varepsilon = \frac{1}{2} \frac{F^3}{\pi^2 R^4 V_{CH}} \quad [\text{m}^2 \cdot \text{s}^{-3}]. \quad (66)$$

Comparison of Experimental Configurations

Review of literature related to the measurement of aerosol wall deposition provides interesting details of measured data and explanations for the observed phenomena. Table 1 provides a summary with values used in the experiments. Table 2 explains the origin of particular data and provides comments to them.

Table 1 Comparison of various aerosol chamber measurements

Origin	Radius [m]	Height (cylinder)	Side	V/S	S/V	Beta [s^{-1}]	$\frac{v_{dep}}{cm.s^{-1}}$	Fan	Volume [m^3]	Surface [m^2]	k_e	n	Epsilon [$cm^2.s^{-3}$]	Condensation nuclei

Table 2 References and comments to Table 1

Notation	References	Comment
[1] CLOUD	Dunnel et al. (2016)	CLOUD (cosmics leaving outdoor droplets) at CERN has apparently no concern for “wall deposition,” the role of fans in plateout of monomers is not considered (plateout rate on fans is much higher than on walls); HV sweep removes ions only; and no HEPA Bionaire air cleaner is used
[2] Cheng	Cheng (1997)	CN levels apparently controlled but not explicitly mentioned; performed the important experiment with “still air”
[3] Holub	Drouillard et al. (1984); Holub and Drouillard (1992)	Two chambers, CN controlled in both
[4] SUJCHBO	Otalal et al. (2017)	CN controlled best (=0); plateout rate not measured or calculated
[5] SUG	Van Dingenen (1989)	CN probably controlled; when $n > 2$ dimensionality mismatch
[6] PYLON	www.pylonelectronics.com	Small chamber, a Rn source, good for measuring plateout of Rn progeny; however, the company is not interested in pursuing it
[7] HO	Ho et al. (1982)	The chamber has been scrapped, as well as all related projects, in 1995. The very interesting data from that unique chamber are still not explained
[8] Liu	Liu et al. (2019)	This is not a chamber but a ventilated room. What is remarkable is that the plateout rate calculated using CFD agrees with our approach reported here. CN not reported
[9] Wonaschuetz	Wonaschuetz et al. (2017)	This small chamber experiment is not addressing plateout, nor radiation-induced unsticking from the surfaces
[10] Takahashi	Takahashi and Kasahara (1967)	This paper is not calculating epsilon from measured quantities
[11] Vanmarcke	Vanmarcke et al. (1991)	CN probably controlled but no epsilon calculated; k_e fitted; even when $n > 2$, dimensionality mismatch

Challenges in Understanding Principles of Particle: Surface Interaction

In this section we indicate problems remaining open for further investigation and challenges which should be met when attempting to understand subtle details of the phenomenon of aerosol particle wall deposition.

Fundamental Problems

Turbulent nature of the air flow. Experiments in aerosol chambers are performed under a variety of flow regimes. The usual velocities produced by the laboratory fans correspond to Reynolds numbers of the order of 10^4 corresponding to the fully developed turbulence that critically influences the diffusive transport in the boundary layer. Some other experiments (e.g., Cheng 1997) perform measurements with the fan turned off. However, the data obtained suggest that the framework of the eddy diffusivity is still applicable. We can hypothesize that despite of being unable to measure tiny fluctuations of the air flow and its temperature, there are still some irregular air motions exhibiting properties of turbulence, even though not fully developed. A decisive experiment to study this anomaly would require a thermally isolated chamber with temperature differences between the walls and the inside atmosphere being less than 0.05 K. Such systems, where the *stagnant layer* stretches across the whole chamber, have been used by Hirst and Harrison (1938), when measuring the diffusion coefficient of radon gas in air.

The challenges in understanding the diffusion limited phenomena could be presented by a particular example to roughly estimate the time it takes for a particle of a size about 1 nm to reach the surface of a chamber. Using the parameters of Cheng (1997) who had a spherical chamber of the radius 0.338 m, the deposition velocity given by $V_{\text{dep}} = \beta_a \frac{S}{V}$ is 0.025 cm s^{-1} . Therefore, the particle needs 1300 s or less to reach the wall if considering the deposition rate as the characteristic parameter. However, the one-dimensional diffusion equation (see Friedlander 2000, Eqs. [2.4, 2.7]) yield values of 3000–7000 s. Therefore, this discrepancy that is occurring when there is no apparent source of momentum in a laboratory-controlled enclosure needs to be understood.

Fractional dependence of the deposition rate on the particle size. The quadratic dependence of the eddy diffusivity on the distance from the wall originally suggested by the algebraic models of turbulence (see Crump and Seinfeld 1981) was soon challenged by experimental results (e.g., in Okuyama et al. 1986; Holub et al. 1988; Pandian and Friedlander 1988; Beneš and Holub 1996; Cheng 1997 up to Wallace et al. 2019), and a fractional power dependence was suggested. However, some results were accompanied by a dimensional discrepancy when using such a fractional power. This discrepancy was resolved by Beneš and Holub (1996) in two ways, suggesting a dimensionally correct fractional formula and, alternatively, matching the experimental data by considering the usual quadratic formula and a geometrically complex boundary between the diffusion layer and the turbulent bulk. For further studies of this phenomenon, it would be desirable to have a Rn/Tn aerosol chamber that produce condensation nuclei whenever needed and generate monodispersed aerosols at $\sim 1 \text{ nm}$ size. Such a chamber has to be sufficiently large ($4\text{--}10 \text{ m}^3$) to allow for taking samples without seriously disturbing the regime inside.

Understanding the reverse processes. Under some circumstances, the particles attached to the enclosure surface can be released back to the bulk volume. Although such effects have lower probability, their understanding still requires more knowledge coupling driving forces such as radioactive decay, thermal oscillations of air particles, strong diffusion flux toward the surface, or even quantum effects on surfaces (see Hsu et al. 1991 or Kong et al. 2020).

Arbitrariness of characteristic quantities. Some constitutive relations in the models of deposition contain dimensionless quantities obtained by the dimensional analysis (compare Ruzicka 2008; Szücs 1980). These quantities, e.g., the Reynolds number, are evaluated using a characteristic length or velocity, which typically provide orders of magnitude, not precise values. This uncertainty undermines the accuracy of the results of the modeling of the experiment.

Cunningham slip correction. Holub and Knutson (1987) first suggested that when the size of a particle approaches the size of air molecules, their size should be added into the denominator in the slip correction formula. Soon after Ramamurthi and Hopke (1989) did that by proposing an empirical correction. The unaddressed problem is that even this correction should be tailored to the specific shape of the molecules (not only to the diatomic air molecules) that are hitting the aerosol particle.

Technical Problems

Experimental data for ultrafine aerosols. Some authors did their measurements for such types of particles and anchored their data for sizes 1 nm using the radioactive Rn/Tn progeny producing monodispersed aerosols of 1 nm size in a condensation-nuclei-free chamber and modified the Cunningham slip correction at such sizes (see Cheng 1997; Holub and Knutson 1987; Ramamurthi and Hopke 1989; Rabajczyk et al. 2020 and others). In some other references, the ultrafine data have just been extrapolated.

Wall friction. In literature, the friction velocity as an adjustable parameter is used to fit data to the regression formulas. However, such a quantity is hardly measurable, even meaningful when there is no prevailing flow direction. As a measure of dissipation, the specific energy supplied to the volume is easier to be evaluated, usually by knowing the pressure drop or fan power delivered to the volume, as explained before.

Advice

As mentioned earlier, isotopic labels are recommended to be used. When embedded in the particles, the sensitivity would be orders of magnitude higher than the best aerosol instruments. Prior Rn/Tn work in a CN-free chamber produced ~1 nm particles that can be measured with incredible sensitivity. It gives invaluable data at smaller size aerosols (ultrafine particles, below 100 nm).

Test the assumption that plated out aerosols on surfaces do not become airborne (SVOCs, possibly even NVCs, nonvolatile compounds), all labelled by appropriate radioactive aerosols. If there is reentry, it would change the field of wall deposition.

Routinely use aerosol generators spiked with suitable radioactive isotopes and become familiar with standard radiochemical methods and their measurements.

As published in the past, and mentioned previously, Rn/Tn daughters in CN-free chambers create monodispersed ~1 nm aerosols. Because they have high specific radioactivity, they can be measured with orders of magnitude greater sensitivity, as mentioned before. When these get attached to larger particles, using graded screen array (GSA) methods (Holub and Knutson 1987; Cheng et al. 1992), one can get aerosol size distribution from 1 to ~500 nm. By combining data from an impactor with data from a GSA diffusion-based sampler, it was possible to cover the particle size range from 0.5 to 5000 nm; an unprecedented four orders of magnitude size span was demonstrated by Knutson and Tu (1996).

Extending this approach would be to label the particle sources with radioactive isotopes with suitable half-lives and chemical properties for concentrations that are too low to analyze by conventional means. For instance, surfaces are often covered with SVOCs and possibly NVCs (Wallace et al. 2013). When slightly heated, say 40–100 °C, generated particles can be measured. Usually their composition is unknown because standard analytical methods are not sensitive enough. If surfaces, exposed to heat, or stress, emit monomeric molecules, it would nullify the usual assumption that the surfaces do not emit anything. Also, composition could be determined.

Further extension of this idea would be to spike all aerosol generators, using different salts as a base (NaCl or Li_2SO_4), with radioactive isotopes and then measure their distribution using the GSA method. Each screen then would be measured using the deconvolution programs commonly used in deconvoluting radon and thoron progeny size spectra. It would require the full cooperation between two disparate subfields groups, or either one to learn the expertise of others.

To summarize this section, there are many unexplained anomalies, most at the molecular/nanometer sizes, that require measurements and explanations. They cannot be included here because it represents another entire chapter not directly relevant to indoor air quality. There is sufficient material to be summarized that a book would be needed to list all of them, and then suggest their potential explanations which is beyond the scope of this chapter.

Conclusions

The chapter summarizes the achievements in research on aerosol wall deposition. Based on the conservation laws related to the turbulent aerosol transport and the deposition on the surfaces, the deposition rates can be evaluated and used in experimental studies. The chapter formulates challenges in the detailed

understanding of the deposition processes. For their resolution, experimental enclosures with accurately controlled condensation nuclei, air flow and thermal properties together with a radioactive aerosol represent the most advanced tools in deposition research.

This work was partly supported by the Ministry of Education, Youth and Sports of the Czech Republic under the OP RDE grant number https://www.isvavai.cz/cep?s=jednoduche-vyhledavani&ss=detail&h=EF16_019%2F0000753 “Research center for low-carbon energy technologies,” and by the project number 21-09093S of the Czech Science Foundation “Multiphase <https://starfos.tacr.cz/en/project/GA21-09093S> flow, transport, and structural changes related to water freezing and thawing in the subsurface.”

Abstract

Resuspension is an important source of indoor airborne particulate matter in occupied environments. Resuspension of settled particles from flooring, furnishings, clothing, and other surfaces can occur when the settled particles are disturbed via human activity, air currents, or other external forces. Resuspension models have been developed at multiple scales, from describing individual particle adhesion and detachment to estimating bulk effects from settled dust disturbance. Researchers have investigated the effects of many resuspension factors, including particle size, particle composition and morphology, particle

loading on surfaces, surface roughness, relative humidity, flooring type, walking style, and shoe type. Future work should address a better characterization of resuspension from clothing, improved incorporation of relative humidity and electrostatic effects into resuspension models, composition of size-resolved dust loading in various microenvironments, resuspension-related exposure in micro-environments of concern, such as hospitals and schools, and resuspension of specific dust components of concern such as nanoparticles, viruses, and per- and polyfluoroalkyl substances (PFAS) compounds.

Introduction

Resuspension of particles from surfaces into the air is a major source of indoor particulate matter (PM) and its constituents (Kopperud et al. 2004). Human activities, such as walking, sitting on furniture, seated movements such as shuffling or stomping one's feet, vacuuming, sweeping, dusting, and folding clothes, result in measurable increased PM from resuspended particles (Ferro et al. 2004; Qian et al. 2014; Licina et al. 2017). Airflow from natural and mechanical ventilation can also resuspend dust from air ducts and indoor surfaces, although typical room air velocities are too low to initiate dust resuspension (Zhou et al. 2011; Nasr et al. 2019). The resuspension source has been characterized for many human activities, including walking, crawling, seated activities, and sleeping (Thatcher and Layton 1995; Wu et al. 2021; Licina et al. 2017; Boor et al. 2015). PM₁₀ mass emission rates for resuspension for human walking have been found to be on the order 1–10 mg/min, similar to emission rates for other major indoor PM sources including vacuuming, frying, candle burning, smoking, and incense burning (Qian et al. 2014). However, estimates for resuspension emission rates from human walking range over orders of magnitude, and, unlike combustion sources, the resuspended particle mass is dominated by supermicron particles (Qian et al. 2014; Thatcher and Layton 1995).

Indoor dust is a heterogeneous mix of particles generated from indoor sources, particles present in outdoor air that enter the indoor environment, and particles tracked in by humans and pets. Pollutants of concern in house dust include many organic pollutants, such as phthalates, flame retardants, pesticides, polycyclic aromatic hydrocarbons (PAHs) from combustion sources, and per- and polyfluoroalkyl substances (PFAS) compounds, heavy metals, allergens (e.g., mold spores, pollen, pet dander, and dust mite), and other biological particles (Lewis et al. 1999; Hytyäinen et al. 2018; Qian et al. 2012; Dodson et al. 2012; Morales-McDevitt et al. 2021; DeLuca et al. 2021; Raja et al. 2010).

Within the size range of inhalable particles (particle diameter D_p ≤ 10 µm), larger particles are easier to resuspend than smaller particles because the adhesion forces,

which include van der Waals, electrostatic, and capillary forces, are proportional to the particle diameter D_p , while the external forces exerted by air currents, such as those formed under the foot during human walking, are proportional to D_p^2 , and gravitational, vibrational, and centrifugal forces are proportional to D_p^3 (Hinds 1999). Thus, with increasing particle size, the magnitude of the removal forces to adhesion forces ratio increases for an applied external force. On the other hand, the resulting human inhalation exposure depends on the airborne concentration in the breathing zone and the length of time the person remains in the indoor space, which is discussed in ► Chap. 34, “Fundamentals of Exposure Science.” Thus, the lower deposition rates of, for example, 1 μm particles compared to 10 μm particles may result in higher exposures to the 1 μm particles even though they are more difficult to resuspend.

As an indoor source caused by occupant activity, resuspended dust has a relatively high intake fraction. Licina et al. (2017) estimated the particle intake fraction from human walking to be ~1/100, meaning an estimated 1 out of 100 particles resuspended are inhaled. This value is similar to the intake fraction for other indoor sources (Nazaroff 2008). As a comparison, outdoor sources have much lower intake fractions. For example, Taimisto et al. (2011) estimated the intake fraction for particles resuspended from vehicle traffic to be ~1/100,000. While the particle emission rate for moderate seated activities is less than half of that for walking, the intake fraction for resuspended particles from seated movements, estimated at ~1/10 to 1/20, is higher than that for human walking due to the fluid flow surrounding a seated person (Licina et al. 2017). Typically, a person’s body temperature is warmer than the indoor air temperature and buoyancy effects from the air warmed by the body result in a thermal plume that moves air up toward the breathing zone. The airflow pattern in the room is also strongly impacted by ventilation airflow, fans, temperature gradients from walls, windows and other objects, and wake effects from moving bodies in the room (Wu and Gao 2014).

Numerous studies have been undertaken to quantify resuspension and the factors affecting resuspension at the bulk and single-particle scales. Rather than provide an exhaustive review of the literature, the primary objective of this chapter is to describe the current state of knowledge and identify open scientific questions that have implications for indoor air and human exposure.

Definitions

Resuspension is the detachment and entrainment of particles from surfaces into the air. Particle resuspension in indoor, occupied environments has been reported in various ways. For bulk aerosol resuspension studies, resuspension has been reported as the:

- 1) Increase in airborne concentration (e.g., $\mu\text{g}/\text{m}^3$ or $#/ \text{m}^3$) above the background concentration resulting from a resuspension event (Serfozo et al. 2014).
- 2) Resuspension emission rate (e.g., $\mu\text{g}/\text{h}$, mg/min , $#/ \text{min}$) (Ferro et al. 2004; Lai et al. 2017; Benabed et al. 2019).

- 3) First-order resuspension rate coefficient (e.g., 1/h), which is multiplied by the settled dust loading on the surface and resuspension surface area to determine the particle mass or number emission rate (Thatcher and Layton 1995; Gomes et al. 2007; Qian et al. 2008; Qian and Ferro 2008; You and Wan 2015).
- 4) Resuspension fraction(–), which is the fraction of settled dust resuspended from one contact event. The resuspension fraction is multiplied by the frequency of contact events, the settled dust loading on the surface, and the contact area to estimate the resuspension emission rate (Tian et al. 2014; Lai et al. 2017; Benabed et al. 2020).
- 5) Resuspension emission factor (e.g., 1/m), which is the ratio of the airborne particle concentration in the volume and settled dust loading on the surface during a resuspension event (Rosati et al. 2008).
- 6) Dust-to-breathing zone transport efficiency(–), which is the probability of a settled particle being resuspended into the breathing zone (Wu et al. 2021).

For single-particle resuspension studies, resuspension is typically observed in a wind tunnel and defined as the detachment fraction(–), which is the fraction of particles on the surface that become detached for a given air velocity (e.g., Goldasteh et al. 2013).

Bulk Aerosol Resuspension Measurement and Modeling

Measurement and modeling studies have been conducted for experimental chambers, homes, commercial buildings, and mechanical foot apparatuses (Thatcher and Layton 1995; Tian et al. 2014; Wang et al., 2020). Figure 1 presents a typical PM concentration time series pattern due to human occupancy in an office building. The number concentration measurements were made with optical particle spectrometers located in an office area and conference room. Resuspension and infiltration of outdoor particles were the only particle sources at this location, and the influence of outdoor particles was minimal for the size range shown (5–10 μm) due to filtration in the heating, ventilation, and air conditioning (HVAC) system. The particle concentration was close to zero when the building was not occupied, and large peaks associated with human activity were observed during periods of occupancy. The concentration peaks in the conference room are higher than in the office area due to the relatively small volume of dilution air.

Typical Bulk Aerosol Resuspension Experiments

Typical bulk aerosol resuspension experiments include monitoring of airborne PM during background, resuspension, and decay periods in a chamber or room to quantify the resuspension source and the effect of various factors affecting particle resuspension, including:

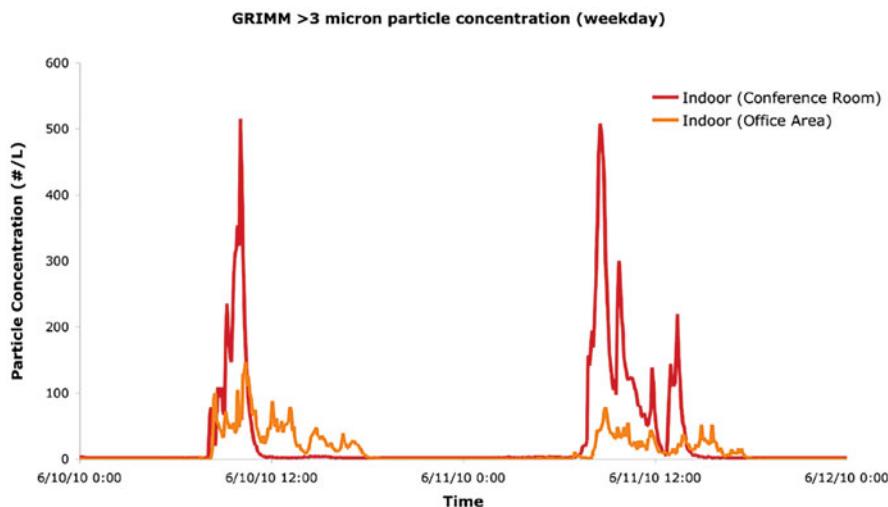

Fig. 1 Particle number concentration for particles greater than 5–10 μm in optical diameter measured with Grimm Technologies (Douglasville, GA, USA) model 1.108 portable laser aerosol spectrometer in an office area and conference room that were occupied during the work day

- Particle type
- Flooring type
- Shoe type
- Surface dust loading
- Relative humidity
- Electrostatic charge
- Individual walking style

During the experimental resuspension periods, particles are resuspended from surfaces via external forces resulting from actual human activity, simulated activity via mechanical apparatuses, air jets, or other mechanisms. Almost all experimental studies to date have employed semicontinuous optical and time-of-flight particle measurement techniques, which measure particles in the range of 0.3–20 μm in diameter, or integrated mass-based samples (e.g., Qian et al. 2008). More recently, particle resuspension for particles smaller than 0.3 μm have been reported (Benabed et al. 2020).

Two-Compartment Material Balance Model

For many bulk aerosol resuspension studies, experimental data are analyzed using a material balance approach. A two-compartment material balance model can be applied to quantify the resuspension rate and/or resuspension fraction (Schneider et al. 1999; Qian and Ferro 2008). The material balance for the air compartment is:

$$V \frac{dC_j}{dt} = E_{resusp,j} + E_{other,j} + C_{out,j}(Q) - C_j(\beta_j V + Q) \quad (1)$$

And the material balance for the surface compartment is:

$$A \frac{dL_j}{dt} = C_j(\beta_j V + Q) - E_{resusp,j} \quad (2)$$

Using units of meters (m), hours (h), and particle number (#), V is the volume of the air compartment (m^3), A is the area of the surface compartment (m^2), Q is the airflow rate into and out of the chamber (m^3/h), $C_{out,j}$ is the particle concentration of the air entering the compartment via the airflow rate for particle size bin j , C_j is the concentration in the compartment for particle size bin j ($\#/ \text{m}^3$), L_j is the surface dust loading for particle size bin j ($\#/ \text{m}^2$), $E_{resusp,j}$ is the size-dependent source emission rate ($\#/ \text{h}$) for resuspension, $E_{other,j}$ is the size-dependent source emission rate ($\#/ \text{h}$) for other indoor particle sources, and β_j is the size-dependent particle loss coefficient (1/h), which is dominated by particle deposition to surfaces following a resuspension source. The resuspension emission term is a source term for the air compartment and a sink, or loss, term for the surface compartment.

When the contribution of particles from outside the compartment and other indoor sources is negligible, the terms $E_{other,j}$ and $C_{out,j}$ can be ignored. Note that Eq. (1) does not include recirculation and filtration of air and Eq. (2) does not include track-in/track-out of particles to and from the surface compartment. Equations (1) and (2) also assume that particles remain in their original size bins throughout the resuspension/deposition process, and that the air and surface compartments are uniformly mixed. Because the fraction of particles removed from the surface is typically small, the surface dust loading is often assumed to be constant. This assumption is reasonable for experiments conducted over a large surface area with relatively short resuspension periods, but not when repetitive resuspension activity is targeted to a small surface area since the particle reservoir can become depleted.

The other parameters in Eqs. (1) and (2) can be either estimated or measured. The airflow rate is determined by the HVAC volumetric flowrate setting, face velocity measurements at the supply and/or return ducts, or via a tracer gas approach. The size-resolved particle loss rate can be determined by solving Eq. (1) during decay periods (periods following a particle source periods when indoor sources have been shut off or removed) with $E_{resusp,j}$ and $E_{other,j}$ set equal to zero. Thus, with known initial concentration/loading in the compartments and the measured time-resolved concentration C_j , the time-resolved resuspension emission rate can be determined by solving the two-compartment material balance. Alternatively, the average resuspension emission rate can be estimated by finding the best fit of the model to the concentration time series using $E_{resusp,j}$ as the fitting parameter.

Resuspension Emission Rate Estimates

Figure 2 provides resuspension emission rates estimates using the material balance approach. The reported resuspension emission rates are a function of particle size, and all studies show a general trend of increasing emission rate with increasing particle diameter, consistent with theoretical models for particle detachment. Most of these studies employed actual humans walking, although Wu et al. (2021) used a mechanical infant that mimicked crawling and Tian et al. (2014) used a mechanical foot that mimicked heel-toe walking. For the studies using human participants, the emission rates for $10 \mu\text{m}$ particles range from approximately 10^{-2} mg/min to 10^2 mg/min . The wide range of size-resolved estimates for resuspension emission rates is due to different experimental conditions. There are also differences in particle size binning from study to study. Note that Ferro et al. (2004) and Qian et al. (2008) reported cumulative mass concentrations of $\text{PM}_{2.5}$ and PM_5 , respectively.

One of the largest factors affecting resuspension rate is difference in surface dust loading. Because the resuspension rate is dependent on the amount of dust on the surface, variation in resuspension estimates can be reduced by separating the floor loading term from the resuspension rate and instead reporting the fraction of settled dust that is resuspended per footstep or unit of repeated activity. To account for the surface dust loading factor, the resuspension rate coefficient R_j is defined as:

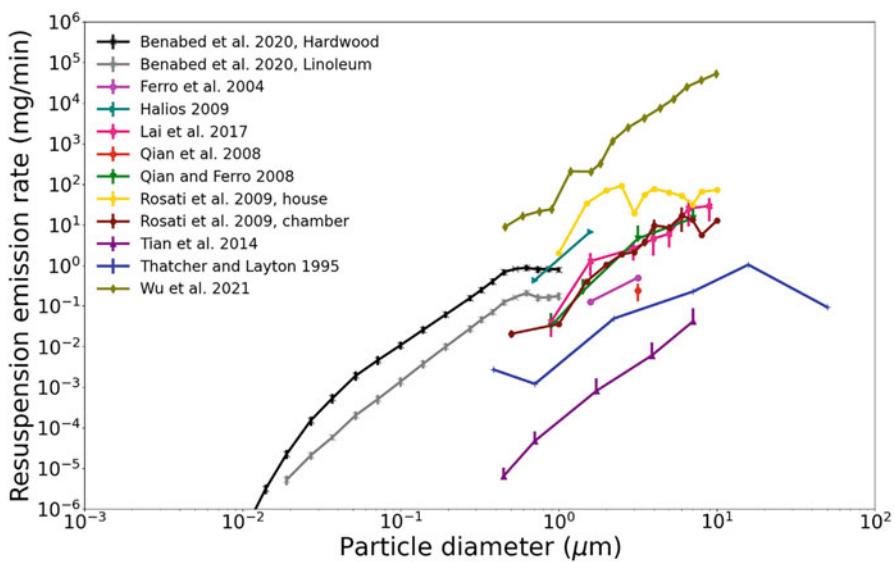

Fig. 2 Resuspension emission rate (mg/min) estimates by optical particle diameter and study. (Adapted and updated from Qian et al. 2014 for this publication by Jing Qian)

$$R_j = \frac{E_j}{AL_j} \quad (3)$$

Such that:

$$E_{resusp,j} = R_j AL_j \quad (4)$$

Using this form of the resuspension emission rate, the emission rate increases linearly with an increase in surface dust loading. This simplified linear relationship ignores the difference in the particle-to-particle adhesion force and the particle-to-surface adhesion force (Tian et al. 2014; Boor et al. 2013). Accordingly, previous studies have found that the resuspension rate increases with surface dust loading, but not linearly (Serfozo et al. 2014).

Because the entire surface area A (e.g., the floor area of a room) is typically not disturbed by human activity during the resuspension event, the surface area is not the same as the resuspension contact area, resulting in differences in resuspension rate coefficient estimates from this assumption alone. For repetitive activities, such as walking, with frequency f (steps/h), the resuspension fraction $r_j(-)$ is defined as the fraction of particles size j that are resuspended from the contact surface area A_s (m^2) per step:

$$r_j = \frac{E_{resusp,j}}{f A_s L_j} \quad (5)$$

Such that:

$$E_{resusp,j} = R_j AL_j = r_j f A_s L_j \quad (6)$$

Thus, resuspension rate coefficient or resuspension fraction can be incorporated into Eqs. (1) and (2) by substituting the corresponding expression for $E_{resusp,j}$.

Resuspension Fraction Estimates

The resuspension fraction accounts for both the surface dust loading and the contact area and therefore is more easily compared across different studies (Fig. 3). While the resuspension fraction estimates still vary widely, the variation is smaller than that for resuspension rates shown in Fig. 2. Additional factors that contribute to the wide range of results include the type of resuspension mechanism (e.g., mechanical device and walking style), material properties, and environmental conditions.

High person-to-person variability and even experiment-to-experiment variability with the same participant is a major challenge for the quantification of factors affecting resuspension, such as flooring type, dust loading, and environmental conditions (Qian et al. 2008). To address this variability, Tian et al. (2014) used a

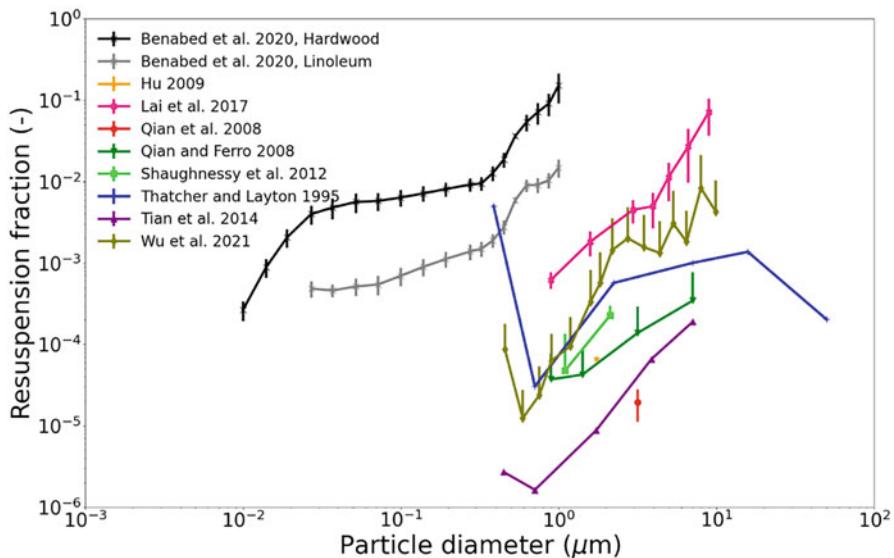

Fig. 3 Estimated size-resolved resuspension fraction by study (adapted and updated from Qian et al. 2014 for this publication by Jing Qian)

resuspension mechanism in a well-characterized and controlled experimental chamber on consistently seeded and conditioned flooring samples to characterize walking-induced particle resuspension as a function of flooring type, relative humidity, surface dust loading, and particle size. Similar to the results shown in Fig. 3, they found that the resuspension fraction r_j generally increases with particle size, with r_j values range from 10^{-6} for the smallest two size fractions to 10^{-4} – 10^{-3} for the largest size fraction. As described above, these values are lower than estimates for actual humans walking. However, the study design allowed for a direct comparison of the flooring effect. There were no statistical differences based on flooring for the smaller size fractions. However, for the coarse particles (3.0 – 5.0 μm and 5.0 – 10.0 μm), higher resuspension fractions were observed for carpets than for hard flooring, and higher resuspension fractions were observed for cut-pile carpets compared with closed-loop carpets of the same material. The low-density, cut-pile carpet resulted in the highest resuspension fractions of all the flooring types. Tian et al. (2014) also observed statistically significant differences for relative humidity and surface dust loading factors on the resuspension fraction, although these effects were smaller than for the flooring type, and multiple interaction effects between the factors were observed. The interaction effects, especially between flooring type, particle loading, and relative humidity, deserve further study.

The findings of higher resuspension from carpeted flooring than from hard flooring are consistent with most chambers and full-scale studies (e.g., Benabed et al. 2020; Qian and Ferro 2008; Ferro et al. 2004). One exception is Shaughnessy and Vu (2012), who reported that resuspension from hard flooring was higher than

for carpet for the particle size fraction of 0.8–1.5 μm and a relatively high surface dust loading of 18 g/m². This dust loading would have resulted in a multilayer of dust for which adhesion forces are primarily particle to particle, rather than a monolayer for which adhesion forces are particle to surface (Boor et al., 2013). Boor et al. (2013) found that the resuspension of particles that are deposited in multilayers can be enhanced compared to those in monolayers.

While almost all bulk aerosol resuspension studies have focused on particles >0.3 μm in diameter, Benabed et al. (2020) reported that particles ranging from 0.01–0.1 μm in diameter could be resuspended by human walking and estimated resuspension fractions for this size range an order of magnitude lower than those for 1 μm particles. Thus, while resuspension is not a major pathway of inhalation exposure for ultrafine particles, these particles could be resuspended singly or as agglomerates with larger particles. The formation of particle aggregates on surfaces would tend to enhance resuspension and result in the resuspension of particles that would not be predicted to detach as single particles. More studies are needed to quantify resuspension for ultrafine particles of concern, such as manufactured nanoparticles and pathogenic viruses.

Particle Surface Loading

As described above, two of the largest factors affecting bulk aerosol resuspension from human walking are flooring type and surface dust loading. Flooring type also influences the chemistry and microbiology of the dust settled on the flooring surface, acting as a reservoir for environmental contaminants and providing surfaces for chemical and biological transformations (Haines et al. 2020).

Surface dust loading estimates collected by Adgate et al. (1995) in more than 200 locations and Bramwell et al. (2015) in 20 locations show geometric mean mass loadings of dust on carpets were approximately 20 times higher than those on hard floorings. Few studies have characterized size-resolved surface loading in different microenvironments for particles in the inhalable range (<10 μm in diameter), and there are scant data for compositional characterization for <10 μm fraction of the house dust. Resuspension estimates to support inhalation exposure studies would greatly benefit from filling this knowledge gap.

Clearly, an effective mitigation strategy would be more regular cleaning of the flooring to reduce the surface dust loading. However, vacuuming carpets does not consistently reduce the particle resuspension due to human activity on the carpet, possibly because vacuuming can dislodge deep seeded particles and bring them closer to the surface or because studies often do not control for resuspension from other surfaces, such as clothing (Qian et al. 2008). Vacuuming has been shown to reduce the overall particle surface loading, although the remove is incomplete and depends on the efficiency of the vacuum cleaner, the velocity of the nozzle over the floor, and the number of passes made over the area (Reponen et al. 2002). Ong et al. (2014) found

that four passes moving the nozzle at 55 cm/s removed ~50% of the fungi, dust mites, and dust allergens from a carpet. Accordingly, Wu et al. (2021) found that airborne concentrations during resuspension events generally decreased after vacuuming the carpets.

Dust Components of Concern

Resuspended dust has a very different composition than ambient particulate matter. As described above, the intake fraction of resuspended dust is orders of magnitude higher than that of outdoor sources. Therefore, applying health-based ambient PM standards to indoor particle concentrations due to resuspension is not logical. However, levels of specific constituents of the resuspended dust can be compared with health-based standards.

Indoor surfaces act as reservoirs for environmental contaminants and provide sites for chemical and biological transformations (Haines et al. 2020). Thus, indoor dust has been found to be a reservoir of emerging and legacy pollutants (Morales-McDevitt et al. 2021; Dodson et al. 2012). As described above, pollutants of concern in house dust include many organic and inorganic pollutants, including PAHs, flame retardants, bisphenols and phthalates, heavy metals, allergens, and other biological particles. Many semi-volatile organic compounds (SVOCs) are also dust components of concern and the inhalation exposure estimates from resuspension are complicated by the partitioning between the dust and gas phases.

Resuspension of biological materials in indoor dust is an area of particular concern. Resuspension for bacterial and fungal species from human occupancy was reported by Qian et al. (2012) and Hospodsky et al. (2015) in both university classroom and children's classrooms, respectively. For these studies, resuspension was the primary source of the bacterial and fungal species in the indoor air (Qian et al. 2012; Hospodsky et al. 2015). Gomes et al. (2007) summarized studies reporting increases of roach, dog, cat, and dust mite allergens in indoor air due to dust disturbance, with the airborne concentration increasing 5–50 times after the floor dust was disturbed. Crawford et al. (2009) reported indoor and outdoor concentrations for fungal spores, pollen, and $(1 \rightarrow 3)$ - β -d-glucan for four single-family homes measured in four locations in the homes (living room, kitchen, bedroom, and basement). They found the highest fungi and pollen concentrations in living room samples where occupants are the most active, supporting the importance of human activity-induced resuspension as a major source of exposure for bioaerosols (Crawford et al. 2009). While there are no reported resuspension studies using live virus, there is some evidence that resuspension of SARS-CoV-2 from indoor surfaces and clothing may be an exposure pathway due to higher virus concentrations found in hospital changing rooms and bathrooms than in patient rooms (Liu et al. 2020). However, the importance of resuspension in viral transmission remains an open question.

Human-Generated Particle Emissions

Human-generated particle emissions include respiratory emissions as well as emissions from the human body, such as desquamation of skin flakes, fabric fragments, other particles that are intrinsic to clothing, and particles that are extrinsic to clothing. Like flooring, furnishings, and other objects, clothing acts as a reservoir for particles (Licina et al. 2017, 2019). Bhangar et al. (2016) compared airborne concentrations in a chamber with an exposed floor and covered floor and estimated that for both walking and seated activities conducted in a chamber, 30–40% of fluorescent biological particle emissions came from the clothing versus the floor. McDonagh and Byrne (2014) compared dust resuspension from different clothing materials and found the weave pattern had a larger effect than fiber type, with the highest concentration during the activity period resulting from loosely woven fleece material. They also found that high physical activity resulted in much higher airborne particle concentrations than low physical activity (McDonagh and Byrne 2014). Particle resuspension from the clothing is an important aspect of resuspension from human activity sources. However, the resuspension mechanism, particle composition, surface/fabric materials, temperature, and relative humidity, and other characteristics are different than those for floorings and require further investigation.

Resuspension by Crawling Infants

Most experimental resuspension studies have focused on human activity for adults; however, exposure from resuspended particles for children and crawling infants is of particular concern given their relatively high activity levels, the proximity of their breathing zone to the floor, and growing bodies. Hyytiäinen et al. (2018) reported that crawling (for a mechanical infant) resulted in a cloud of microbial content surrounding the infant, and they found average airborne levels of fungi and bacteria to be 8 to 21 times higher in the infant breathing zone than in the adult breathing zone. Wu et al. (2021) conducted bulk aerosol resuspension experiments using the same mechanical infant crawling on 12 carpets borrowed from residents in Helsinki, Finland, measuring the size-resolved aerosol and collecting integrated samples for later bioaerosol analysis in the near-floor zone and in the bulk air. The experimental protocol included background, activity, and decay periods, similar to the standard protocol described above, and the material balance model used is similar to that described in Eqs. (1–6), but with the air compartment divided into the two zones: a near-floor zone close to the robotic infant and a bulk air zone. They found resuspended particle concentrations in the near-floor zone ranged from 10^5 – 10^6 m³ during crawling activities, up to tenfold higher than those measured in the bulk air.

Application of the material balance resulted in estimated size-resolved resuspension fractions for crawling ranging from 10^6 – 10^1 . Wu et al. (2021) introduce the dust-to-breathing zone transport efficiency as the probability of a settled particle being resuspended into the breathing zone. Dust-to-breathing values ranged orders of magnitude from 0.1–200 per million, with expected increases with particle

size and strong dependence on carpet type. Resuspension emission rates from crawling ranged from $0.1\text{--}2 \times 10^4 \mu\text{g/h}$, the rate that increases increasing with increasing particle size, which are in the midrange of those reported for human walking.

Uniform Mixing Assumption

Illustrated by the difference in concentration in the near-floor zone and bulk air for the experiments conducted by Wu et al. (2021), the uniform mixing assumption is a source of error for the material balance results. For experimental studies, depending on the airflow in the room and proximity of the particle monitor to the source, this assumption may result in an overestimation or underestimation of the inhalation exposure. For modeling studies, this assumption tends to result in an underestimation of exposure in the breathing zone during a human activity resuspension event. Characteristic mixing times for indoor room air are on the order of minutes to tens of minutes, depending on the volume of the room, ventilation conditions, sunlight, and human activity (Mage and Ott 1996). Therefore, care should be taken when selecting the monitoring locations and averaging time used to represent the exposure (Klepeis 1999).

Single-Particle Resuspension Measurement and Modeling

Measurements and models for single-particle resuspension investigate the balance of adhesion and detachment forces at the particle scale. This is a rich area of research with landmark studies on particle adhesion dating back half a century or more (Hertz 1896; Johnson et al. 1971; Derjaguin et al. 1975). Single-particle resuspension studies investigate and incorporate intrinsic particle and surface properties, including particle size, morphology, surface roughness, surface chemistry, hygroscopicity, Young's modulus of elasticity (tensile or compressive stiffness of a solid material), as well as fluid mechanic structures of the applied airflow (Goldasteh et al. 2013).

For a single particle, particle detachment occurs when the external removal forces on the particle overcome the adhesion forces. For particle sizes of interest to human exposure, lift and gravity forces are typically neglected due to the relatively large van der Waals force between the particle and the substrate. Special cases include electrostatic, capillary, and vibrational forces. The capillary force adds to particle adhesion when the humidity is high enough for the meniscus to form between the particle and surface. The vibration could induce an external detachment force. The electrostatic force can increase the adhesion force if the particles and the surface carry opposite charges via triboelectric charging when the foot separates from the floor or act as an external detachment force when the particle and the surface carry similar charges.

For a spherical particle in the viscous sublayer exposed to turbulent fluid flow, the force required for rolling detachment is less than that for sliding or lifting detachment

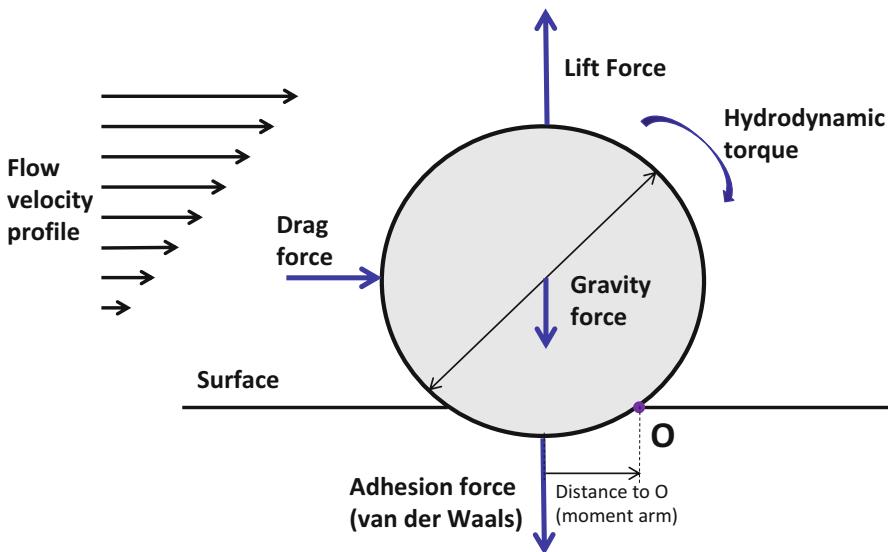

Fig. 4 Schematic force diagram showing rolling detachment of a particle from a substrate for an applied external airflow

(Soltani and Ahmadi 1994). Thus, detachment occurs when the external force moment around the point of contact O overcomes the resisting moment. As shown in Fig. 4, the external force moment for a particle in fluid flow includes the moment of the drag force and the hydrodynamic torque.

Because the particle is attached to the surface of the substrate, the flow surrounding the particle is characterized by the shear velocity. The shear velocity u^* (m/s) is defined as the square root of the wall shear stress τ_w divided by the fluid density ρ

$$u^* = \sqrt{\frac{\tau_w}{\rho}} \quad (7)$$

and can be estimated from the free-stream velocity based on the wind tunnel geometry. Multiple models exist to determine the adhesion force of a particle on a substrate and the pull-off force required to remove a spherical particle from a smooth substrate in the turbulent flow regime (Rumpf 1990; Johnson et al. 1971; Derjaguin et al. 1975; Tabor 1977; Rabinovich et al. 2000; Soltani et al. 1995).

Comparison of experiments with theory for spherical particles on smooth surfaces show that the particles detach at a critical shear velocity u_c^* (m/s) much lower than what is predicted by the theory, even for smooth materials such as glass beads on glass substrates (Nasr et al. 2019). This is because the materials have small-scale surface roughness that reduces the actual contact area with the substrate. The surface roughness can be modeled via surface asperities, each of which is in contact with the particle (Soltani and Ahmadi 1994). By incorporating the surface roughness effects via a roughness parameter and representing the nonsphericity of the particle with three bumps in contact with the rough surface, the models can reasonably predict

particle resuspension from most real substrates (Goldasteh et al. 2013; Nasr et al. 2019).

Single-particle detachment models are typically validated with wind tunnel experiments measuring particle detachment in turbulent flow regimes. However, due to the high velocity required to remove smaller particles from the surface, most experimental studies have investigated the resuspension of particles larger than 10 μm in diameter (Nasr et al. 2019). Thus, experimental validation of models for resuspension of particles less than 10 μm in diameter is limited and represents an important research need as many dust components of concern, such as microbial particles, are smaller than 10 μm .

Conclusions

Particle resuspension is a major source of indoor particulate matter. While the mechanisms for particle adhesion, detachment, and re-entrainment are well understood, there remain many open research questions. Most current estimates for resuspension are from human ambulation, either with human participants or with mechanical stepping or crawling devices. Even so, estimates for size-resolved resuspension emission rates and resuspension fractions per step range widely. Resuspension factors include walking style, flooring type, surface dust loading, relative humidity, and electrostatic charge. Of these factors, the electrostatic charge effect for resuspension from human walking is the least characterized. Resuspension of particles smaller than 0.3 μm is also an important area of research, especially for specific dust components of concern, such as manufactured nanoparticles and viruses. Finally, a better understanding of the size fractions associated with different pollutants would greatly improve human exposure models, as settled dust composition is often used as a proxy for chronic exposure to dust-related pollutants, and resuspension is a strong function of particle size and surface roughness.

Abstract

Gas-phase chemicals can interact with and subsequently be retained by indoor particles, including both airborne particles and settled dust (particles deposited on indoor surfaces). Therefore, understanding the distribution and interactions between gas-phase chemicals and indoor particles is fundamental to exposure analysis and is especially important for semi-volatile organic compounds (SVOCs) with strong sorptivity. This chapter provides a summary of the available models for describing gas-particle interactions and the existing methods for estimating/measuring the key parameters involved in these models (especially the particle-gas partition coefficients). Due to the differences between mass transfer processes related to airborne particles and settled dust, this chapter is mainly divided into two parts, one for airborne particles and the other for settled dust.

Indoor air quality (IAQ) · Semi-volatile organic compounds (SVOCs) · Dynamic model · Partitioning · Airborne particles · Settled dust

Introduction

Gas-phase chemicals can interact with or partition to various indoor surfaces, e.g., walls, ceiling, window glass, clothing, human skin, and particles (including airborne particles and settled dusts), depending on their physicochemical properties (Salthammer et al. 2018). Therefore, indoor chemicals may enter human body via various pathways, e.g., inhalation of air and airborne particles, nondietary ingestion of dust, and dermal absorption from air, deposited particles, and contacted surfaces, as discussed in another chapter of this handbook ► [Chap. 35, “Exposure Routes and Types of Exposure”](#). Understanding the distribution of indoor chemicals is therefore fundamental to effective exposure analysis (Salthammer et al. 2018). Because airborne particles and settled dust can be either inhaled or ingested by people (especially children who frequently put their hands in mouths), it is important to investigate the interactions between gas-phase chemicals and indoor particles (Bi 2018).

Organic compounds in indoor environments are often categorized according to their volatility as very-volatile organic compounds (VVOCs, e.g., formaldehyde), volatile organic compounds (VOCs, e.g., benzene and toluene), and semi-volatile organic compounds (SVOCs, e.g., phthalate esters and organophosphate flame retardants) (Salthammer et al. 2018). The volatility (or vapor pressure) is one of the critical properties that determines the sorptivity of gas-phase chemicals on indoor surfaces, i.e., lower volatility corresponds to greater sorptivity (Weschler and Nazaroff 2008). For VVOCs and VOCs, most of their mass in the indoor environments tends to remain in the gas phase. Taking the interaction between gas phase and airborne particles as an example, Liu et al. (2013) found that the distribution into the particle phase can be neglected for VVOCs and VOCs due to their low sorptivity. While for SVOCs with higher sorptivity, distribution into the particle phase is dominant (Liu et al. 2013). For an SVOC with octanol-air partition coefficient (K_{OA}) > 13 , over 99% of its mass in the indoor air may be bound to airborne particles (with <1% presented in the gas phase) (Weschler and Nazaroff 2008). Note, K_{OA} is the ratio of a chemical’s concentration in octanol to its concentration in air at equilibrium, which is useful for predicting the partitioning behavior between air and environmental matrices such as particles, soil, and vegetation. Generally, lower volatility typically corresponds to greater K_{OA} ; K_{OA} of VVOCs and VOCs is often less than 10^8 , while K_{OA} of SVOCs with vapor pressures between 10^{-14} and 10^{-4} atm at indoor environmental temperatures is often greater than 10^8 (Weschler and Nazaroff 2008). Therefore, studies of the interaction between gaseous constituents and indoor particles have mainly focused on SVOCs.

This chapter provides a summary of studies about the interaction between gas-phase SVOCs and airborne particles or settled dust in indoor environments, especially summarizing the available models for describing gas-particle interactions and the existing methods for estimating/measuring key parameters that govern these interactions. Due to the differences between mass transfer processes related to airborne particles and settled dust, this chapter mainly comprises of two parts, one for airborne particles and the other for settled dust. The following SVOC-specific contents may also be practicable, in principle, for VVOCs and VOCs (and some inorganic chemicals) if the interactions between gas-phase VVOCs/VOCs and indoor particles are not negligible.

Interaction Between Gas-Phase Pollutants and Airborne Particles

Overview

Indoor airborne particles may strongly affect transport of, and human exposure to, indoor SVOCs, because SVOCs with low volatility partition strongly to airborne particles (Weschler et al. 2008). Apart from the aspects for human exposure mentioned above, several studies suggested that airborne particles may facilitate the transport of SVOCs from their source to the surrounding environments (Benning et al. 2013; Liu et al. 2012). For example, Lazarov et al. (2016) found that the presence of airborne particles might increase the emission rate of tris (1-chloroisopropyl) phosphate (TCPP, widely used as organophosphate flame retardant, a typical SVOC in indoor environments) by a factor of three, and subsequently increase human exposure to TCPP.

There have been many studies that have measured indoor airborne SVOC concentrations (Bu et al. 2016; Wang et al. 2014; Wei et al. 2017; Wensing et al. 2005; Weschler and Nazaroff 2010), most of which measured either the gas-phase concentration (C_g , $\mu\text{g}/\text{m}^3$) or the particle-phase concentration (C_{sp} , $\mu\text{g}/\text{m}^3$) (Bu et al. 2016; Wei et al. 2017; Weschler and Nazaroff 2010). In addition, some studies measured only the total airborne SVOC concentration (designated as C_{tot} , $C_{tot} = C_g + C_{sp}$) (Wensing et al. 2005). However, when assessing human exposure to indoor SVOCs, both C_g and C_{sp} are indispensable inputs (Eichler et al. 2021). For example, dermal exposure to gas-phase and particle-phase SVOCs have quite different transport processes, and hence assessment of exposure through these two pathways should be done separately (Shi and Zhao 2014). In existing studies on evaluating pollution levels or health risks of indoor SVOCs, C_g or C_{sp} was always predicted using a relationship between C_g and C_{sp} if the other was measured (Wei et al. 2016, 2017; Weschler et al. 2008). Therefore, understanding the relationship between gas- and particle-phase SVOCs is vital for accurately describing transport and fate, assessing human exposure, and determining effective control strategies for indoor SVOCs (Guo 2013; Salthammer et al. 2018; Xu and Little 2006).

Equilibrium Models

With the assumption of equilibrium interaction between gas phase and particles, the distribution of a gaseous substance and particle is defined both by the physical characteristics of this substance and by the laws of the adsorption and/or absorption processes (Salthammer and Goss 2019).

Gas-particle partitioning of organics in the air was first described quantitatively by Junge (1977), who developed an adsorption-based model for the transport of persistent compounds in the atmosphere. Based on the Brunauer-Emmett-Teller (BET) isotherm, Junge (1977) linked the fraction (Φ , dimensionless) of the substance adsorbed on solid airborne particles with its vapor pressure (P_s , Pa) and particle surface area concentration (C_{Ap} , m^2/m^3 , i.e., particle surface area per volume of air):

$$\Phi = \frac{\text{const} \cdot C_{Ap}}{P_s + \text{const} \cdot C_{Ap}} \quad (1)$$

where the constant (*const*, $\text{Pa}\cdot\text{m}$) depends on the molecular weight and heat of condensation of the sorbate.

Pankow (1987) showed that the BET isotherm assumed by Junge (1977) corresponds with the linear range of the Langmuir isotherm if the partial pressure (P , Pa) of the substance is significantly below the saturation vapor pressure ($P \ll P_s$). The expression for the Langmuir isotherm is:

$$\theta_L = \frac{b_L P}{1 + b_L P} \quad (2)$$

where θ_L (dimensionless) is the fraction of the sorption sites occupied by the sorbates, and b_L (Pa^{-1}) is the constant in the Langmuir isotherm. If the partial pressure of the sorbate is sufficiently low (i.e., $1 \gg b_L P$), Eq. (2) can be simplified as:

$$\theta_L = b_L P \quad (3)$$

Pankow (1987) further pointed out that the particulate-associated concentration of the adsorbing compound (C_{sp} , $\mu\text{g}/\text{m}^3$) for a Langmuirian sorption is:

$$C_{sp} = 10^6 M W_s \theta_L C_{Ap} N_s \quad (4)$$

where $M W_s$ (g/mol) is the molecular weight of the sorbate and N_s (mol/ m^2) is the moles of sorption sites per m^2 on particle surface. The factor of 10^6 converts 1 g to $10^6 \mu\text{g}$.

Using the ideal gas law, the gas-phase concentration (C_g , $\mu\text{g}/\text{m}^3$) and partial pressure (P , Pa) of the sorbate can be linked,

$$C_g = \frac{10^6 M W_s P}{R T} \quad (5)$$

where T (K) is the temperature and R (J/mol/K) is the ideal gas constant.

Combining Eqs. (3), (4), and (5), Pankow (1987) gave the following equation:

$$C_{sp} = b_L N_s R T C_{Ap} C_g = K_{pA} C_{Ap} C_g \quad (6)$$

where K_{pA} (m) is defined as the surface-area-normalized gas-particle partition coefficient, and $K_{pA} = b_L N_s R T$.

The fraction (Φ) of the substance adsorbed on particles is then

$$\Phi = \frac{C_{sp}}{C_g + C_{sp}} = \frac{K_{pA} \cdot C_{Ap}}{1 + K_{pA} \cdot C_{Ap}} \quad (7)$$

By assuming that the surface area concentration available for adsorption is proportional to the mass concentration of total suspended particles (TSP, $\mu\text{g}/\text{m}^3$), i.e., $C_{Ap} = A_{tsp} \cdot \text{TSP}$ (A_{tsp} [$\text{m}^2/\mu\text{g}$] is the specific surface area for total suspended particles), Yamasaki et al. (1982) first suggested the following approach for describing the equilibrium interaction between gas phase and particles:

$$C_{sp} = \text{TSP} \cdot K_p \cdot C_g \quad (8)$$

$$\Phi = \frac{\text{TSP} \cdot K_p}{1 + \text{TSP} \cdot K_p} \quad (9)$$

where K_p ($\text{m}^3/\mu\text{g}$) is defined as the particle-mass-normalized gas-particle partition coefficient. In this way, the particle-phase concentration (C_{sp}) is linearly related to the gas-phase concentration (C_g) and the mass concentration of total suspended particles (TSP, which is much easier to be obtained as compared to C_{Ap}). Comparing Eqs. (8) and (6), we can get $K_p = K_{pA} \cdot C_{pA} / \text{TSP} = K_{pA} \cdot A_{tsp}$ ($A_{tsp} = C_{pA} / \text{TSP}$).

Except for adsorptive partitioning, the gaseous substances can also absorb into liquid particles such as environmental tobacco smoke or liquid (organic and/or water) films on particles with solid cores. Gas-particle partitioning of organic pollutants in urban areas is better explained as absorption than adsorption (Pankow 1987). Junge (1977) also noted that the presences of “organic ether soluble matter may cause true absorption of some of the rather lipophilic compounds.” Since the 1990s, it has been postulated that SVOCs partition through an absorption process rather than by physical adsorption onto the surface of particles. SVOCs would “dissolve” in the amorphous organic matter (OM) in the atmosphere, which exists both as primary and as secondary organic aerosols (Lohmann and Lammel 2004). The absorptive partitioning of SVOCs into the OM in the particles is like a gas dissolving in a liquid, and the equations describing the absorptive partitioning between gas phase and particles takes the same form as Eqs. (8) and (9) (Pankow 1994).

Overall, Eqs. (8) and (9) have been commonly used for describing the equilibrium interaction between gaseous substance and airborne particles, regardless of the adsorptive partitioning or absorptive partitioning. The validity of Eqs. (8) and (9) has also been confirmed by experimental observations and theoretical considerations (Cousins and Mackay 2001). The particle-gas partition coefficient (K_p) is the only key parameter in the equilibrium model, which characterizes the sorption capacity of particles for the gas-phase substances. Various approaches have been proposed for predicting K_p of SVOCs.

Note, the equivalence between Eqs. (6) and (8) (or K_{pA} and K_p) for adsorptive interaction should be used with caution because the assumption made by Yamasaki et al. (1982) (the surface area concentration available for adsorption is proportional to the mass concentration of total suspended particles) may be invalid in some cases. For example, Wu et al. (2018) found that the K_p of di(2-ethylhexyl) phthalate (DEHP) adsorbed by $(\text{NH}_4)_2\text{SO}_4$ particles varied with particle size ($0.011 \text{ m}^3/\mu\text{g}$ for particles with media diameter of 70–80 nm versus $0.032 \text{ m}^3/\mu\text{g}$ for particles with median diameter of 40–50 nm). These two K_p were then converted into K_{pA} by Wu et al. (2018), and consistent results were obtained ($K_{pA} = 300 \text{ m}$ for 70–80 nm particles versus $K_{pA} = 360 \text{ m}$ for 40–50 nm particles). The reason is that the specific surface area of particles (A_{tsp}) varies with particle size distribution (particle surface area is proportional to the square of particle diameter, while particle mass is proportional to the cube of particle diameter). If the assumption of Yamasaki et al. (1982) fails for adsorptive interaction, the adsorption-specific model (Eq. (6)) and the surface-area-normalized gas-particle partition coefficient (K_{pA}) should be used instead of Eq. (8) and K_p . The following approaches for predicting K_p are all on the basis that the assumption of Yamasaki et al. (1982) is tenable. If not, the predicted K_p of adsorptive interaction should be converted to K_{pA} by $K_p = K_{pA} \cdot C_{pA}/\text{TSP} = K_{pA} \cdot A_{tsp}$.

Adsorption-Based Approach for Predicting K_p

In the case of adsorption, Pankow (1987) showed that K_p is inversely proportional to the saturation vapor pressure of the sorbates (P_s) at a specific temperature

$$K_p = \frac{N_s R T A_{tsp} e^{(Q_L - Q_V)/RT}}{P_s} \quad (10)$$

where Q_L and Q_V (kJ/mol) are the enthalpy of desorption from the surface and the enthalpy of vaporization of the adsorbed substance, respectively.

In other words, $\log K_p$ and $\log P_s$ are linearly related at a specific temperature (Cousins and Mackay 2001),

$$\log K_p = m \cdot \log P_s + b \quad (11)$$

where m and b are constants that are dependent on the properties of the corresponding chemicals and airborne particles. Regression of the measured $\log K_p$ against $\log P_s$ at similar temperature could yield the values of m and b for a class

of compounds. For chemicals that are solid in the observed temperature range, the vapor pressure of the subcooled liquid (P_L^0) is used instead of P_s . Theoretically, the value of m should be close to -1.0 but is typically in the range of -0.7 to -1.0 (Cousins and Mackay 2001). Possible reasons for this deviation are sampling artifacts, nonequilibrium partitioning, and the lack of constancy in Q_L and activities within a class of compounds (Cousins and Mackay 2001).

Absorption-Based Approach for Predicting K_p

Pankow (1987, 1998) demonstrated that K_p and the use of P_s as its descriptor was valid both for adsorption and absorption of SVOCs. In the case of absorptive partitioning, Pankow (1998) derived

$$K_p = \frac{f_{om}RT}{10^6 MW_{om}\zeta_{om}P_s} \quad (12)$$

where f_{om} is the fraction of OM in the particles, MW_{om} (g/mol) is the mean molecular weight of OM, and ζ_{om} is the activity coefficient of SVOCs in the OM on a mole fraction basis. ζ_{om} is a function of the properties of SVOCs and the composition of the particle, and characterizes the nonideality of the interaction between gaseous SVOCs and the OM of the particle. The factor of 10^6 accomplishes the unit conversion ($1 \text{ g} = 10^6 \mu\text{g}$).

Finizio et al. (1997) showed that P_s can be replaced with the octanol-air partition coefficient (K_{OA}) of SVOCs. Pankow (1994) and Harner and Bidleman (1998) replaced P_s in Eq. (12) by K_{OA} and obtained

$$K_p = f_{om} \frac{MW_{oct}\zeta_{oct}}{MW_{om}\zeta_{om}10^{12}\rho_{oct}} K_{OA} \quad (13)$$

where MW_{oct} (g/mol) is the molecular weight of octanal, ρ_{om} (g/cm³) is the density of octanol, and ζ_{oct} is the activity coefficient of SVOCs in octanol (*oct*). The factor of 10^{12} accomplishes the unit conversion ($1 \text{ g/cm}^3 = 10^{12} \mu\text{g/m}^3$). According to Eqs. (12) and (13), it can be seen that both K_p and K_{OA} are inversely proportional to P_s . The use of K_{OA} has the advantage that, unlike P_s , K_{OA} can be measured experimentally at ambient temperatures for solid solutes (Cousins and Mackay 2001).

Equation (13) was simplified by Harner and Bidleman (1998) with the assumption that both activity coefficients of SVOCs in octanol and OM and molecular weights of octanal and OM are similar and the octanol density is 0.82 g/cm^3 ,

$$\log K_p = \log K_{OA} + \log f_{om} - 11.91 \text{ or } K_p = 1.22 \times 10^{-12} f_{om} K_{OA} \quad (14)$$

Due to the differences of activity coefficients and molecular weights between octanol and OM, the constant(-11.91) may vary for different pairs of SVOCs and particle compositions and the slope of $\log K_{OA}$ may not be unity in some cases (Finizio et al. 1997; Wei et al. 2016). It also remains uncertain whether octanol can

adequately represent both polar and nonpolar classes of OM in particles (Cousins and Mackay 2001).

There is some debate whether the mechanism of gas-particle interaction is adsorption to active sites on the particle surface or absorption into organic matters in particles, or a combination of both. Pankow (1994) has shown that both absorptive and adsorptive partitioning mechanisms predict a fundamental inverse proportionality between K_p and P_s . Therefore, it is difficult to determine the mechanism of sorption based solely on the dependence of K_p on P_s (Cousins and Mackay 2001). In addition, the reported constants in Eqs. (11) and (14) may be significantly different among studies, and users may encounter difficulties in the selection of constants for the prediction of K_p (Wei et al. 2016). Based on the quantitative error analysis, Salthammer and Schripp (2015) demonstrated that the K_p values calculated on the basis of P_s and K_{OA} can be riddled with substantial error for indoor scenarios. The P_s - and K_{OA} -based approaches may cause high uncertainties for compounds with a K_p in the range of $0.01 \sim 0.1 \text{ m}^3/\mu\text{g}$ although such predictions yield quite reliable results for compounds of very high and very low volatility. However, it is clear that (1) particles of different origin have different sorptive properties, (2) humidity affects sorption, and (3) chemical-to-chemical differences and the effect of temperature can be described by both P_s and K_{OA} (Cousins and Mackay 2001).

Poly-Parameter Approach for Predicting K_p

Apart from the above two single-parameter approaches (P_s or K_{OA} as the single parameter), Salthammer and Goss (2019) applied a more complex approach, the poly-parameter linear free energy relationship (pp-LFER), to predict the gas-particle distribution of 14 SVOCs commonly found in indoor environments.

In contrast to the single-parameter approaches that ignore the intermolecular interactions, the pp-LFER approach uses a suite of five parameters to cover all relevant intermolecular interactions comprehensively. These five parameters are used to include interaction abilities like van der Walls, H-accepting (e-donating) and H-donating (e-accepting), the size of the sorbing compound, and the polarizability (which describes polar interactions that are not covered by the other parameters). Thus, the pp-LFER approach provides a more mechanistic understanding of the partition process, and Salthammer and Goss (2019) suggested that the pp-LFER approach would be a promising alternative for predicting K_p .

According to Goss (2005), the distribution of an organic compound between air and any condensed phase using the pp-LFER approach can be described by

$$K_p (\text{m}^3/\text{g}) = s \cdot S + a \cdot A + b \cdot B + l \cdot L + v \cdot V + c \quad (15)$$

where S , A , B , L , and V are compound-specific descriptors. S is the polarizability, A is the hydrogen bond acidity (donor), B is the hydrogen bond basicity (acceptor), V is the McGowan volume, and L is the logarithmic hexadecane-air partition coefficient ($\log K_{HdA}$). K_{HdA} is the equilibrium partition coefficient of chemicals between hexadecane and air, which is specifically used in the LFERs of Abraham (1993) and Goss (2005) because $\log K_{HdA}$ is proportional to their ability to interact by van

der Waals interactions for all compounds. The sorbent-specific parameters (here: particle-specific), i.e., s , a , b , l , and v , describe the complementary sorbent properties. Together with the fitting constant c , they need to be determined at the given relative humidity (RH) by multiple linear regression using experimental $\log K_p$ values, which is one of the drawbacks of the pp-LFER approach.

The McGowan volume V can be calculated from the molecular structure of the respective target compound following a procedure as described by Abraham and McGowan (1987). L can be determined experimentally by gas chromatography because the retention time of an organic substance is proportional to the stationary phase-gas partition coefficient in an isothermal gas chromatographic system with a suitable, completely nonpolar column (Salthammer and Goss 2019). For many compounds, S , A , and B are available via the UFZ-LSER database (Ulrich et al. 2017). For compounds with unknown descriptors, quantitative structure property relationships (QSPRs) based on structures provided as SMILES24 strings (simplified molecular-input line-entry system) have been developed for S , A , B , and L (Salthammer and Goss 2019). Among these descriptors, Salthammer and Goss (2019) found that the L -value is the single most influential molecular descriptor for the gas-particle interactions of SVOCs, and its accuracy is crucial for the predicted result. Therefore, they emphasized the necessity to determine the L -values of the target SVOCs experimentally although QSPR estimations are available.

According to the comparison results of Salthammer and Goss (2019), K_p 's estimated by the pp-LFER approach tend to be lower than those from the single-parameter approaches in most cases. The K_p value calculated from the pp-LFER approach agrees well with the experimental K_p for DEHP sorbed to pure organic particles (squalane and oleic acid). However, when considering uncertainties of the experimentally determined and calculated predictors as well as the heterogeneity of aerosols, it seems to be unlikely that precise estimates of K_p can be made. Finally, the direct comparison between K_p predicted by the pp-LFER approach (as well as the P_s - and K_{OA} -based approaches) and the measured K_p of SVOCs taken up by realistic indoor particles is still lacking.

Problems

The equilibrium model, i.e., Eq. (8), and the subsequent K_p -predicting approaches are helpful for understanding and describing the gas-particle interaction of indoor SVOCs. Several studies have used Eq. (8) to predict the interaction between gas-phase SVOCs and airborne particles in indoor environments by assuming that the gas-particle interaction has reached the equilibrium (Salthammer and Schripp 2015; Wei et al. 2016, 2017; Weschler et al. 2008). However, the equilibrium assumption should be interpreted with caution since significant deviations have been observed between measured data and predictions based on the equilibrium model (Cao et al. 2018; Shi and Zhao 2012). As predicted by Weschler and Nazaroff (2008) and Liu et al. (2013), the time required for mass transfer between gas-phase SVOCs and airborne particles to reach gas-particle equilibrium (i.e., the critical time for reaching equilibrium) falls in the range of seconds to days (which increases with increasing particle diameter or decreasing SVOC volatility), while the residence time

of indoor airborne particles is just on the order of 1 h (Guo 2013). Thus, the critical time for reaching gas-particle equilibrium can be longer than the residence time of indoor airborne particles. Consequently, the equilibrium between gas-phase SVOCs and airborne particles in the indoor environments is not a reasonable assumption for some cases, especially for less volatile compounds (or SVOCs with high K_{OA}), e.g., DEHP ($K_{OA} = 10^{12.9}$ at 25 °C (Weschler and Nazaroff 2010)). Thus, dynamic models considering the effects of particle residence time, instead of assuming equilibrium, have received increasing attention (Guo 2013; Liu et al. 2013; Shi and Zhao 2012).

Dynamic Models

Diffusion-Based Model

To describe the dynamic interactions between gas-phase SVOCs and airborne particle, Liu et al. (2013) developed a dynamic model involving the time period that airborne particles absorb (or adsorb) gas-phase SVOCs in the indoor air and the transient mass transfer between airborne particles and gas-phase SVOCs. Note, the following contents (the model developed by Liu et al. (2013) and other models derived from it) mainly focused on the organic layer of airborne particles. However, the surface of indoor particles can be either organic or aqueous (depending on the relative humidity [RH] of indoor air and the particle origin). Further study is required to involve the aqueous layer in the dynamic models and consider the effects of indoor RH on the dynamic interactions between gas-phase SVOCs and particles.

After summarizing the morphology observation and model description of airborne particles in the literature, Liu et al. (2013) concluded that the morphologies of various airborne particles may share a similar essential characteristic, i.e., a spherical particle consisting of an impermeable core and a homogenous outer layer that is capable for the adsorptive partitioning of gaseous compounds, as shown in Fig. 1. For SVOCs partitioning to particles, Liu et al. (2013) considered the outer layer as a liquid-like organic matter in the particles. Note, the adsorptive outer layer may not exist for some particles, such as the pure mineral particles. In this case, $R_1 = R_2$ in Fig. 1, the gas-phase SVOCs would be adsorbed on particle surfaces and an adsorption-based dynamic model should be used.

The transient mass transfer processes between gas-phase SVOCs and spherical particles are also shown in Fig. 1. Particles are exposed to air with a constant gas-phase SVOC concentration (C_g). The concentration of SVOCs absorbed in the particles (C_p , $\mu\text{g}/\text{m}^3$, mass of SVOCs per volume of particles) is initially equal to zero. The mass transfer process incorporates two stages, an external one (from bulk air and particle surface) and internal one (intraparticle diffusion between particle surface and inside). Assuming that the physical properties of particles are constant and there is no chemical reaction within particles, Liu et al. (2013) developed a model to describe the transient mass transfer absorption process, with the governing equation, boundary conditions, and initial condition listed below:

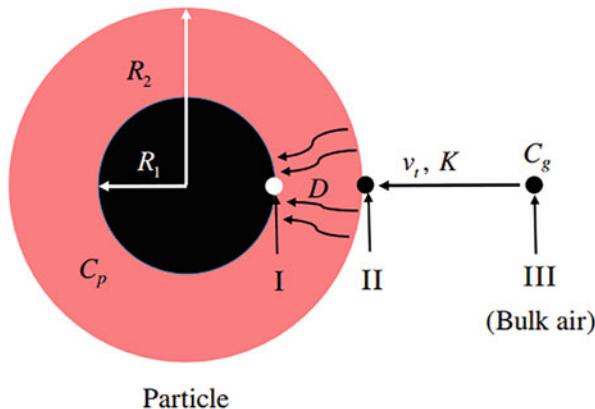

Fig. 1 Schematic of simplified morphology of airborne particles and the transient mass transfer between gas-phase SVOCs and airborne particles. The black region is impermeable for SVOCs. C_g is the SVOC concentration in the air, C_p is the SVOC concentration in a single particle, R_1 is radius of impermeable part, R_2 is radius of the whole particle, v_t is the mass transfer coefficient between air and particle, D is the diffusion coefficient of SVOCs within the particle, and K is the particle-gas partition coefficient (K_{part} in the following text). (Reprinted from Liu et al. (2016), Copyright (2021), with permission from Elsevier)

$$\begin{cases} \frac{\partial C_p}{\partial t} = D \left(\frac{\partial^2 C_p}{\partial r^2} + \frac{2}{r} \frac{\partial C_p}{\partial r} \right), & R_1 < r < R_2 \\ \frac{\partial C_p}{\partial r} = 0, & r = R_1 \\ -D \frac{\partial C_p}{\partial r} = v_t \left(\frac{C_p}{K_{part}} - C_g \right), & r = R_2 \\ C_p(r, t=0) = 0 \end{cases} \quad (16)$$

where t (s) is the time, D (m^2/s) is diffusion coefficient of SVOCs inside the particles, r (m) is radial distance, v_t (m/s) is mass transfer coefficient between gas-phase SVOCs and particles, K_{part} (dimensionless) is particle-gas partition coefficient of SVOCs, R_1 (m) is radius of impermeable part of the particle, and R_2 (m) is radius of the whole particle.

v_t characterizes the uptake rate of gas-phase SVOCs by airborne particles, which depends on the particle size relative to the mean free path of SVOC molecular in the air surrounding the particle. v_t is often estimated by (Cao et al. 2019; Seinfeld and Pandis 2016):

$$v_t = 2 \frac{D_g}{d_p} \cdot F = 2 \frac{D_g}{d_p} \cdot \frac{1 + Kn}{1 + 0.377Kn + 1.33Kn(1 + Kn)/\alpha} \quad (17)$$

where D_g (m^2/s) is the diffusion coefficient of SVOCs in the air; F is the Fuchs-Sutugin correction factor for noncontinuum effects (Seinfeld and Pandis 2016); α is the mass accommodation coefficient of SVOCs; Kn is Knudsen number, which is

determined by $Kn = \frac{3D_g}{d_p} \sqrt{\frac{2M}{2RT}}$; and M (kg/mol) is the SVOC molecular weight. Several other formulas are also available for estimating v_t as listed in Table 12.1 of Seinfeld and Pandis (2016), most of them exhibit the performance similar to Eq. (17). There are two unknown parameters in Eq. (17), D_g and α . D_g of SVOCs can be easily obtained by using experimental data or empirical correlations reported in the literature (Cao et al. 2017; Fuller et al. 1966). α was assumed to be unity ($\alpha = 1$) by Liu et al. (2013). Details about α are introduced in the next subsection “[Methods for Measuring/Estimating Key Parameters](#),” as well as the method for estimating D used by Liu et al. (2013).

Please note the difference between C_{sp} in Eq. (8) (mass of SVOCs per volume of air) and C_p in Eq. (16) (mass of SVOCs per volume of the liquid-like organic matter in a single particle). C_{sp} is a combination of C_p of different sizes of particles (Cao et al. 2018). Additionally, K_{part} is a dimensionless particle-gas partition coefficient of SVOCs, and K_{part} can be converted to K_p (particle-mass-normalized particle-gas partition coefficient) by $K_{part} = K_p \cdot \rho_p$ (ρ_p is the density of particles, $\mu\text{g}/\text{m}^3$).

The analytical solution for Eq. (16) were obtained by Liu et al. (2013):

$$C_p = K_{part} C_g \left(1 - \frac{\sum_{i=1}^{\infty} C_i X_i e^{-\beta_i^2 F_{O_m}}}{R_p} \right) \quad (18)$$

where

$$C_i = 2A \cdot B \quad (19)$$

$$X_i = \beta_i \cos [\beta_i (R_p - R_{12})] + H_1 \sin [\beta_i (R_p - R_{12})] \quad (20)$$

$$A = \left[(\beta_i^2 + H_1^2) \left(1 - R_{12} + \frac{H_2}{\beta_i^2 + H_2^2} \right) + H_1 \right]^{-1} \quad (21)$$

$$B = \left(1 + \frac{H_1}{\beta_i^2} \right) \sin [\beta_i (1 - R_{12})] + \frac{1 - H_1}{\beta_i} \cos [\beta_i (1 - R_{12})] \quad (22)$$

$$H_1 = \frac{1}{R_{12}}, \quad H_2 = \frac{Bi_m}{K_{part}} - 1 \quad (23)$$

$$R_p = \frac{r}{R_2}, \quad R_{12} = \frac{R_1}{R_2} \quad (24)$$

$$F_{O_m} = \frac{Dt}{R_2^2}, \quad Bi_m = \frac{v_t R_2}{D} \quad (25)$$

and β_i ($i = 1, 2, 3, \dots$) is the root of

$$\tan [\beta_i(1 - R_{12})] = \frac{\beta_i(H_1 + H_2)}{\beta_i^2 - H_1H_2}, \quad i = 1, 2, 3, \dots \quad (26)$$

The analytical solution of the diffusion-based dynamic model (Eq. 16) is quite complicated because an infinite series and a transcendental equation are involved in the solution. Additionally, if the gas-particle interaction reaches equilibrium, the equilibrium SVOC concentration in the particle will equal $K_{part}C_g$, i.e., $C_{p, equ} = K_{part}C_g$. Therefore, much more input parameters are required in the dynamic model as compared to the equilibrium model. According to Eqs. (18), (19), (20), (21), (22), (23), (24), (25), and (26), the SVOC concentration in the particle, C_p , takes the function form: $C_p = f(C_g, K_{part}, D, v_t, R_1, R_2, r, t)$. Therefore, six additional parameters are required to solve the diffusion-based dynamic model (except for K_{part} and C_g). Nevertheless, the diffusion-based dynamic model provides a clear mathematical description of the transient mass transfer between gas-phase SVOCs and airborne particles.

Simplified Model Based on Lumped Parameter Method

As indicated in Fig. 1, the mass transfer process between gas-phase SVOCs and airborne particles incorporates two parts, the external one from air to particle surface and the internal one via intraparticle diffusion. According to Eq. (16), it is the intraparticle diffusion that complicates the model. Therefore, the dynamic model may be greatly simplified if the intraparticle diffusion can be ignored. Weschler and Nazaroff (2008) compared the estimated timescales for the internal process to that for the external one for the organic constituents of airborne particles. They concluded that for airborne particles with a diameter smaller than 2 μm , it was the external process that dominated the partitioning process. Additionally, the kinetic evaporation of secondary organic aerosol and other organic aerosols in a thermodenuder was examined by including only the external mass transfer process (Cappa 2010).

In order to judge whether the internal or the external process dominates the dynamic gas-particle interaction, Liu et al. (2013) defined the following parameter:

$$\varepsilon = \frac{K_{part}C_g - C_p(R_2)}{K_{part}C_g - C_p(R_1)} \quad (27)$$

which represents the ratio of the concentration difference between particle surface and gas phase (external concentration difference) to the concentration difference between the innermost of the organic outer layer and gas phase (total concentration difference).

If ε is greater than 0.95, the external concentration difference accounts for more than 95% of the total concentration difference. Liu et al. (2013) considered that in such a situation, the external process was dominant, and the spatial concentration distribution inside the organic layer on this particle could be considered as uniform. Under such condition, the lumped parameter method (LPM), which lumps concentration

distribution inside the particle into one value, can be applied to address the gas-particle transient mass transfer problem.

The LPM is briefly introduced here. In mass transfer, the Biot number divided by the partition coefficient is defined as the ratio of internal mass transfer resistance to external mass transfer resistance, i.e., the Little number (Lt) (Zhang et al. 2016):

$$Lt = \frac{Bi_m}{K_{part}} = \frac{v_t L}{DK_{part}} < 0.1 \quad (28)$$

where Bi_m (dimensionless) is the Biot number for mass transfer and L (m) is the characteristic length (typically equals R_2 for a spherical particle). When this characteristic number (Lt) is smaller than 0.1 (Liu et al. 2013, 2016), the concentration difference between the surface of the particle (point II in Fig. 1) and the innermost of the organic layer of the particle (point I in Fig. 1) is less than 5% of the difference between gas phase (point III in Fig. 1) and the innermost of the organic layer of the particle (point I in Fig. 1). That is, the value of ϵ defined in Eq. (27) will be greater than 0.95 when $Lt < 0.1$. According to the analysis of Liu et al. (2013), Lt for SVOCs commonly found in the realistic environments (for particles in the size range of 0.01–10 μm) is significantly smaller than the critical value for the use of LPM ($Lt < 0.1$), as indicated in Fig. 2.

Overall, the above analysis indicates that the intraparticle mass transfer resistance can be neglected for gas-particle interaction of SVOCs, and the diffusion-based dynamic model (Eq. 16) can be simplified to only include the external mass transfer process:

$$V_p \frac{dC_p}{dt} = v_t A_p \left(C_g - \frac{C_p}{K_{part}} \right) \quad (29)$$

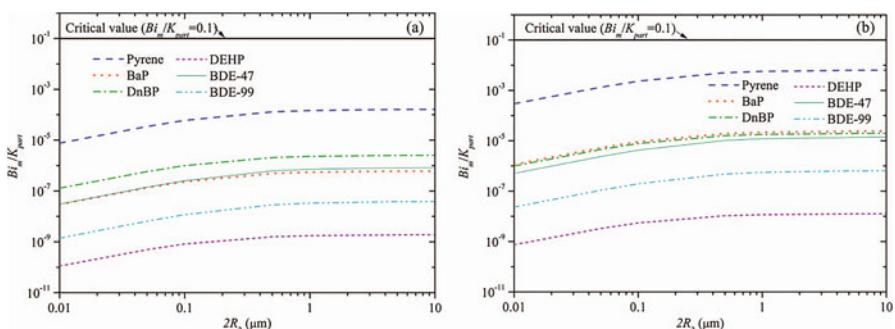

Fig. 2 For six commonly identified SVOCs indoors, comparison between calculated Bi_m/K_{part} and the critical value for neglecting the internal mass transfer resistance (0.1). X-axis: particle diameter. The fraction of absorptive volume in the particles equals 1 for both (a) and (b). (a) Nonporous particles, the volumetric fraction of organic materials equals 1. (b) Porous particles, the volumetric fraction of organic materials equals 0.3, and the volumetric fraction of elemental carbon equals 0.05. (Reprinted from Liu et al. (2013), Copyright (2021) @ The American Association for Aerosol Research, with permission from Taylor & Francis Ltd)

where V_p (m^3) and A_p (m^2) are the volume and surface area of a single particle. If the particle is treated as a sphere, $V_p = \frac{\pi}{6}d_p^3$ and $A_p = \frac{\pi}{4}d_p^2$ (where d_p [m] is the particle diameter, $d_p = 2R_2$ in Fig. 1).

Assuming that the SVOC concentration in the particle (C_p) is initially equal to zero, the analytical solution to Eq. (29) is:

$$C_p = K_{part}C_g(1 - e^{-\varphi t}) \quad \text{with} \quad \varphi = \frac{v_t A_p}{V_p K_{part}} = \frac{3v_t}{R_2 K_{part}} = \frac{6v_t}{d_p K_{part}} \quad (30)$$

where φ (s^{-1}) is the characteristic parameter that governs the timescale of SVOC gas-particle interactions. When C_p reaches 95% of the equilibrium concentration ($K_{part}C_g$), equilibrium can be considered to have been attained. Using this criterion, the critical time required for the attainment of equilibrium, t_c ($1 - e^{-\varphi t_c} = 0.95$, i.e., $\varphi t_c = -\ln 0.05 \approx 3$), is

$$t_c \approx 3\varphi^{-1} = \frac{d_p K_{part}}{2v_t} \quad (31)$$

Comparing Eq. (30) to Eq. (18), it can be seen that the analytical solution of LPM-based model is much simpler than that of the diffusion-based model. In addition, the number of input parameters of the LPM-based model decreases to 5 (C_g , K_{part} , v_t , R_2 , t) compared to that of the diffusion-based model (8 parameters). All these five parameters (C_g , K_{part} , v_t , R_2 , and t) can be directly measured or estimated. Due to the relatively simple function form and availability of parameters, the LPM-based model (Eq. 30) has been frequently used to describe the dynamic interaction between gas-phase SVOCs and airborne particles (Eichler et al. 2021). By comparing the experimental data (measured indoor gas-phase and particle-phase concentrations of polycyclic aromatic hydrocarbons) with model predictions, Shi and Zhao (2012) proved that the predictions of the LPM-based model agreed well with the experimental data.

It should be noted that C_p is the SVOC concentration within a single particle (mass of SVOCs per volume of a particle), while the particle-phase SVOC concentrations in the indoor air are always measured in the form of SVOC mass per volume of air (C_{sp}). Therefore, the prediction of Eq. (30) should be converted to C_{sp} by combining C_p of different sizes of particles (Cao et al. 2018),

$$C_{sp} = \int \frac{\partial \left(V_p \sum_{j=1}^{N_p} C_{pj} \right)}{\partial d_p} dd_p = \int \frac{\partial (N_p V_p \bar{C}_p)}{\partial d_p} dd_p = \frac{\text{TSP}}{\rho_p} \int \frac{\partial (\alpha_v \bar{C}_p)}{\partial d_p} dd_p \quad (32)$$

where N_p ($1/\text{m}^3$ (room volume)) is the number concentration of airborne particles with a specific diameter; the subscript j represents the j th particle ($j = 1 \sim N_p$) with a

specific diameter; α_V is the volume fraction of airborne particles with a specific diameter, $\alpha_V = N_p V_p / V_{tp}$; V_{tp} (m^3 (particle volume)/ m^3 (room volume)) is the total volume concentration of indoor airborne particles, $V_{tp} = \text{TSP}/\rho_p$; and \bar{C}_p is the mean C_p for all particles with a specific diameter; according to Eq. (30) we can get:

$$\bar{C}_p = \sum_{j=1}^{N_p} C_{p,j} / N_p = K_{part} C_g \sum_{j=1}^{N_p} \left(1 - \exp \left(-3 \frac{t_j}{t_{c,j}} \right) \right) / N_p \quad (33)$$

Note that, in most studies of dynamic models for indoor airborne SVOCs, t in Eq. (33) has always been regarded as the mean residence time of airborne particles in the indoor air (designated as $\bar{\tau}_r$), i.e., $\bar{C}_p = K_{part} C_g \sum_{j=1}^{N_p} \left(1 - \exp \left(-3 \frac{\bar{\tau}_{r,j}}{t_{c,j}} \right) \right) / N_p$ (Liuet al. 2013). If the indoor air is well mixed, $\bar{\tau}_r$ can be estimated by

$$\bar{\tau}_{r,j} = (ACH + \beta_j)^{-1} \quad (34)$$

where ACH (s^{-1}) is the air exchange rate of the room and β (s^{-1}) is the first-order deposition loss rate coefficient of airborne particles (which is size dependent).

Because the airborne particles can only be measured in several size bins, the integration in Eq. (32) can be replaced by the summation of different size bins, and noting that $K_{part} = K_p \cdot \rho_p$, we can get:

$$\begin{aligned} C_{sp} &= \frac{\text{TSP}}{\rho_p} \sum_{i=1}^n \alpha_{V,i} \bar{C}_{p,i} = K_p \cdot C_g \cdot \text{TSP} \sum_{i=1}^n \alpha_{V,i} \left(1 - \exp \left(-3 \frac{\bar{\tau}_{r,i}}{t_{c,i}} \right) \right) \\ &= \eta \cdot K_p \cdot C_g \cdot \text{TSP} \end{aligned} \quad (35)$$

where the subscript i represents the i th particle size bin ($i = 1 \sim n$, n is the number of particle size bins) and η is the ratio of C_{sp} estimated by the dynamic model to C_{sp} estimated by the equilibrium model. Because $\sum_i \alpha_{V,i} = 1$ and $1 - \exp \left(-3 \frac{\bar{\tau}_{r,i}}{t_{c,i}} \right) < 1$, it is easy to find that $\eta < 1$.

Dynamic Model Involving Intraparticle Reaction of SVOCs

The above models assume that there is no chemical reaction for SVOCs within the airborne particles. While in the diffusion process within the particles, several SVOCs (as well as other particle-associated compounds) may experience further chemical reactions (Liu and Cao 2018; Zhou et al. 2013). Therefore, Liu and Cao (2018) further provided a dynamic partitioning model of SVOCs by considering intraparticle diffusion, particle-phase reaction, and external mass transfer from bulk air to particle surfaces. Assuming that the intraparticle reaction follows the first-order chemical reactions and the whole particle is absorptive for SVOCs (i.e., $R_1 = 0$), the governing equations for SVOCs in airborne particles and boundary conditions and initial conditions are as follows (Liu and Cao 2018):

$$\begin{cases} \frac{\partial C_p}{\partial t} = D \left(\frac{\partial^2 C_p}{\partial r^2} + \frac{2}{r} \frac{\partial C_p}{\partial r} \right) - k_c C_p, & 0 < r < R_2 \\ \frac{\partial C_p}{\partial r} = 0, & r = 0 \\ -D \frac{\partial C_p}{\partial r} = v_t \left(\frac{C_p}{K_{part}} - C_g \right), & r = R_2 \\ C_p(r, t = 0) = 0 \end{cases} \quad (36)$$

where k_c (1/s) is a first-order rate constant and the term $-k_c C_p$ represents the rate of particle-phase chemical reaction.

The analytical solution for Eq. (36) were obtained as:

$$C_p = -\frac{K_{part} C_g}{R_p} \left[G_1 \left(e^{-R_p \sqrt{q}} - e^{-R_p \sqrt{q}} \right) + e^{-q F_{O_m}} \sum_{i=1}^{\infty} \left(e^{-\beta_i^2 F_{O_m}} C_i X_i \right) \right] \quad (37)$$

where

$$q = \frac{k_c R_2^2}{D} \quad (38)$$

$$G_1 = -\frac{1 + H}{\sqrt{q} e^{\sqrt{q}} + \sqrt{q} e^{-\sqrt{q}} + H e^{\sqrt{q}} - H e^{-\sqrt{q}}}, \quad H = \frac{Bi_m}{K_{part}} - 1 \quad (39)$$

$$\begin{aligned} C_i &= 2 A_i B_i, \quad A_i = \frac{\beta_i^2 + H^2}{\beta_i^2 + H^2 + H}, \quad B_i \\ &= -G_1 \frac{\frac{\sqrt{q} \sin \beta_i}{\beta_i^2} (e^{\sqrt{q}} + e^{-\sqrt{q}}) - \frac{\cos \beta_i}{\beta_i} (e^{\sqrt{q}} - e^{-\sqrt{q}})}{1 + q/\beta_i^2} \end{aligned} \quad (40)$$

$$X_i = \sin(\beta_i R_p) \quad (41)$$

and β_i ($i = 1, 2, 3, \dots$) is the root of

$$\beta_i \cot \beta_i = -H, \quad i = 1, 2, 3, \dots \quad (42)$$

The parameter, q , is designated as the dimensionless chemical term, which characterizes a ratio of diffusion timescale (R_2^2/D) to reaction timescale ($1/k_c$). Compared to the diffusion-based model for gas-particle interaction with the absence of chemical reactions, the above model (Eqs. 36, 37, 38, 39, 40, 41, and 42) is also very complicated. Furthermore, another parameter (k_c) is required for solving this model.

Similar to the simplification of Eq. (16) to Eq. (29), the above complicated diffusion-based model can also be simplified using the lumped parameter method. If ε defined in Eq. (27) is greater than 0.95, the above model (Eqs. 36, 37, 38, 39, 40, 41, and 42) can be simplified as:

$$V_p \frac{dC_p}{dt} = v_t A_p \left(C_g - \frac{C_p}{K_{part}} \right) - k_c V_p C_p \quad (43)$$

The analytical solution of Eq. (43) is:

$$\begin{aligned} C_p &= \frac{C_g}{M} (1 - e^{-MNt}), \text{ with } M = \frac{1}{K_{part}} + \frac{V_p k_c}{A_p} = \frac{1}{K_{part}} + \frac{k_c R_2}{3}, \text{ } N = \frac{v_t A_p}{V_p} \\ &= \frac{3v_t}{R_2} \end{aligned} \quad (44)$$

It can be seen that Eq. (44) can be converted into Eq. (30) in the absence of particle-phase reactions ($k_c = 0$). In addition, Liu and Cao (2018) found that the critical value of Lt for the use of the lumped parameter method ($(Lt)_{cr}$) can be greater with the presence of particle-phase reactions, i.e., $(Lt)_{cr}$ increases as q (or k_c) increases (chemical reaction gets more intense). Particularly, impact of chemical reactions on $(Lt)_{cr}$ becomes significant for q higher than 10. $(Lt)_{cr}$ changes little for q smaller than 10. $(Lt)_{cr}$ approaches 0.1 as q decreases. This is in sharp contrast with the case when chemical reaction is absent, for which $(Lt)_{cr}$ is a constant of 0.1 (see the above analysis related to Eq. (28)). Overall, the results of Liu and Cao (2018) indicate that taking particle-phase reaction into consideration allows a wider range to neglect intraparticle diffusion.

However, most of existing studies about the dynamic interactions between gas-phase SVOCs and indoor airborne particles ignores the particle-phase reactions, and the models involving chemical reactions (Eq. (36) and/or Eq. (43)) had not been applied for the gas-particle interactions in indoor environments, mainly due to the limited information about the particle-phase reaction rate constant (k_c). Further studies are therefore required for characterizing the particle-phase reactions of indoor SVOCs, especially quantifying the values of k_c .

Adsorption-Based Model

The above models all assume that the gas-particle interaction is dominated by absorption. However, the particles may be in semi-solid or solid states under some conditions, e.g., inorganic particles at low humidity (Shiraiwa et al. 2011), inorganic particles generated by laboratory apparatus (Cao et al. 2019; Wu et al. 2018), or organic particles at low temperature (Liu and Cao 2018). In these cases, SVOCs tend to accumulate on the particle surfaces, instead of diffusing into the particles, and the gas-particle interaction is more suitable to be described as surface adsorption (i.e., $R_1 = R_2$ in Fig. 1).

If the surface adsorption occurs, the corresponding dynamic model can be expressed as:

$$A_p \frac{dC_{pA}}{dt} = v_t A_p \left(C_g - \frac{C_{pA}}{K_{pA}} \right) \quad (45)$$

where C_{pA} ($\mu\text{g}/\text{m}^3$) is the SVOC concentration on the surface of a single particle.

The analytical solution to Eq. (45) is:

$$C_{pA} = K_{pA} C_g \left(1 - e^{-\frac{v_t t}{K_{pA}}} \right) \quad (46)$$

Methods for Measuring/Estimating Key Parameters

According to the above models, several parameters are required to be known before predicting the relationship between C_g and C_{sp} (or C_p) of indoor SVOCs with the absence of particle-phase reactions. They are the particle-gas partition coefficient (K_p or K_{par}) in both the equilibrium model and dynamic models, the mass transfer coefficient between bulk gas-phase SVOCs and particles (v_t) in the dynamic models, the diffusion coefficient of SVOCs inside the particles (D) in the diffusion-based dynamic model, the size distribution of airborne particles (α_V) for the dynamic models, the mass concentration of airborne particles (TSP) in all models, and the air exchange rate of the room (ACH) and the first-order deposition loss rate coefficient of airborne particles (β) to get the mean residence time of airborne particles. Among these parameters, α_V and TSP can be directly obtained by using particle sizers, such as the laser particle sizer and/or scanning electrical mobility sizer. ACH is always a routine parameter used for indicating the indoor air quality, which can be easily measured by releasing inert gases without indoor sources (e.g., SF₆ and CO₂ [without people in the room]) into the room and monitoring the decay rate of the released gases. v_t can be predicted using Eq. (17) if the mass accommodation coefficient (α) is known. The remained parameters, K_p , D , β , as well as α , should be adequately predicted or/and measured.

Particle-Gas Partition Coefficient (K_p)

Except for the estimation approaches introduced above (Eqs. 10, 11, 12, 13, 14, and 15), the values of K_p can also be obtained by measurements. In existing studies, the methods commonly used to measure K_p for indoor SVOCs are based on the equilibrium model, e.g., C_{sp} , C_g , and TSP in the realistic environments are measured simultaneously and K_p is calculated by $C_{sp}/(C_g \cdot \text{TSP})$ (Wang et al. 2014). According to Eq. (35), K_p measured in this way actually equals $\eta \cdot K_p$ ($\eta < 1$), which may significantly vary among homes with different ACH s since η tends to decrease as ACH increases (Cao et al. 2018).

Benning et al. (2013) was the first to quantify K_p of SVOCs after the interaction between gas-phase SVOCs and particles reaches equilibrium in a well-controlled chamber. However, the accuracy may be reduced by the complexity of the air velocity field within the chamber if the equilibrium cannot be attained at the chamber outlet, especially for SVOCs with greater K_p and airborne particles with larger diameters (as K_p or d_p increase, the critical time for equilibrium may be longer than the particle residence time in the chamber) (Cao et al. 2018; Wu et al. 2018).

To simplify the air velocity field and control the residence time of particles within the chamber, Wu et al. (2018) proposed a novel method for measuring K_p using a

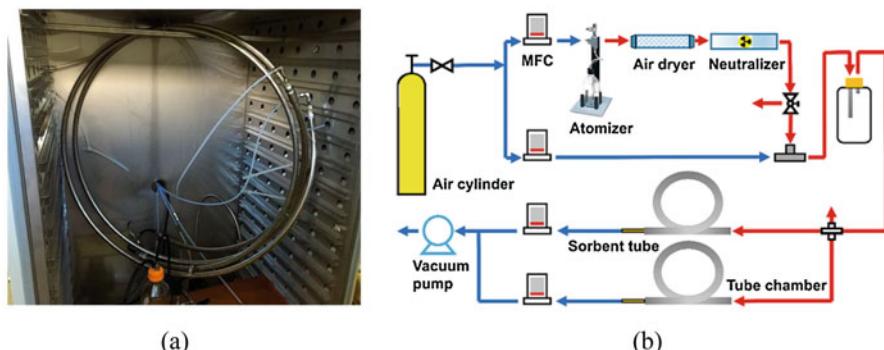

Fig. 3 The experimental setup for measuring K_p developed by Wu et al. (2018). (a) Photo and (b) schematic representation of the experimental setup with inorganic particle introduction. (Reused with permission from Wu et al. (2018). Copyright (2021) American Chemical Society)

laminar flow tube chamber (inner diameter: 1.72 cm, length: 3.60 m) coated with a thin layer of pure SVOC liquid on the inner surface as shown in Fig. 3.

Particle-laden air (polydisperse particles with median diameter in the ranges of 40–170 nm) at a controlled flow rate, which ensures air flow in the chamber is laminar, was introduced into the chamber. Two sorbent tubes were connected in parallel to the chamber outlet, one with a filter measuring the effluent C_g , the other without a filter measuring the sum of C_g and C_{sp} (i.e., $C_{tot} = C_g + C_{sp}$), with effluent C_{sp} obtained as $C_{tot} - C_g$. Given that the tube was sufficiently long, equilibrium between gas-phase SVOCs and particles was attained at the chamber outlet, and K_p was determined by $C_{sp}/(C_g \cdot TSP)$. However, for the cases of particles with larger diameters or SVOCs with higher K_p , significant uncertainty may be still introduced in the determined K_p because equilibrium might not be attained at the chamber outlet. In addition, integration of measurement errors of C_g and C_{sp} may also reduce the accuracy of K_p because separating C_g and C_{sp} experimentally is a challenge for SVOCs (Benning et al. 2013; Wang et al. 2015; Weschler and Nazaroff 2010). For example, measurement of C_g using sorbent tubes with a filter may be biased, with C_g underestimated due to sorption of gas-phase SVOCs to the filter or overestimated due to penetration of particles into the sorbent and the volatilization of SVOCs from the collected particles (Wang et al. 2015).

Cao et al. (2019) modified the method of Wu et al. (2018) by using a shorter tube (inner diameter: 1.72 cm, length: 0.30 m). A model (combining the above dynamic model for gas-particle interaction, Eq. (29), and the model describing the mass transfer of gaseous SVOCs in the chamber) was established to describe the dynamic mass transfer of SVOCs in the tube. The total airborne SVOC concentration (C_{tot}) was measured at the tube outlet. K_p was obtained by fitting the model to the measured C_{tot} (as well as particle size distribution and concentration). In this way, the requirements to reach equilibrium before the chamber outlet and to separate C_g and C_{sp} can be eliminated. However, the mass accommodation coefficient of SVOCs on particle surface

(α) should be known when applying this method to determine K_p , which would strongly limit its application for the cases where α is not available (as discussed below).

The above chamber methods have only been applied to measure K_p of DEHP sorbed by generated particles (inorganic: $(\text{NH}_4)_2\text{SO}_4$ particles, and organic: pure squalane and oleic acid particles). DEHP was selected as the target SVOC because it is ubiquitous in the indoor environment (Weschler and Nazaroff 2008) and because of the very low gas-phase concentration that means that the experiments are realistically challenging (Cao et al. 2017; Liang and Xu 2014). If accurate results can be obtained for DEHP, the proposed method should also be applicable to SVOCs with higher gas-phase concentrations because measurements are considered to be easier and more accurate (Xu et al. 2012). However, the K_p values measured in these studies exhibit relatively low reproducibility in parallel measurements and high inconsistency among different studies. For example, K_p of DEHP for the oleic acid particles was measured to be $0.23 \pm 0.13 \text{ m}^3/\mu\text{g}$ ($n = 8$) with a relative standard deviation of 57% by Wu et al. (2018). The situation was even worse for squalane particles ($K_p = 0.11 \pm 0.10 \text{ m}^3/\mu\text{g}$ [$n = 10$], with a relative standard deviation of 91%). The differences may be mainly caused by the unstable concentration and size distribution of the generated particles and the measurement uncertainty related to the SVOC concentrations. Therefore, further study is required to improve the method accuracy for measuring K_p and to measure K_p for more SVOC-particle pairs in the indoor environments.

Mass Accommodation Coefficient of SVOCs on Particle Surface (α)

When gas molecules strike the particle surface, the gas molecules can either be reflected (diffusely or specularly) or taken up at the surface (Davis 2006). The mass accommodation coefficient (α , also referred to as the evaporation coefficient at equilibrium) is defined as the probability that an SVOC molecule striking the particle surface is captured by the particle (Cao et al. 2019). Due to limited information about its value, α in Eq. (17) is always assumed to be unity in existing studies (Liu et al. 2013; Weschler and Nazaroff 2008). Under this condition, Eq. (17) can be simplified as:

$$v_t = 2 \frac{D_g}{d_p} \cdot \frac{1 + Kn}{1 + 1.71Kn + 1.33Kn^2} \quad (47)$$

However, some measurements of α have obtained values significantly smaller than unity (e.g., 0.28–0.46 (Saleh et al. 2012)). According to Eq. (17), the overall gas-particle transport rate (i.e., v_t) tends to decrease as α decreases (the decreasing tendency is more significant for smaller particles), as depicted in Fig. 4a. In addition, the value of η in Eq. (35) will increase as α increases, as shown in Fig. 4b for various K_p . This means that assuming α to be unity may lead to an overestimation of the particle-phase concentration (C_{sp}) estimated by Eq. (35) if the actual α is lower than unity. Taking DEHP as an example, C_{sp} will be overestimated by 20% if α equals 0.2 and K_p equals $0.1 \text{ m}^3/\mu\text{g}$ (for the interaction between DEHP and organic

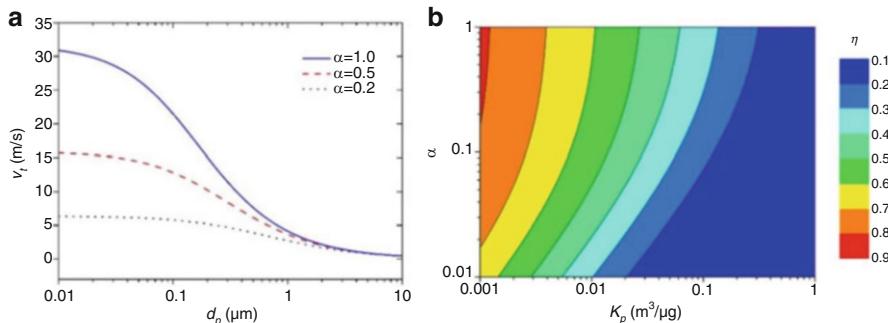

Fig. 4 (a) Gas-particle mass transfer coefficient of SVOCs (ν_t) as a function of particle diameter (d_p) for various mass accommodation coefficients (α). For the calculation, DEHP was selected as the target SVOC ($M = 391$ g/mol and $D_g = 2.64 \times 10^{-6}$ m²/s (Wu et al. 2018)), and temperature was set to 25 °C. (b) Value of η in Eq. (35) for various partition coefficients (K_p) and mass accommodation coefficients (α). The particle size distribution (α_s) measured by Yang et al. (2014) was used for the calculation. The air change rate of the room (ACH) was set as 0.5 h⁻¹. The particle deposition rate (β) was calculated from the empirical equation provided by Cao et al. (2018). (Reprinted from Cao et al. (2019), Copyright (2021) @ The American Association for Aerosol Research, with permission from Taylor & Francis Ltd)

particles (Wu et al. 2018)), i.e., $C_{sp} = 0.30K_p \cdot C_g \cdot \text{TSP}$ when $\alpha = 0.2$ vs. $C_{sp} = 0.36K_p \cdot C_g \cdot \text{TSP}$ if $\alpha = 1$. Consequently, selecting a correct α value in Eq. (17) may be helpful for accurately predicting the $C_g - C_{sp}$ relationship using the dynamic model, especially for particles with diameter less than 100 nm.

Two types of methods have generally been used to measure α . In both, α was obtained by fitting the corresponding models to the monitored dynamic response of d_p (particle diameter) or C_g of the target species to perturbations in the gas-particle equilibrium. The perturbations were achieved either by heating the particles generated in a cold environment (e.g., heated from 10 °C to 30 °C) (Cappa 2010; Saleh et al. 2012) or by injecting particles into an environment with a steady gas-phase concentration of the target species (Jefferson et al. 1997). One challenge associated with these methods is that the sorption of gas-phase species to the chamber walls is neglected. The wall loss may strongly affect the dynamic response to the perturbations and neglecting this effect may lead to uncertainty in the measured α (Cappa 2010; Ye et al. 2016). The wall loss effect may be even more significant for SVOCs which partition strongly to chamber walls such as DEHP (Xu and Little 2006), and thus may limit the applications of these methods to measure α for these SVOCs. The other challenge is that for some methods using a flow tube (also referred to as a thermodenuder) (Cappa 2010), gas-phase SVOCs were assumed to be uniformly distributed in the cross-section of the tube, which is not representative of actual conditions (Wu et al. 2016) and may lead to variations in the measured results.

Cao et al. (2019) proposed a tube chamber method for measuring α to overcome the limitations of these methods. Taking the interaction between DEHP and

$(\text{NH}_4)_2\text{SO}_4$ particles (with diameters in the range of 10–600 nm) as an example, the value of α was measured to be 0.20 ± 0.05 by Cao et al. (2019), preliminarily implying that assuming α to be unity may not be suitable for modeling the dynamic interaction between SVOCs and airborne particles. However, their method requires the knowledge of K_p , which may again limit the use of their method because K_p is also subject to considerable uncertainties as discussed above. Overall, further studies are required to quantify the uncertainty caused by assuming α as unity and to develop an accurate and simple method for measuring α of indoor SVOCs on airborne particles.

Intraparticle Diffusion Coefficient of SVOCs (D)

The method for estimating D used by Liu et al. (2013) is introduced here. For porous particles, D can be calculated with the following formula according to Weber and Digiano (1996):

$$D = \frac{D_l/\tau}{1 + \frac{(1-\alpha_p)K_{sl}}{\alpha_p}} \quad (48)$$

where D_l (m^2/s) is the diffusion coefficient in the free liquid, τ is tortuosity of particles, α_p is porosity of particles, and K_{sl} is the partition coefficient between the liquid in the pore and the pore material. Levin (1980) used the following correlation to estimate D_l :

$$D_l M^{0.5} = \text{constant} \quad (49)$$

Theis et al. (2001) experimentally determined the diffusion coefficient of benzene, toluene, ethylbenzene, and o-xylene in octanol at 25 °C. The constant in Eq. (49) from D_l and M of these chemicals is $(1.1 \pm 0.11) \times 10^{-10}$.

A common method to estimate the tortuosity of particles (τ) was provided by Wakao and Smith (1962):

$$\tau = \frac{1}{\alpha_p} \quad (50)$$

The value of porosity of particles (α_p) has been used as 0.5 in Eqs. (48) and (50) by Liu et al. (2013).

Assuming that the organic liquid and the pore material behave like octanol and elemental carbon (EC), respectively, K_{sl} can be calculated with the following formula (Liu et al. 2013):

$$K_{sl} = K_{EC_o} = \frac{K_{EC_w}}{K_{ow}} \quad (51)$$

where K_{EC_o} and K_{EC_w} are the partition coefficients between EC and octanol and water, respectively, and K_{ow} is the partition coefficient between octanol and water.

Table 1 Intraparticle diffusion coefficient of six typical SVOCs obtained by Liu et al. (2013)

SVOCs	Pyrene	BaP	DnBP	DEHP	BDE-47	BDE-99
$D \times 10^{11}$ (m ² /s)	0.0777	0.0350	9.08	8.39	2.24	2.40

BaP: benzo(a)pyrene; DnBP: di-n-butyl phthalate; DEHP: di(2-ethylhexyl) phthalate; BDE: brominated diphenyl ethers

With Eqs. (48), (49), (50), and (51), D 's of six SVOCs commonly found indoor were estimated to be in the range of $10^{-13} \sim 10^{-10}$ m²/s by Liu et al. (2013), as listed in Table 1.

Up to now, relatively few studies have been focused on the estimation and measurement of D . The above method for estimating D can be treated as a rough estimation and may be subject to huge uncertainty. Nevertheless, we may not necessarily need to know the accurate value of D for the gas-particle interaction of indoor SVOCs because the intraparticle diffusion can be reasonably neglected for both porous and nonporous particles with a diameter between 0.01 and 10 μm according to Liu et al. (2013), as discussed above.

Deposition Loss Rate Coefficient of Airborne Particles (β)

The deposition rate of airborne particles (β) is synthetically affected by particle size, gravitational settling, Brownian and turbulent diffusion, turbophoresis, thermophoresis (if there is a temperature difference), and diffusiophoresis (if there is a humidity difference). Several models have been established to predict β of indoor airborne particles under different conditions (Lai and Nazaroff 2000; Zhao and Wu 2006). ► Chap. 11, “Deposition,” of this handbook gives detailed discussions about deposition of airborne particles in indoor environments.

For the simplification of applications, Cao et al. (2018) provided a formula to estimate β by fitting the measured data from various studies (measured indoors) summarized by Riley et al. (2002):

$$\begin{aligned} \log \beta = & 0.00911(\log d_p)^6 + 0.0952(\log d_p)^5 + 0.0190(\log d_p)^4 - 0.536(\log d_p)^3 \\ & + 0.327(\log d_p)^2 + 1.53 \log d_p - 4.20 \end{aligned} \quad (52)$$

where the units of β and d_p are s⁻¹ and μm, respectively.

Interaction Between Gas-Phase Pollutants and Settled Dust

Overall

Settled dust are deposited particles on surfaces and always is a heterogeneous matrix. Indoor settled dust may incorporate harmful chemicals either by adsorption of gas phase, partitioning between dust and source material if dust is deposited on source

surface, or deterioration of indoor materials or consumer products (including microplastics in some cases). Due to its large specific area, settled dust is an important transfer and storage medium of indoor chemical pollutants (Bi 2018). The mixture of chemicals frequently detected in indoor settled dust include (Melymuk et al. 2020):

- Plastic additives: flame retardants (including polybrominated diphenyl ethers, hexabromocyclododecanes, and organophosphate ester flame retardants) and plasticizers (mainly phthalate esters and their alternatives)
- Polymer components such as bisphenols (bisphenol A, F, S, and AF) and alkylphenols
- Personal care and cleaning product components: parabens, synthetic fragrance compounds, triclosan, siloxanes, and UV filters
- Perfluorinated alkyl substances (PFASs) and related fluorinated compounds
- Pesticides: both banned “legacy” pesticides (like DDT and hexachlorocyclohexanes) and currently used pesticides (such as chlorpyrifos and permethrin)
- Industrial compounds, such as polychlorinated biphenyls (PCBs) and chlorinated paraffins
- Combustion by-products, e.g., polycyclic aromatic hydrocarbons, poly-chlorinated dibenzo-p-dioxins/dibenzofurans, and degradation products (e.g., polybrominated dibenzo-p-dioxins/dibenzofurans), and related compounds (e.g., nicotine)
- Heavy metals, particularly lead

According to the definition of SVOCs by Weschler and Nazaroff (2008), i.e., organic compounds with vapor pressures between 10^{-9} and 10 Pa, most of the above chemicals are SVOCs (except for heavy metals). This behavior can be expected because the relatively low volatility of SVOCs leads to their strong partitioning from gas phase to dust.

The highly contaminated dust may result in significant human exposure to chemicals by ingestion via hand-to-mouth or hand-to-object-to-mouth contact, inhalation of re-suspended particles, or dermal penetration by contact, as discussed in ► Chap. 35, “Exposure Routes and Types of Exposure” of this handbook. Particularly, Glorennec et al. (2021) pointed out that dust ingestion can be a strong contributor to total dust exposure for brominated flame retardants, certain phthalates, and polycyclic aromatic hydrocarbons. Therefore, Glorennec et al. (2021) further suggested to consider an indoor settled dust guideline as part of a policy to reduce exposure indoors to a given chemical or group of chemicals.

Settled dust that is sampled from floors, mattresses, moldings, and shelves has been widely used as an indicator for indoor pollutants (especially for SVOCs), due to its merits of low cost to collect and high concentrations of chemical pollutants (Melymuk et al. 2020). Indoor settled dust can often be regarded as a “passive sampler” for assessing the levels and human exposure of indoor pollutants. Therefore, it is of great importance to understand the transport of

SVOCs to settled dust, including the interaction between gas-phase SVOCs and settled dust.

Equilibrium Model

Similar to airborne particles, an equilibrium model was also often used to describe the interaction between gas-phase SVOCs and settled dust. Thus, SVOC concentration in settled dust is linearly correlated with gas-phase SVOC concentration by assuming that the gas-dust interaction reaches equilibrium immediately (Weschler and Nazaroff 2010),

$$X_{dust} = K_d C_g \quad (53)$$

where X_{dust} ($\mu\text{g/g}$) is the mass fraction of SVOCs in settled dust and K_d (m^3/g) is the dust-air partition coefficient of SVOCs.

Weschler and Nazaroff (2010) compared X_{dust} predicted by Eq. (53) to the measured median data reported in literature for 66 different SVOCs whose K_{OA} span more than five orders of magnitude. Even though the predictions correlated reasonably well with measurements ($R^2 = 0.76$), the authors also noted that the measured X_{dust} were systematically less than the predicted results for SVOCs with high K_{OA} , especially for SVOCs with K_{OA} larger than 10^{12} . The differences are mainly caused by the assumption of gas-dust equilibrium because X_{dust} may not have sufficient time to reach the equilibrium state as the value of K_{OA} increases (or K_d increases). Taking DEHP as an example, the time scale required to reach gas-dust equilibrium may be over 200 days according the model analysis of Kang et al. (2021) ($K_{OA} = 10^{11}$ for DEHP in their calculations), which may be significantly longer than the residence time of indoor settled dust (> 2000 hours if dust resuspension is the only removal mechanism according to Shi and Zhao (2015)). Thereafter, many studies have intended to model the dynamic interaction between SVOCs and indoor settled dust.

Dynamic Models

The migration of chemicals to settled dust mainly involves three pathways: (1) direct contact between the source surface and dust (direct contact), (2) volatilization from the source material and then accumulation in dust via the air (non-direct contact), and (3) abrasion of particles from product directly forming dust (Melymuk et al. 2020; Rauert and Harrad 2015; Sukiene et al. 2016). The dominant pathway depends on the source type as well as the compound's chemical properties (Sukiene et al. 2016). For example, Rauert and Harrad (2015) indicated that nondirect contact is minimal and abrasion/direct contact dominate for PBDEs from plastic TV casing, while Sukiene et al. (2016) postulated that the nondirect contact might be the dominant pathway (based on a small-scale field study for nine

SVOCs) and K_{OA} was a major determinant for the transfer of SVOCs into settled dust (SVOC with high K_{OA} is more likely to be found in dust than in air). To study the dynamic migration of SVOCs into settled dust, several models have been proposed.

Model Based on Aerosol Dynamics

With the assumption that indoor settled dust is a thin layer of particles on nonsource surfaces, Shi and Zhao (2015) developed a model to estimate X_{dust} of SVOCs by considering aerosol dynamics including particle deposition and resuspension. The particles were divided into n size bins. For i th size bin, they predicted the indoor mass load of settled dust on surface by the following equation:

$$\frac{dM_i}{dt} = v_{d,i}C_{mp,i} - R_{p,i}M_i \quad (54)$$

where M ($\mu\text{g}/\text{m}^2$) is the mass load of settled dust on surface, v_d (m/s) is the particle deposition velocity onto surface, and R_p (s^{-1}) is the particle resuspension rate. Details about v_d and R_p can be found in ► Chaps. 11, “Deposition,” and ► 12, “Resuspension,” of this handbook.

The indoor SVOCs associated with settled dust are affected by suspended particle deposition and settled dust resuspension. The concentration of SVOC in the settled dust in the i th size bin was then expressed as:

$$\frac{d(M_i X_{dust,i})}{dt} = h_{md} A_{dn,i} N_{dn,i} \left(C_g - \frac{X_{dust,i}}{K_d} \right) + v_{d,i} C_{sp,i} - R_{p,i} M_i X_{dust,i} \quad (55)$$

where h_{md} (m/s) is the mass transfer coefficient at the surface of settled dust, A_{dn} (m^2) is the surface area of a single dust particle, and N_{dn} (m^{-2}) is the number concentration of dust particles. The first term on the right-hand side represents the kinetic sorption between gas-phase SVOCs and settled dust. The second and third terms on the right-hand side represent the deposition of SVOCs associated with suspended particles and resuspension of SVOCs associated with settled dust, respectively. A_{dn} equals $\pi \cdot d_{dn}^2$ if dust particles are treated as a sphere, where d_{dn} is the diameter of dust particle. N_{dn} can be estimated by $M/(\rho_{dust} \cdot \pi \cdot d_{dn}^3 / 6)$, where ρ_{dust} is the density of dust particles. h_{md} was set to be the convective mass transfer coefficient of SVOCs onto flat surfaces, which may be biased because the surface of settled dust may be less smooth than flat surfaces.

Finally, the mass fraction of SVOCs in settled dust can be obtained by

$$X_{dust} = \sum_{i=1}^n X_{dust,i} \quad (56)$$

Shi and Zhao (2015) compared the predictions of Eqs. (54), (55), and (56) with the measured X_{dust} of 66 SVOCs reported in the literature (similar to the dataset of Weschler and Nazaroff (2010)). Compared to the equilibrium model, greater

consistency was observed between the predictions and measurements, demonstrating the good performance of their model.

The dust layer is a type of porous medium. The above model (Eqs. 54, 55, and 56) did not consider the influence of the structure of the dust layer on the concentration and change in the concentration gradient within the dust layer (Kang et al. 2021). Therefore, it is not possible to understand the mass transfer mechanism of phthalates in settled dust at the microlevel. More importantly, some of the published studies have demonstrated that the direct-contact pathway may play a much more extensive role than the nondirect contact pathway (Rauert and Harrad 2015; Schripp et al. 2010; Shinohara and Uchino 2020) that was not considered in the model. Therefore, Bi et al. (2021) proposed a diffusion-based model to estimate the direct transfer of SVOCs from the source surface to settled dust by considering the diffusion of gas-phase SVOCs in voids of dust layer. Soon afterward, Kang et al. (2021) extended the model to consider both the direct contact and nondirect contact pathways as well as solid-phase diffusion of SVOCs within the dust particles, which is introduced as follows.

Diffusion-Based Model

The transfer process of SVOCs from indoor sources to settled dust is shown schematically in Fig. 5. For simplification, the effects of the aerosol dynamics

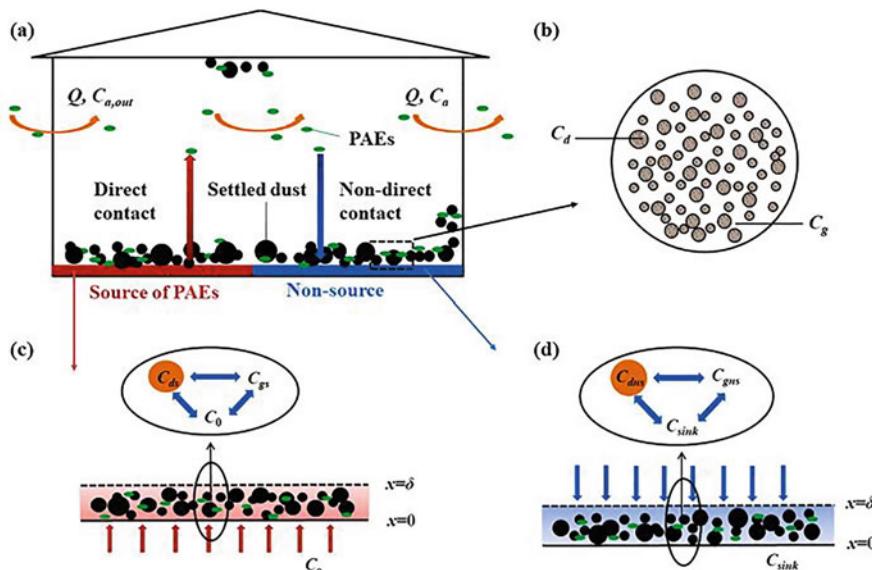

Fig. 5 Schematic representation of (a) migration of SVOCs from source to settled dust, (b) the equilibrium state in the dust layer, (c) the boundary condition of PAEs on the source surface, and (d) the boundary condition of PAEs on the nonsource surfaces. (Reprinted from Kang et al. (2021), Copyright (2021), with permission from Elsevier)

including particle deposition and dust resuspension are ignored. The change in the thickness and mass load of the settled dust is not considered in the model. Figure 5b is a downward view of the dust layer. As shown, the dust on the floor can be regarded as porous media, and an instantaneous equilibrium between gas-phase SVOCs in the pores and the sorption phase SVOCs in the matrix of the dust is assumed to be existed.

For a specific thickness of dust, the governing equations describing the migration of SVOCs between the source and nonsource surface with the dust on the surfaces can be expressed as:

$$(1 - \varepsilon)D_d \frac{\partial^2 X_{dust,s}}{\partial x^2} + \varepsilon D_g \frac{\partial^2 C_{g,d,s}}{\partial x^2} = (1 - \varepsilon) \frac{\partial X_{dust,s}}{\partial t} + \varepsilon \frac{\partial C_{g,d,s}}{\partial t}, \quad 0 < x < \delta \quad (57)$$

$$(1 - \varepsilon)D_d \frac{\partial^2 X_{dust,ns}}{\partial x^2} + \varepsilon D_g \frac{\partial^2 C_{g,d,ns}}{\partial x^2} = (1 - \varepsilon) \frac{\partial X_{dust,ns}}{\partial t} + \varepsilon \frac{\partial C_{g,d,ns}}{\partial t}, \quad 0 < x < \delta \quad (58)$$

where δ (m) is the thickness of the settled dust, x (m) is the distance to the surface, ε (dimensionless) is the porosity of the settled dust, D_d (m^2/s) is the diffusion coefficient of SVOCs in the dust matrix, $C_{g,d}$ ($\mu\text{g}/\text{m}^3$) is the gas-phase concentration of SVOCs in the voids of dust matrix, and the subscript s and ns represent the source surface and nonsource surface, respectively. The first and second terms on the left-hand side represent the solid-phase diffusion of SVOCs with the dust particles and the diffusion of gas-phase SVOCs in voids of dust matrix, respectively. The first and second terms on the right-hand side represent the temporal variation of dust- and gas-phase SVOC concentrations, respectively.

Within the dust matrix, a linear partition relationship between the gas-phase concentration and dust-phase concentration can be obtained due to the assumption of instantaneous equilibrium, i.e., Eq. (53). For settled dust on source surface, if there is an equilibrium state between the concentration in the source, dust-phase concentration, and gas-phase concentration at the interface on the source, as shown in Fig. 5c, the boundary condition at the interface between the source and settled dust can be expressed as:

$$X_{dust,s}|_{x=0} = \frac{K_d C_0}{K_{sg}} \quad (59)$$

$$C_{g,d,s}|_{x=0} = \frac{C_0}{K_{sg}} \quad (60)$$

where K_{sg} (dimensionless) is the partition coefficient between gas phase and the source and C_0 ($\mu\text{g}/\text{m}^3$) is the concentration of SVOCs in the source (which is always treated as a constant due to the slow loss of SVOCs from the source material (Xu and Little 2006)).

At the interface between the settled dust and gas phase, the convective mass transfer boundary for settled dust on source surfaces can be expressed as:

$$-(1 - \varepsilon)D_d \frac{\partial X_{dust,s}}{\partial x} \Big|_{x=\delta} - \varepsilon D_g \frac{\partial C_{g,d,s}}{\partial x} \Big|_{x=\delta} = h_{m,s}(C_{g,s} - C_g) \quad (61)$$

where C_g ($\mu\text{g}/\text{m}^3$) is the gas-phase concentration of SVOCs in the surrounding air.

For the nonsource surface, the boundary condition is similar to the boundary conditions for the source when $x = \delta$. Although the parameters for the dust on the source and nonsource surfaces may be different, the same properties and morphologies were assumed. When $x = 0$, the dynamic adsorption of gas-phase SVOCs onto the nonsource surface should be considered. If there is a state of equilibrium between the surface-phase concentration and gas-phase concentration, as shown in Fig. 5d, the boundary conditions for the nonsource can be described mathematically by the following equations:

$$-(1 - \varepsilon)D_d \frac{\partial X_{dust,ns}}{\partial x} \Big|_{x=0} - \varepsilon D_g \frac{\partial C_{g,d,ns}}{\partial x} \Big|_{x=0} = \frac{dC_{ns}}{dt} \quad (62)$$

$$-(1 - \varepsilon)D_d \frac{\partial X_{dust,ns}}{\partial x} \Big|_{x=\delta} - \varepsilon D_g \frac{\partial C_{g,d,ns}}{\partial x} \Big|_{x=\delta} = h_{m,ns}(C_{g,d,ns} - C_g) \quad (63)$$

$$C_{ns} = K_{ns} \cdot C_{g,d,ns} \Big|_{x=0} \quad (64)$$

where C_{ns} ($\mu\text{g}/\text{m}^2$) is the surface-phase concentration of SVOCs on nonsource surface and K_{ns} (m) is the partition coefficient between the gas and the sink (nonsource).

Assuming that the settled dust has no SVOCs initially, and the initial conditions are:

$$X_{dust,s} = X_{dust,ns} = 0, \quad C_{g,d,s} = C_{g,d,ns} = 0 \quad (65)$$

Based on Eqs. (57), (59), (60), (61), and (65), the dynamic transfer of SVOCs from the source into settled dust on the source surface can be estimated. Eqs. (58), (62), (63), (64), and (65) can be used to describe the corresponding process on nonsource surface.

For settled dust on source surface, good agreement between model predictions and measurements (experimental data of DEHP from Bi et al. (2021)) was obtained by Kang et al. (2021). However, the model performance has not been evaluated for nonsource surface. In addition, the effects of aerosol dynamics were ignored in the model of Kang et al. (2021), which may limit its application for realistic cases where airborne particles are continuously settled onto the surface.

None of the above models considered the source abrasion pathway, which may lead to underestimation of X_{dust} in realistic settled dust. In addition, the age (or residence time) of settled dust is another key parameter in the dynamic models, which is usually unknown and challenging to be obtained. Shi and Zhao (2015) set the residence time of settled dust to 7 days by assuming that settled dust was removed by cleaning activities once a week. While in the calculations of Kang

et al. (2021), the residence time of settled dust was well controlled because the measurements were obtained using chamber experiments that would be very different from the actual indoor conditions. Overall, further study is required for developing approaches for the accurate estimation of X_{dust} .

Dust-Gas Partition Coefficient (K_d)

K_d is always expected to be directly proportional to K_{OA} and the fraction of organic matter in the settled dust (f_{om_dust} , dimensionless), and inversely proportional to the dust density (ρ_{dust} , g/m³):

$$K_d = \frac{f_{om_dust} \cdot K_{OA}}{\rho_{dust}} \quad (66)$$

In existing studies using Eq. (66) to estimate K_d , f_{om_dust} and ρ_{dust} were often set to be 0.2 and 2.0×10^6 g/m³ (Weschler and Nazaroff 2010), respectively, if there are no measured results. As discussed above, acceptable agreement between measurements and estimations can be obtained using Eq. (66) and these values, especially for SVOCs with $K_{OA} < 10^8$. Additionally, the pp-LFER approach may also be applicable for estimating K_d . However, its performance has not yet been evaluated.

Studies have attempted to measure K_d of SVOCs by assuming that the interaction between gas-phase SVOCs and settled dust had reached equilibrium. According to the equilibrium model (i.e., Eq. 53), K_d can be calculated by X_{dust}/C_g by simultaneously measuring X_{dust} and C_g . Table 2 listed the results of K_d obtained from some published studies. It can be seen that K_d 's for similar SVOCs are inconsistent among the studies, e.g., K_d of DEHP varies from 258 m³/g to 1.1×10^5 m³/g. The inconsistencies may be due to the difference in the composition of the measured dust (mainly f_{om_dust}) and the migration pathways of SVOCs to dust (nondirect versus direct contact). Another potential reason may be the nonequilibrium interaction between SVOCs and settled dust, i.e., lower K_d values were measured in field tests (realistic indoor environments, the equilibrium state is not guaranteed), while the extremely high K_d values were measured in chamber studies (in which the equilibrium was observed in the experiments). Finally, significant deviations between the measured K_d and the predictions of Eq. (66) have also been noted, especially for SVOCs with larger K_{OA} (or K_d) (Bu et al. 2016). How to improve the accuracy of the estimation or measurement of K_d is worthy of further study.

Conclusions

Gas-phase pollutants can interact with or partition to indoor particles (including both airborne and settled particles) and subsequently influence the transport, fate, and human exposure of these pollutants in indoor environments. Several models including equilibrium and dynamic approaches have been proposed to describe the interactions between gas-phase pollutants and indoor particles. Methods have also been

developed for measuring key parameters involved in these models, especially for the particle-gas partition coefficients (K_p for airborne particles and K_d for settled dust). These studies are helpful for understanding and describing the interactions between gas-phase pollutants and indoor particles. However, in many cases, equilibrium is not achieved and the parameter values needed in the models are not well known. Additionally, the surface of particles can be either organic or aqueous (depending on the RH of indoor air and the particle origin). RH should be a key factor that may significantly affect the gas-particle interactions of indoor pollutants (for both hydrophilic and hydrophobic species). However, the existing studies about the gas-particle interactions of indoor SVOCs have paid much less attention to the aqueous layers of particles and the effects of RH, especially in those studies that developed the dynamic models and the measurement methods for key parameters (both K_p and K_d). Thus, further study is required for comprehensively evaluating the performance of existing models (evaluating the agreement between model predictions and experimental measurements), improving the accuracy, stability, and practicability of the methods for measuring/predicting key parameters, and revealing the role of some key factors (such as the indoor temperature and RH, the organic and aqueous constituents of particles, and the physicochemical properties of SVOCs, e.g., the hydrophilic/hydrophobic property, the lipid solubility, and the volatility).

Abstract

Among different indoor sources of aerosol, cooking has been well understood to be one of the major sources of indoor aerosol. This source contributes to indoor ultrafine particles (UFPs) even smaller than 3 nm. Over 700 articles have been published in the past 30 years that address the cooking aerosol. Still this area of research is open for scientists to uncover the underlying mechanisms of the cooking emissions and its health impact. Different areas of the publication have been recognized including emission/concentration/composition, exposure, health, physics/dynamics, and chemistry. We recommend current scientists to concentrate their research to the areas of cooking aerosol and health, and cooking aerosol chemistry and physics that have been given less attention with a particular attention to cluster mode particles (particles smaller than 3 nm). Factors that influence the emission of aerosol during cooking using gas and electric stoves have been reviewed in this chapter. Such factors include cooking method, burner size, type of stove (gas vs. electricity), fuel quality, cooking pan, position of the cooking pan on the stove, surface area of the pan, cooking oil, additives, food, cooking temperature, and ventilation. Changes to the cooking habit may result in significant reductions in the exposure of the cooks and indoor occupants to cooking aerosol.

Keywords

Cooking aerosol · Ultrafine particles · Secondary organic aerosol · Frying · Health

Introduction

People spend a vast majority of their time (up to 87% of their time) indoors (Klepeis et al. 2001). Exposure to indoor air pollution could be more important than exposure to ambient air pollution due to the factors such as higher exposure time and exposure within a confined environment. These differences result in higher exposure to indoor pollutants compared to outdoor pollutants.

Epidemiology, human exposure, and risk assessment studies confirmed the potential health effects associated to cooking emissions. Solid fuel (kerosene, biomass, and coal) cooking and heating in open fires and inefficient stoves have been practiced by three billion people worldwide, particularly in low- and middle-income countries. World Health Organization reported close to four million premature death every year due to household air pollution resulted from inefficient stoves operated by solid fuels and kerosene (WHO: <https://www.who.int/news-room/fact-sheets/detail/household-air-pollution-and-health>). Asthma showed to be positively associated with employing solid fuels cooking including wood, coal, and biomass through large population studies in India (Agrawal 2012) and the USA (Barry et al. 2010).

The contribution of solid fuels to cooking has decreased globally such that the highest reductions were observed in developed countries (Bonjour et al. 2013). In such countries, the indoor level of particulate matter (PM) has been reported to be significantly lower compared to the indoor PM concentration in developing countries (Abdullahi et al. 2013) including Uganda, Ghana, Gambia, Bangladesh, Pakistan, and India (Chowdhury et al. 2012; Hankey et al. 2015; Nasir et al. 2013; Singh 2014; Zhou et al. 2014). This difference is likely to be due to the type of the energy source such as gas or electric stoves used for cooking and heating. However, still there exist risks to human health due to the exposure to cooking particles when gas or electric stoves are used, particularly in poorly ventilated environments (Gorjinezad et al. 2017; Zhang et al. 2017; Sze-To et al. 2012). Category Group 2A, probably carcinogenic to human, was registered to high-temperature frying emissions by International Agency for Research on Cancer (IARC) (Anttila et al. 2006). Polycyclic aromatic hydrocarbons (PAHs) emitted during cooking are marked as potential carcinogenic and mutagenic compounds (Bekö et al. 2013; Jørgensen et al. 2013). A high potential of adverse health effects was reported for people exposed to emissions from Chinese cooking (See and Balasubramanian 2006a). Exposure to cooking emissions on a daily basis was reported to be a risk factor for lung cancer among nonsmoking Taiwanese women. This risk can be greater three times with the number of cooked meals per day (Ko et al. 2000).

Cooking has been proven to be a major source of indoor PM (Dennekamp et al. 2001; Wan et al. 2011). Exposure to cooking PM was found to be higher than the exposure to PM from most other everyday activities (Wallace and Howard-Reed 2002; Wallace and Ott 2011). PM_{2.5} and particle number emission rates during cooking in the kitchen can be higher than the particle emission rate during smoking in the living room (Nasir et al. 2013). Cooking was reported to be the major source of PM_{2.5} and submicron particle (7–808 nm) among 20 indoor activities in 15 houses in Australia (He et al. 2004).

Particles produced by about 1 min of cooking on gas are of similar number to the particles produced by 10 min of cigarette smoking or 1 min driving with heavy-duty vehicles (Kumar et al. 2013). A 3-year study in the USA that investigated particle emissions in indoor environments, including occupied homes, cars, and restaurants, found cooking using gas or electric stoves and toaster ovens to be the major sources of indoor ultrafine particles (UFP) (Wallace and Ott 2011). However, with advancements in aerosol instrumentation such studies deserve revisiting. For example, with the development of new Scanning Mobility Particle Sizer (SMPS), it is currently possible to measure the mobility diameter down to 1 nm.

Numerous studies have shown that several factors including energy sources (gas burners and electric burners) (Wallace et al. 2004b, 2008), cooking additives (Amouei Torkmahalleh et al. 2013a, 2017a), meat (Amouei Torkmahalleh et al. 2017b), cooking oil and cooking temperature (Amouei Torkmahalleh et al. 2012), and cooking pan (Broomandi et al. 2020; Amouei Torkmahalleh et al. 2018, 2019; Wallace et al. 2015) contributed to the particle production.

The particle mode diameter values (the diameter representing the highest particle concentration) during cooking for nine studies and 23 cooking episodes

were reviewed by Abdullahi et al. (2013) and reported to be between 20 and 100 nm. However, recent studies using advanced technologies such as a 1 nm SMPS (TSI, USA) or A11 Nano Condensation Nucleus Counter system (A11-nCNC, Airmodus Oy, Helsinki, Finland) revealed the production of copious numbers of particles smaller than 10 nm during cooking (up to an order of magnitude in count higher than particles larger than 10 nm) (Patel et al. 2020; Wallace et al. 2008). It was found that heating an electric stove or gas-stove burning itself without any cooking materials (such as pan, food, oils, and additives) could be a source of particles smaller than 10 nm with the peak diameter around 5 nm (Wallace et al. 2008).

The most important chemical properties of particles include inorganic ions, elemental composition, and carbonaceous compounds, including black carbon that is found in the cooking PM as well (Abdullahi et al. 2013; Gorjinezad et al. 2017; Zhang et al. 2010). Chronic exposure to cooking PM containing toxic trace elements such as Cu, Fe, and Zn and Polycyclic Aromatic Hydrocarbons (PAHs) could pose adverse health impacts (See and Balasubramanian, 2008). PAHs are among the carcinogenic and mutagenic compounds of cooking emissions that exist in the emitted gas phase as well as the particulate phase (Bekö et al. 2013; Jørgensen et al. 2013). Schauer et al. (2002) investigated the gas phase-emitted compounds during stir-frying in soybean oil, stir-frying in canola oil, and deep-frying potatoes in hydrogenated oil. Results showed carbonyls accounted for 84% of the mass of quantified gas-phase organic compound emitted during stir-frying vegetables in soybean oil. The next largest fraction of the emitted gases accounted for n-alkanoic acids (+25.2 mg/kg of vegetables cooked). Carbonyl emissions in the gas phase were 252 and 108 mg/kg of vegetables cooked during stir-frying in canola oil and deep-frying in hydrogenated soybean oil, respectively.

Naphthalene was the dominant PAH in all three kinds of oils. The emission rate was higher during stir-frying with soybean oil than canola oil and deep-frying. The PAH emission rate was reported to be 654 µg/kg of vegetable cooked, 588 µg/kg of vegetable cooked, and 338 µg/kg of potato cooked, during stir-frying in soybean oil, stir-frying in canola oil, and deep-frying potatoes in hydrogenated oil, respectively. Phenanthrene was the second abundant aromatic hydrocarbon with the emission rate of 138 µg/kg of vegetable cooked, 120 µg/kg of vegetable cooked, and 83 µg/kg of potato cooked, during stir-frying in soybean oil, stir-frying in canola oil, and deep-frying potatoes in hydrogenated oil, respectively.

Among all aliphatic aldehydes, acetaldehyde emission rate was higher for stir-frying in soybean oil (50,100 µg/kg of vegetable cooked) than canola oil (42,200 µg/kg of vegetable cooked) and more than twice bigger than deep-frying (20,900 µg/kg of potato cooked) when stir-frying in soybean oil, stir-frying in canola oil, and deep-frying potatoes in hydrogenated oil were conducted, respectively.

N-Alcanoic acid emission rate during stir-frying in soybean oil, stir-frying in canola oil, and deep-frying of potatoes was as the dominant fatty acid with the concentrations of 11,890 µg/kg of vegetable cooked, 12,200 µg/kg of vegetable cooked, and 3270 µg/kg of potato cooked, respectively. Katragadda et al. (2010) studied VOC emissions including aldehydes during the controlled heating of four

different cooking oils coconut, safflower, canola, and extra virgin olive oils. They reported increased VOC emissions with time such that these emissions increased considerably when the temperature exceeded the oils' smoke temperatures. The temperature at which the cooking oil continuously produces visible smoke is referred as smoke temperature. They found canola oil to emit the lowest amount of toxic compounds compared to other oils. It was concluded that coconut oil was inappropriate for cooking and frying given its low smoke temperature (175 °C). Even at temperatures as low as 180 °C, acrolein (2-propenal), a carcinogenic compound, was found in the cooking emissions (Katragadda et al. 2010).

Peng et al. (2017) examined aldehydes in fumes emitted during cooking using palm oil, rapeseed oil, sunflower oil, and soybean oil, and three cooking methods including stir-frying, panfrying, and deep-frying of two foods (potato and pork loin). The highest total aldehyde emissions were from deep-frying, followed by panfrying, and then stir-frying. Sunflower oil emitted the highest quantity of total aldehydes compared to the other two oils irrespective of cooking method and food type. Peng et al. (2017) suggested that stir-frying using oils structured with low unsaturated fatty acids such as palm oil or rapeseed oil can reduce the production of aldehydes in cooking oil fumes (COFs), in particular longer chain aldehydes such as hexanal and *t,t*-2,4-Decadienal. More information about composition of cooking PM and vapors emitted during cooking was presented by Abdullahi et al. (2013).

Animal studies demonstrated that inhaled insoluble UFPs may translocate to the secondary organs including heart, brain, kidney, and liver through alveolar deposition and the subsequent dissolution into the blood circulation. This translocation may impose subsequent toxicity (Bello and Warheit 2017). Cooking fumes produce a large number of small particles offering high surface area, which could be a crucial factor for particle toxicity. Such small ultrafine particles (UFPs) generated during cooking can be soluble and insoluble. However, the relative contribution of soluble and insoluble cooking particles in total particles has not been addressed in the literature. The insoluble cooking particles including liquid and solid particles may translocate into the blood circulation. However, the morphology of the cooking particles could be crucial for such a translocation. Soluble cooking particles are likely to dissolve into the blood and wash out through the kidney. The composition, size, and morphology of the cooking particles that could be critical factors from health point of view vary with the heating source such as gas burners, electric stoves, and solid fuels. It can also be correlated with the age and gender of the people exposed to the cooking fumes. Thus, studying the health effects of cooking aerosol is of the utmost importance, which has not been carefully explored in the literature so far.

Interest in publishing research articles sharing data on cooking PM has been increasing over past 30 years such that the cumulative number of articles in this field increased from 1 article in 1990 to 24 articles between 1990 and 2000, 153 articles between 1990 and 2010, and 785 articles between 1990 and 2020. The highest number of research articles published data on cooking PM was observed in 2020. From 2015 to 2020, an up to 100% increase in the number of published articles was observed (Fig. 1).

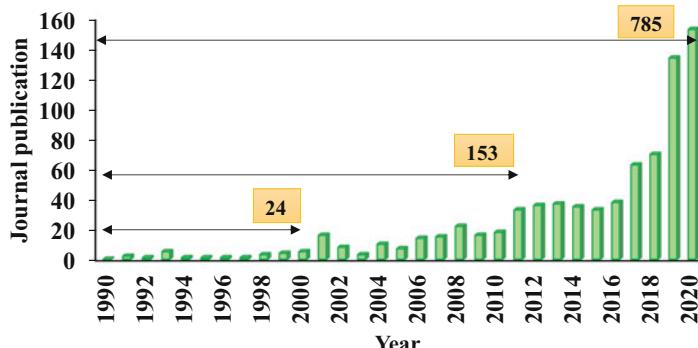

Fig. 1 The number of journal articles addressed cooking PM with time from 1990 to 2020 (all types of energy sources, including gas, electricity, and solid fuels). The numbers on the bars show the cumulative value

Methods

A comprehensive literature search using several keywords including “cooking,” “aerosol,” “particulate matter,” and combinations of these keywords was conducted to find the articles related to cooking emissions (with a focus on cooking PM). Studies on cooking using solid fuels were excluded from further review, and therefore, the focus of this chapter was on the emissions from cooking using gas and electric stoves.

Frying Process

Cooking oils undergo a dynamic and complex chemistry during the frying process. This chemistry is driven by the high temperature of the oil, the presence of the air, and moisture (Sebedio and Juaneda 2007). Fatty acids containing a chain of aliphatic carboxylic acid groups are abundant in vegetable oils (Scrimgeour 2005). Carboxyl and unsaturated groups found in the fatty acids that are among reactive components of the vegetable oils add to the complexity of the chemistry of the frying. Within this chemistry, there are three major chemical reactions during heating oils including hydrolysis, oxidation, and thermal alteration that result in a variety of products (Dobarganes and Márquez-Ruiz 2007).

The major constituents of the cooking oils are triglycerides. Triolein and trilinolein are the dominant triglycerides in cooking oils (Zambiazi et al. 2007). When the temperature of the cooking oils is sufficiently elevated during frying, the triglycerides decompose. As a result, fatty acids such as palmitic acid, linoleic acid, and oleic acid are produced (Crossley et al. 1962) and are likely to be found in the cooking emissions (Amouei Torkmahalleh et al. 2017a). Table 1 presents the composition of the vegetable oils (Zambiazi et al. 2007). As shown in Table 1, triolein and trilinolein are the major constituents of the vegetable oils.

Table 1 Mole fraction of different triglycerides in vegetable oils (Amouei Torkmahalleh et al. 2017a; Zamhiazi et al. 2007). Hydrolysis

Fats undergo hydrolysis reactions (breakage of the ester bonds) in the presence of the moisture. This simple reaction produces diacylglycerides (DG) and free fatty acids (FFA). Further hydrolysis of DG leads to the formation of monoglycerol (MG), FFA, and glycerol. These chemicals are more polar and have lower molecular weights compared to the parent triglycerides (TG). The fatty acids formed as a result of hydrolysis are reactive and lead to the formation of the volatile organic compounds (VOCs) after the decomposition (Perkins 2007; Ericson 2007). Such VOCs influence the flavor of the fried food. For example, degradation of linoleic acid (C18:2) leads to the formation of acetaldehyde, 1-pentanol, pentanal, hexanal, 2-nonenal, 2-octanal, 2-heptanal, and 2,4-decadienal (Feron et al. 1991; Qu et al. 1992; Subramanian and Nakajima 1997; Wan et al. 1996). Similarly, degradation of oleic acid (C18:1) results in the formation of heptane, octane, heptanol, octanal, nonanal, decanal, 2-decanal, 1-undecen, and 2-undecenal (Feron et al. 1991; Qu et al. 1992; Subramanian and Nakajima 1997; Wan et al. 1996).

Oxidation

Lipid oxidation in air is defined as a classic set of free radical chain reactions involving initiation, propagation, and termination reactions (Schaich 2005). First, hydrogen abstraction occurs on an unsaturated fatty acid resulting in spontaneous free radical formation as presented in Reaction 1:

The resulting radical reacts with oxygen and other TGs (L_n) forming new radicals that propagate the chain reactions as shown below

Heating oil at high temperature triggers new chains producing alkoxyl and hydroxyl radicals as shown by Reaction 5.

Allylic hydroperoxides (LOOH) are the primary products of the FFA oxidation, which are unstable compounds. They decompose and recombine to terminate the radical reactions (Denisov and Afanas'ev 2005; Gunstone et al. 2007). Cyclization

of the alkoxy radical leads to the production of the epoxy, hydroxyl, and hydroperoxy acids located on one of the unsaturated fatty acids of the parent triglyceride. Therefore, oxidized monomers are formed that have at least one oxygenated group such as hydroxyl, epoxy, and keto (Dobarganes and Márquez-Ruiz 2007). Frying represented by high-temperature oil and air favors polymerization reactions that results in the formation of the oxidized dimers and oligomers.

Besides oxidized compounds with higher molecular weights compared to the parent triglycerides, lighter compounds are formed as well. Aldehydes, alkanes, carboxylic acids, esters, and ketones that constitute a major part of VOCs are formed as a result of the scission of peroxides, that is, the breakdown of LOOH products. The recombination of alkoxy radicals (LO^*) yields peroxides and ketones.

Thermal Alteration

High-temperature frying results in the formation of the cyclic fatty acids and nonpolar dimers. Under oxygen deficiency, isomerization and cyclization reactions in the presence of the unsaturated fatty acids take place. The products of such reactions include cis- and transfats with saturated and unsaturated cyclopentyl and cyclohexyl rings (Dobson 1998; Christie and Dobson 2000).

Contribution of Food in the Frying Chemistry

Carbohydrates or sugars in the food experience hydrolysis reactions in the presence of water during thermal cooking. Degradation of sugar molecules takes place during heating such that rings of sugar break and produce aldehydes and acids (Katragadda et al. 2010). As temperate increases sufficiently, the degradation products recombine to make chain-like molecules that can react with the amino acids resulting in the production of VOCs.

Primary Organic Aerosol (POA)

Cooking particles are classified into two groups including primary organic aerosol (POA) and secondary organic aerosol (SOA). However, the SOA is not directly emitted. Rather it is generated through reactions with the vapors emitted during cooking. This process is explained below.

During frying when cooking oil is heated at sufficiently high temperature, a variety of VOCs are generated through hydrolysis, oxidation, and thermal alteration. These VOCs immediately cool to room temperature and become supersaturated in the air above the cooking pan. As a result, the nucleation of these vapors takes place resulting in the production of a copious amount of POA (Amouei Torkmahalleh et al. 2017a).

Secondary Organic Aerosol (SOA)

Indoor SOA chemistry was reviewed by Weschler and Carslaw (2018) and in the section of this handbook on indoor air chemistry. Such chemistry takes place through reactions between ozone and variety of unsaturated indoor vapors such as terpenoid (Weschler and Carslaw 2018), limonene (Chen and Hopke 2010), α and β -pinene (Chen and Hopke 2009a), linalool (Chen and Hopke 2009b), and terpene mixtures (Fan et al. 2005). Typical indoor sources of such vapors could be consumer products (Corsi et al. 2007), building materials (Aoki and Tanabe 2007), and cleaning products (Destaillets et al. 2006). Formation of SOA during cooking has been reported in the literature (Liu et al. 2017b; Klein et al. 2019). Yet, we need more comprehensive and systematic studies to better understand the mechanisms of SOA formation during cooking, the fraction of SOA in total cooking particles (SOA+ Primary organic aerosol (POA)), and the contribution of cooking SOA to indoor SOA.

The main sources of vapor precursors during cooking were reported to be cooking oils (Liu et al. 2017a), additives, and condiments (Liu et al. 2017b). Liu et al. (2017b) studied VOCs from frying corn oil without and with some common Chinese additives including garlic, ginger, *Myrcia*, and *Zanthoxylum piperitum* (Sichuan pepper). Their experiments were conducted in two modes including with ozone and without ozone. To form SOA, cooking emissions were introduced into a continuous flow reactor where high-ozone concentrations oxidized the cooking-generated VOCs under dark conditions. While no VOCs and particles were observed during heating the pan itself, heated corn oil predominantly produced aldehydes (Liu et al. 2017a). However, during stir-frying the additives, other dominant vapors were produced including dihydrohydroxymaltol and diallyldisulfide (garlic), and monoterpenes and terpenoids (ginger, *Myrcia*, and *Zanthoxylum piperitum*). The SOA emission rates from stir-frying *Zanthoxylum piperitum* and *Myrcia* were $8.7 \mu\text{g min}^{-1} \text{ g}_{\text{spice}}^{-1}$ and $1.8 \mu\text{g min}^{-1} \text{ g}_{\text{spice}}^{-1}$ equivalent to 53% and 13.4% of their own POA emission rates, respectively. Stir-frying garlic and ginger emitted no SOA (Liu et al. 2017b). SOA formation through heating canola, corn, sunflower, peanut, and olive oils at 220°C in the presence of OH radicals (2.7×10^{10} to 1.7×10^{11} molecules $\text{cm}^{-3} \text{ s}$) was investigated by Liu et al. (2017a). The SOA production rate was ranked from the highest to the lowest as sunflower, corn, canola, olive, and peanut oil. A strong association ($R^2 = 0.97$) was reported between the SOA production rate and omega-6 fatty acids. The carbon-carbon double bond in the omega-6 n-6 position could react with the existing peroxy radicals producing long-chain aldehydes (Liu et al. 2017a) that have been reported to be the precursor of the SOA (Liu et al. 2017b).

Another interesting study (Klein et al. 2019) provided new insights into the formation of SOA during cooking. This study examined more than 100 cooking experiments including frying, deep-frying, charbroiling, and boiling at different temperature and using different oils (olive, canola, and sunflower oils); meat, vegetable, and condiments were employed as potential sources of vapor precursors for the SOA formation. The authors concluded that the cooking is a source of

unsaturated aldehydes while the production rate of terpenes is negligible during cooking. The major source of terpenes was found to be condiments (Klein et al. 2019).

In Chinese and Indian cooking styles, spices are heated before adding meat to the pan. Particularly, in Chinese style, spices are stir-fried at temperatures as high as 240 °C (Liu et al. 2017b) prior to the addition of the food to oils. Some spices such as ginger, *Myrcia*, and *Zanthoxylum piperitum* (Sichuan pepper) are widely used in Chinese cooking, and their essential oils contain monoterpenes (Singh et al. 2005). Thus, it is highly possible for such spices to emit monoterpenes during cooking at high temperature which can then react with indoor ozone and produce secondary organic aerosol (SOA) (Weschler and Carslaw 2018). Liu et al. (2017b) studied the SOA and primary organic aerosol (POA) formations during stir-frying garlic, ginger, *Myrcia*, and *Zanthoxylum piperitum* at 240 °C. They reported no production of SOA from garlic and ginger when they were stir-fried while stir-frying *Myrcia* and *Zanthoxylum piperitum* produced SOA. Nonetheless, this SOA production was much less than POA emission rates produced during the stir-frying of *Myrcia* and *Zanthoxylum piperitum* (13.4% and 53.1% of their own POA, respectively), and also it was 30% higher than the SOA produced from heated cooking oil (220 °C) under photooxidation (Liu et al. 2017a, 2018). This observation suggests that particles emitted during stir-frying spices are dominated by POA rather than SOA. However, it needs further investigation. Black pepper was also reported to produce SOA when it was added to the pan during frying beef using canola oil at 180 °C (Klein et al. 2016).

Controlled Studies

There are many factors such as oil, food, condiments, heating source, and pan affecting the cooking emissions, and understanding the contribution of each factor to overall cooking emission rate is a difficult task. However, through controlled studies such contributions have been uncovered. The following section discusses the impact of cooking components on the emission rates and concentrations of cooking PM.

Cooking Style/Method/Habit

A cooking style such as African, Asian, Western, or Middle Eastern can be defined based on the cooking habit and the cooking method (recipe) of the given nation. Cooking method is defined by the combination of different cooking components such as oil, food, vegetables, condiments (additives), sauces, and other elements that is a common recipe for a given nation. A cooking habit is the way a cook prefers to do the cooking. For example, some cooks prefer cooking at low temperature with a longer heating time while some others cook faster at high temperature. Some cooks add condiments to the food at the beginning of cooking while others do it at the end of cooking.

In Persian (Iranian) style cooking, there are variety of meals that are prepared using stewing and water-based cooking (cooking method) and the cooking may take up to several hours (cooking habit). This cooking style employs turmeric, black pepper, and salt in most of the meals as the three main additives used during the cooking while in Indian style cooking variety of vegetables are involved in cooking together with chilies, red pepper, and curry as main additives. Cooking in Eastern Asia such as Chinese and Taiwanese is mainly based on frying while in Western style cooking grilling and barbequing are practiced. Further information about cooking styles are available in (Abdullahi et al. 2013).

Cooking methods involve wet and dry cooking including but not limited to boiling, steaming, stewing, stir-frying, panfrying [sautéing], deep-frying, grilling, broiling, oven baking, toasting, air frying, and microwaving. Grilling and frying were reported to emit higher PM_{2.5} compared to other cooking methods (Olson and Burke 2006). Oil-based cooking such as frying produces higher concentrations of ultrafine particles (UFPs) and PM_{2.5} compared to water-based cooking such as boiling (See and Balasubramanian 2006b; Zhang et al. 2010). This result was also observed in other studies irrespective of the type of the food being cooked including meat and tofu (Alves et al. 2014; Lee et al. 2001; Huboyo et al. 2011; Zhou et al. 2014).

Some studies also showed higher UFPs and PM_{2.5} during frying compared to other types of cooking particularly grilling when a variety of food were cooked such as onions, eggplant, potato chips pork meat, bacon, and cheese (Buonanno et al. 2011; He et al. 2004; Nasir et al. 2013; See and Balasubramanian, 2008). The water in the cooking oils leads to the formation of the oil bubbles while heating. These bubbles burst at the surface of the oil resulting in the production of many small particles (Dua and Hopke 1996). This phenomenon is observed during frying that could be a reason for the observed increased emissions during frying compared to the grilling. Another reason for the differences in frying and grilling using a same food is the heating temperature. Typically, grilling beyond 100 °C is unpleasant and results in burnt food (Amouei Torkmahalleh et al. 2017b), but frying can be done at temperatures even higher than 200 C (Amouei Torkmahalleh et al. 2017c). This large difference can result in a significant difference in the particle emissions.

Table 2 presents the measured particle concentration and emission rates for different cooking methods reported in the literature.

Energy Source

► Chapter 6, “Appliances for Cooking, Heating, and Other Energy Services,” describes emissions from a variety of stoves including those using solid fuels. This chapter focusses on gas and electric stoves cooking. The gas flame or the heated electric coil itself produces a wide range of particles including UFPs with the major particle size range to be less than 10 nm (Wallace et al. 2008). However, the addition of food or oil to cooking enhances the particle mode diameter to larger than 10 nm.

The literature reports that cooking using gas stove produces higher level of UFPs and PM compared to the electric stove cooking (Buonanno et al. 2009; To and Yeung 2011;

Dennekamp et al. 2001; Jørgensen et al. 2013; Wallace et al. 2008; Zhang et al. 2010). Patel et al. (2020) investigated the size distribution of particles down to 1 nm emitted from stir-frying using a gas (propane) stove and an electric hot plate. They

reported significantly higher (10 times) particle concentration during stir-frying using gas stove compared to the hot plate cooking.

Similarly, particle numbers from gas flame itself were higher (7 times) compared to the number of particles from the hot plate for sizes larger than 4 nm. Wallace et al. (2008) showed that over the size range of 2–64 nm, the average UFP emission rate from gas flame itself ($N = 22$) was 10.6×10^{12} part. min^{-1} while the corresponding value for the electric stove itself ($N = 30$) was 5.4×10^{12} part. min^{-1} .

Both gas and electric burners produce particles but by different mechanisms. The gas flame produces particles through the incomplete combustion (Li and Hopke 1993), the composition of the gas being combusted and the primary aeration affect the particle emission rate (Wagner et al. 2010). The electric coil generates particles through a different mechanism. Wallace et al. (2017) hypothesize that heated surfaces such as electric coils, cooking pans, empty beakers, etc. can produce particles during heating, and this particle emission can reach to zero after successive heating (Amouei Torkmahalleh et al. 2018; Wallace et al. 2015, 2017). The implementation of this hypothesis can be extended to indoor sources of particles such as heated iron, and hair dryer, toaster, etc. This hypothesis explains that a film of semivolatile organic compounds (SVOCs) deposits on the surface of the coil, stove, or pan during the noncooking period. During heating these surfaces, the SVOCs are desorbed from the heated surface, but then they immediately cool down to the ambient temperature resulting in supersaturation of the SVOCs and subsequent nucleation and particle formation. However, if the surface is heated continually, the SVOCs are completely desorbed and the emissions decline until zero emission is achieved. The particles generated through this mechanism contribute to the particle count but generally little to the particle mass. Thus, it was shown that PM mass concentration changes were negligible while UFP concentrations increased substantially (Wallace et al. 2015, 2017). Other possible sources of particles from the heated surfaces could be deposited dust (Glytsos et al. 2010), detergent residue formed on the surface after washing, and also skin oil transferred to the surfaces after touching (Wallace et al. 2015, 2017).

Figure 2 presents a contour plot showing three time intervals including indoor background (no particular sources), when a hotplate is heated at 320 °C and then when an empty beaker is heated on the hotplate at 320 °C. The background measurements started from 10:50 a.m. until 11:38 a.m. The background measurements showed the lack of particles larger than 3 nm with the presence of some particles smaller than 3 nm. At 11:38 a.m., the hotplate is switched on at 320 °C and nucleation of particles larger than 3 nm was observed such that particles between 3 and 10 nm dominate particle sizes <10 nm. As shown in Fig. 2, the number concentration decreases with time while the mode diameter increases creating a banana shape pattern suggesting coagulation over time. The concentration of particles generated by the heated hotplate continues to decrease until 13:50 p.m. when an empty beaker is placed on the hotplate. A copious amount of particles as small as 5 nm are produced. Additionally, particles smaller than 3 nm are produced. Again, a banana shape pattern is produced showing a decline in concentration over time because of continuously heating the beaker.

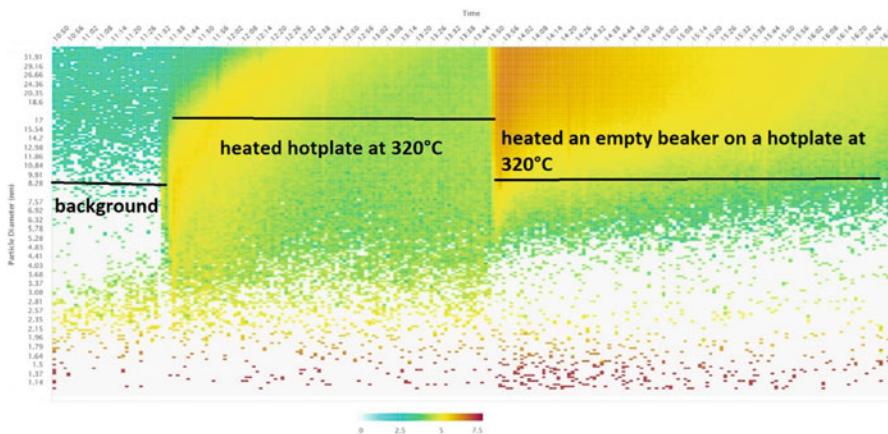

Fig. 2 Contour plot showing the particle size, concentration ($dN/d\log D_p$) and heating time for indoor background, heating hotplate, and heating an empty pan on a hotplate

Many studies showed that gas flames generate particles with higher mode diameters than heated electric stoves (Dennekamp et al. 2001; Wallace et al. 2008; Jørgensen et al. 2013). However, using advanced technologies such studies need to be revisited. For example, it would be interesting to study the differences in the particle mode diameter between gas flame and electric stove using a 1 nm SMPS. There exist studies that investigated size distribution of the particles from gas flame or electric stove itself down to 2 nm. Minutolo et al. (2010) and Wallace et al. (2008) reported average mode diameter for particles emitted from gas flame down to 2 and 5 nm, respectively. Patel et al. (2020) reported the mode diameter of particles generated from stir-frying using gas (propane) stove to be 1.6 nm. However, when an electric hot plate was used for the stir-frying, the mode diameter of the generated particles increased to 3 nm. The presence of the sub-3 nm particles in recent cooking studies as shown in Fig. 2 and also by Patel et al. (2020) and Laursen et al. (2021) needs further investigation to clearly understand the source of the sub-3 nm particles. The presence of such particles has been observed even in clean air (Laursen et al. 2021) or during background (no cooking) periods (Fig. 2) suggesting that these particles cannot be immediately registered for the cooking as possible measurement uncertainties exist. In addition to the cooking and its components including heated pan and stove as the source of sub-3 nm particles, the sub-3 nm particles found in the indoor background (baseline concentration) could be from ambient traffic emissions (Rönkkö et al. 2017) that penetrated indoors during cooking and noncooking periods. Alternatively, the source of uncertainty for counting sub-3 nm particles could be counting some ions instead of particles below 2 nm by the instrument (Patel et al. 2020). Another plausible reason could be uncertainties associated with the loss correction. When a few particles are counted at lower size limit of the instruments (with nano Differential Mobility Analyzer (DMA)), sharp spikes in the concentration typically at the lowest size are observed due to the loss correction (Laursen et al. 2021).

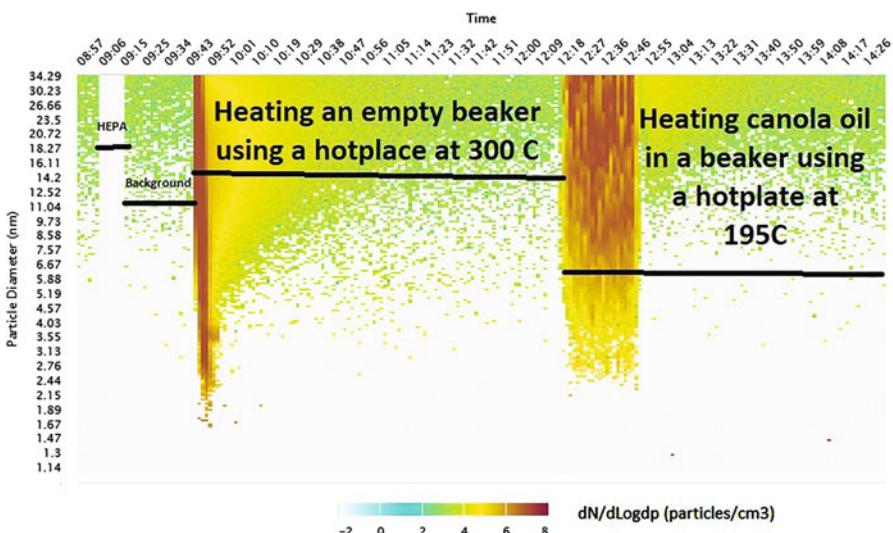

Fig. 3 A contour plot showing the particle size and concentrations ($dN/d\log D_p$) and heating time for indoor background, HEPA filter, Indoor background, heating empty beaker using a hotplate at $300\text{ }^{\circ}\text{C}$, and heating canola oil in the beaker using the hotplate at $195\text{ }^{\circ}\text{C}$

Such spikes may appear occasionally. However, if the particle emission is high in this size range, then the concentration spikes may disappear which was observed by Laursen et al. (2021) for candle burning. Figure 3 shows a contour plot presenting five different regions of particle size (1–35 nm), particle concentrations ($dN/d\log D_p$) and time including indoor background, HEPA filter, indoor background, heating empty beaker using a hotplate at $300\text{ }^{\circ}\text{C}$, and heating canola oil in the same beaker using the same hotplate at $195\text{ }^{\circ}\text{C}$. It is clear that when HEPA filter was connected to the instrument, it could remove all particles at all sizes. Heated beaker and hotplate were both sources of particles down to 1 nm and emitted high concentrations of particles which were about 4 orders of magnitude higher than the indoor background at all size ranges. However, heated canola oil produced particles larger than 2 nm. The concentrations of particles from the heated canola oil increased with the size of the particles such that the highest concentrations were observed for particles larger than 4 nm (four orders of magnitude higher than the indoor background). However, for particles between 3–4 nm and 2–3 nm, the concentrations of particles were almost 3 and 2 orders of magnitude higher than the indoor background concentrations, respectively. Figure 3 presents that continuously heating the beaker for 2 h (from 9:40 a.m. till 11:40 a.m.) using the hotplate at $300\text{ }^{\circ}\text{C}$ resulted in zero particle emissions from the beaker and hotplate collectively. At this time, when the background concentration was re-established, the oil was added to the hot beaker such that its temperature reached $195\text{ }^{\circ}\text{C}$, and the formation of the new particles from the heated oil itself was observed. Using this methodology, the particles from the heated oil itself can be quantified.

Cooking Pan

The literature review found that cooking pans can contribute to the UFP emissions and trace metal emissions (Broomandi et al. 2020). The mechanisms for the UFP emissions are the same as the SVOC mechanisms, explained for the hotplate, electric stove, or heated surfaces in the last section. Additionally, settled dust and detergent residue can contribute to the emissions. Since the SVOC film formation is hypothesized based on the surface adsorption, then the surface material of the pan, and the surface temperature of the pan that is established by its heat conductivity, could potentially influence the adsorption capacity of the SVOCs and thereby the particle emissions. Additionally, the duration of the exposure of the pan to indoor SVOCs is another factor that influences the adsorption loading. Little efforts were done to test this hypothesis (Amouei Torkmahalleh et al. 2019), and thus, it requires further investigations. Amouei Torkmahalleh et al. (2019) showed that the material of the pan can impact the UFPs (>10 nm) measured using the NanoTracer (Philips Aerasense, Netherlands). They reported that after approximately 24 hours of exposure of the all pans to indoor air, a ceramic pan emitted higher UFPs followed by granite, aluminum, and Teflon pans. Figure 4 shows the UFP concentrations in one of the experiments. The experiments were conducted for the four types of the pan that were exposed to indoor air at the same time for 24 hours. We heated during the same experimental day with a same heating level. However, the temperature of the pans might have been different given their heat conductivity. Although heating ceramic pan resulted in the higher UFP concentration (Fig. 4) and emission rate,

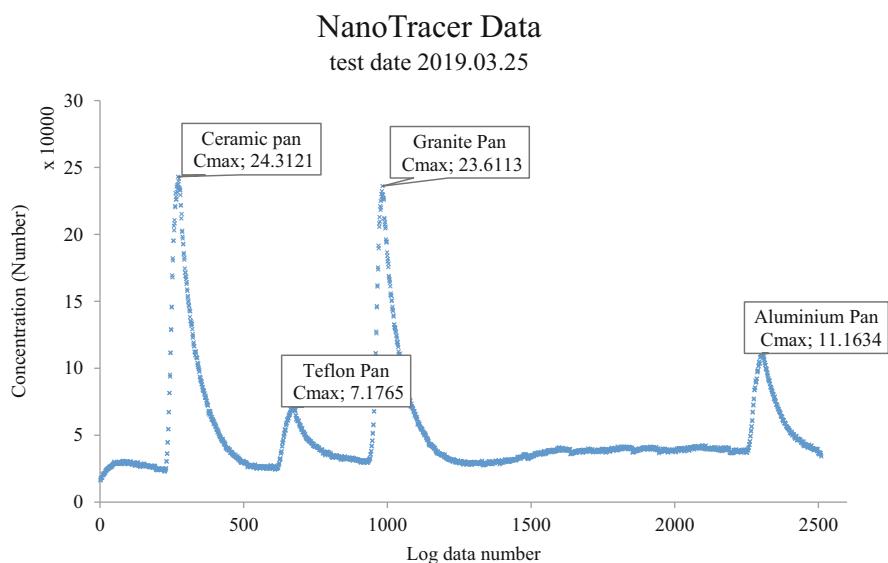

Fig. 4 Impact of the pan type on UFP emissions – X axis represents the time since the start of the experiments

the average temperature of the ceramic pan (185 °C) was less than that of granite pan (192 °C) and similar to the aluminum pan (182 °C) suggesting that pan material is a comparable factor to the pan temperature in particle production process.

A recent study examined the effect of cooking pan on PM_{2.5} emissions during frying (O'Leary et al. 2019). They studied the impact of a coated nonstick pan and stainless steel pan during frying chicken and potatoes in olive oil using a gas stove and reported that the emission rate increased up to 940% when the stainless steel pan was employed. The obvious reason for such a large increase was sticking the potato and chicken into the stainless steel pans. Thus, the material of the pan not only affects the adsorption of the SVOCs but also affects the interaction of the food with the pan, and both these factors influence particle emissions during cooking. The importance of this study was that it simulated a real cooking with three burners being involved in the cooking at the same time, for frying chicken, frying potatoes, and boiling vegetables.

The presence of the trace elements in the PM emitted during cooking has been identified in the literature (Gorjinezad et al. 2017; See and Balasubramanian 2006a, 2008). The source of the trace metals could be the oil, meat, or the pan. Previous studies demonstrated the presence of the trace elements such as Mn, Pb, Ba, Ag, Cu, As, Zn, and Cr in vegetable oils (He et al. 2014). Mendil et al. (2009) also reported the presence of the different trace elements in corn oil with Zn and Mn to be present at high concentrations. When cooking utensils are in contact with hot cooking oils and food during cooking, the dissolution of the trace elements from utensils to the oils is highly possible and the amount of the transferred elements depends on the type of food (Dan and Ebong 2013; Kumar et al. 1994). Trace metals such as Ni, Cr, Fe, Mn, and Al can be leached from different pans including stainless steel, cast iron, and PTFE-coated aluminum to heat oils (Dan and Ebong 2013; Kumar et al. 1994; Müller et al. 1993).

Dan and Ebong (2013) showed when stainless steel utensils were employed for cooking, the concentration of Fe (1.27–2.08 times), Ni (1.4–2.93 times), and Cr (1.34–2.64 times) in the food increased. Similarly, cooking in cast iron and PTFE-coated aluminum pans that are enriched in Fe and Al in their structure, respectively, resulted in leaching Fe (Kumar et al. 1994) and Al (Müller et al. 1993) into the cooked food and heated oils, respectively. Such studies demonstrated the impact of the cooking utensils, particularly cooking pan, on the trace element contents of the oil or food being cooked. However, the literature lacks strong evidence demonstrating the impact of the cooking utensils and pans on the trace element contents of the PM from cooked oil and food.

Four sets of experiments (three replications per experiment) were conducted to investigate the influence of the cooking pans on the concentrations of the trace elements in PM (Amouei Torkmahalleh et al. 2013b). Soybean and canola oils were heated individually in cast iron and ceramic pans. The results of soybean oil experiments were consistent with the results of the canola oil implying the impact of the pan on the trace element emissions. For example, heated cast iron pan in soybean and canola oils resulted in higher Fe concentrations in PM compared to stainless steel and ceramic pans.

Two different studies were conducted in the same apartment and under similar environmental conditions to quantify the trace elements during grilling (Amouei Torkmahalleh et al. 2017b) and heating corn oil (Amouei Torkmahalleh et al. 2017c). Although different cooking temperature (frying to be higher than grilling) and materials (oil vs meat) were employed in these studies, the measured trace element concentrations were statistically insignificant compared to each other suggesting the presence of a more influential source of trace elements compared to the meat or oil itself. This source could be potentially the cooking pan from which the trace elements are dissolved into the hot oil or blood of the meat during cooking. This observation triggered a recent study to better understand the contributions of the cooking pans to the trace element content of the emitted PM during cooking.

Broomandi et al. (2020) developed a hypothesis stating that the trace elements from cooking pan translocate to the cooking PM during cooking. They tried to show that trace elements are dissolved into the hot cooking oil and subsequently appear in the PM phase during the evaporation and the subsequent nucleation of the organic constituents of the cooking oils. This is rather a difficult hypothesis to investigate. To test this hypothesis, Broomandi et al. (2020) quantified the trace elements in PM when soybean oil was heated in three types of pans including cast iron, Teflon, and granitium pans under controlled experimental conditions. They argued that if they observe no statistically significant changes in the concentrations of all the trace elements in PM emitted from the heated soybean oil in three pans, then it is likely that the source of the trace elements is cooking oil. On the other hand, if the concentrations of one or more trace elements undergo statistically significant changes among the three types of the experiments, then the cooking pan is responsible for the emission of the trace elements. They reported that heating soybean oil in the cast iron pan resulted in higher Fe concentration in PM_1 ($8.49 \pm 3.35 \mu\text{g}/\text{m}^3$) compared to the Fe concentrations when Teflon ($8.05 \pm 2.27 \mu\text{g}/\text{m}^3$) and granitium ($7.45 \pm 1.38 \mu\text{g}/\text{m}^3$) pans were employed. Nevertheless, these differences were statistically insignificant. The Mn and Co emission rates were reported to be statistically significantly lower when cast iron was used compared to the granitium and Teflon pans. Thus, the study by Broomandi et al. (2020) with all of its limitations can support the hypothesis that trace elements translocate from cooking pan to PM during cooking. However, more controlled studies providing direct evidence are required to test this hypothesis.

Cooking Oil

Heating cooking oils is practiced during frying activities, and hence, studying the emissions from cooking oil itself is imperative for understanding the overall cooking emissions. Several controlled studies exist in the literature that investigated the impact of the cooking oils on particle emissions. At smoke temperature, the triglycerols of oil breakdown to glycerol and free-fatty acids. Further heating the oil results in the conversion of glycerol to acrolein that can be detected in the oil smokes (Katragadda et al. 2010). The content of the free-fatty acids of the oil influences the

smoke temperature. The smoke temperature of a cooking oil significantly depends on the chain length of the fatty acids rather than degree of unsaturation that is minimal factor. Oils that have higher content of short-chain fatty acids have lower smoke temperature (Katragadda et al. 2010).

The smoke temperature was reported to be the key factor influencing the particle emissions (Gao et al. 2013; Amouei Torkmahalleh et al. 2017d). High emitting cooking oils were reported to have typically low smoke temperature. That is, during cooking such oils are likely to be heated beyond their smoke temperature producing copious amount of particles. It is necessary to cook in oils with higher smoke temperature to reduce exposure to UFPs and PM. The smoke temperatures of the oils vary with the type of oils. Amouei Torkmahalleh et al. (2012) investigated the UFP and $PM_{2.5}$ concentrations and emission rates for seven different cooking oils including soybean, peanut, canola, olive, safflower, corn, and coconut oils. Each oil was heated to approximately 197 °C in a beaker on a hotplate. They characterized particle size distribution down to 10 nm. To separate the cooking particles from hotplate particles, they first heated the oils in the beaker and then transferred the beaker in a different chamber without the hotplate. The UFP and $PM_{2.5}$ concentrations were recorded while the oil temperature dropped below 197 °C. At the time of their study, the mechanisms for the particle emissions from heated surfaces such as hotplate or beaker were not known. Thus, it is likely that the study conducted by Amouei Torkmahalleh et al. (2012) did not exclude UFPs from the heated glass beaker while measuring the UFP emissions from the oils. However, this interference could have been ignored when the emission from the oils were compared assuming similar contribution of the beaker particles for all experiments. It is unlikely that heated beaker affected the $PM_{2.5}$ concentrations from the oil particles as it was demonstrated that particles from heated surfaces do not contribute to particle mass (Amouei Torkmahalleh et al. 2018; Wallace et al. 2015). Amouei Torkmahalleh et al. (2012) reported the particle mode diameter to be between 25 nm (peanut oil) and 80 nm (soybean oil). The lowest UFP and $PM_{2.5}$ emission rates were registered for soybean, canola, and safflower oils that had higher smoke temperature compared to the other tested oils (Amouei Torkmahalleh et al. 2012). Their study showed that selection of a low emitting oil for cooking could reduce the exposure to $PM_{2.5}$ and UFPs by over 90%. While their study showed a reverse association between the oil smoke temperature and the particle emissions, olive oil showed the different behavior. The highest PM emission was registered for olive oil compared to other oils even it was heated below its smoke temperature. This observation could be due to the presence of excess triolein with relatively high molecular weight (compared to other triglycerides) in olive oil compared to other oils (Amouei Torkmahalleh et al. 2017a). Another study by Gao et al. (2013) measured the PM mass emission rates in particles in the range of 0.1 to 10 μm and listed sunflower, soybean, and blended oils as low emitting oils while peanut and olive oil were reported to be high emitting oils consistent with Amouei Torkmahalleh et al. (2012) and Buonanno et al. (2009).

Four types of cooking oils including rapeseed, soybean, corn, and sunflower oils were compared to measure the $PM_{2.5}$ mass concentrations during heating to 265 °C using a pan and liquid petroleum gas as the fuel (Li et al. 2017). Rapeseed,

sunflower, soybean, and corn were ranked first, second, third, and fourth in PM emissions.

Selecting a low emitting cooking oil for frying is instrumental in reducing the exposure of the cooks to cooking fumes. The literature retorts that soybean oil is the least emitting oil while olive oil is among the most emitting oils. However, most of the previous studies compared different cooking oils using instruments only capable of monitoring particles down to 10 nm. Thus, such studies need to be revisited with instrumentation that detects particles below 10 nm and use revised experimental designs that separate the stove/hotplate and pan/beaker particles from oil particles.

Table 3 presents the particle concentration and emission rate values observed for different cooking oils.

Additives

Salt (sea salt and table salt) and black pepper are the most commonly used additives in different cooking styles. Some condiments are the major additives of a specific

Table 3 Influences of cooking oils on particle concentrations and emissions (Amouei Torkmahalleh et al. 2017d)

cooking style. For example, turmeric and curry are commonly used in Iranian and Indian recipes, respectively. Other condiments such as *Myrcia* and *Zanthoxylum piperitum* are employed in Chinese recipes. Additives or condiments may influence the emissions of cooking PM in two ways. Salts and pepper were found to reduce the particle emissions from canola and soybean oil (Amouei Torkmahalleh et al. 2013a). Five different additives including turmeric, garlic powder, black pepper, sea salt, and table salt were added to either canola oil or soybean oil while heating at 200 °C (below the smoke temperature) in a beaker, and the PM_{2.5} and particles number (10 nm to 10 µm) emission rates were quantified (Amouei Torkmahalleh et al. 2013a). When additives including black pepper, table salt, and sea salt were added to the canola oil at 200 °C, 85–90% and 45–53% reductions in PM_{2.5} and UFP emissions were observed, respectively, compared to the heated canola oil without additives. When soybean oil was used, table salt and sea salt reduced PM_{2.5} emissions by 47% and 77%, respectively, compared to the pure oil while black pepper showed no significant changes. Reductions in UFP emissions (51%, 61%, and 68%, respectively) compared to the pure soybean oil were also reported when black pepper, sea salt, and table salt were added to the heated soybean oil. Garlic and turmeric showed no changes in PM_{2.5} and UFPs in the presence of heated soybean and canola oils. This observation is consistent with Liu et al. (2017b) who observed no changes in the particle emissions when garlic and ginger were added to corn oil at 240 °C.

In a simulation study, Amouei Torkmahalleh et al. (2017a) showed that at 197 °C NaCl could reduce the emissions of triolein, trigadolein, and triarachidin from soybean oil by up to 48%. These results can explain the observed reductions in particle emissions when salt is added to the heated oil.

The addition of salt to the meat during grilling led to different observations compared to the heated salty oil. O'Leary et al. (2019) fried chicken and potatoes in olive oil using a coated nonstick pan on a gas stove. Then, they repeated the same experiment when salt was added to the chicken before frying. Although increases in the PM_{2.5} up to 47% were observed, this increase was not statistically significant. Similarly, Amouei Torkmahalleh et al. (2018) reported statistically insignificant increases when salty beef was grilled compared to the grilled unsalted beef. Further investigations are needed to improve our understanding of the underlying mechanisms of particle formation when salt and meat are present during grilling.

Spices may increase the particle emissions as reported by Liu et al. (2017b). They reported that the particle concentrations when *Myrcia* and *Zanthoxylum piperitum* were stir-fried in corn oil at 240 °C were approximately twice the concentrations of particles when the corn oil was heated in the absence of these spices. This increase could be potentially due to the primary particle emissions from heated spices themselves and due to the formation of secondary organic aerosol (SOA). The impact of four types of additives including white pepper, salt, garlic powder, and mixed spices on PM and VOCs during grilling pork was investigated. The meat was marinated with each type of additive before grilling. It was found that PM concentrations significantly decreased by 65.05%, 47.86%, 32.87%, and 56.01% when white pepper, salt, garlic, and mixed spices were employed during grilling. The

average concentrations of total carbonyl compounds (13 components) decreased when the grilling was conducted using the marinated meat with either of white pepper, salt, garlic powder, and mixed spices compared to the grilling with plain meat. Grilling salty meat showed statistically significant lower total VOC concentrations compared to the grilling plain meat, while other types of additives increased VOC concentrations.

Food

Particle emissions during cooking vegetables and meat were investigated in the literature. The current evidence in the literature shows that the frying and grilling meat result in higher particle emissions compared to the frying and grilling vegetables mainly due to the higher fat content. Buonanno et al. (2009) showed that grilling eggplant resulted in the lower particle number emission rates (2.6×10^{12} part. min^{-1}) compared to the grilling cheese, bacon, and wurstel sausage. The highest particle number emission rates were registered to grilling cheese (3.4×10^{12} part. min^{-1}). In another study, they also showed that frying and grilling cheese, bacon, and pork produce higher particles compared to the eggplants, potato chips, and onions using gas and electric stoves (Buonanno et al. 2011). Dennekamp et al. (2001) also showed that frying vegetables in vegetable oils resulted in reduced particle concentrations compared to the frying bacon. Frying tofu was found to produce less particles compared to the frying chicken (Huboyo et al. 2011). A study by Zhang et al. (2010) was in agreement with previous studies such that they also observed higher UFP and $\text{PM}_{2.5}$ concentrations during frying chicken and shrimp compared to the frying eggs, peppers, onions, and tomato.

Frying and grilling bacon emitted particles with larger mode diameter values compared to the frying or grilling eggplants, chips, and cheeses (Buonanno et al. 2011; Dennekamp et al. 2001).

Particle number and mass concentrations reported by the studies discussed in this section are presented in Table 4.

Temperature

Increased cooking temperature resulted in increased particle number and mass concentrations (Buonanno et al. 2009; Kumar et al. 2013; Amouei Torkmahalleh et al. 2012, 2013a; Zhang et al. 2010). The impact of temperature on cooking emissions was reported to be insignificant at the temperature range below the smoke temperature (Zhao et al. 2018). Nevertheless, exceptions may exist such as olive oil (Amouei Torkmahalleh et al. 2012). Buonanno et al. (2009) grilled 50 g bacon using a gas stove and observed 70% in particle number concentration and increase in particle mode diameter from 22 nm to 57 nm when grilling temperature changed from 82 to 114 °C. Amouei Torkmahalleh et al. (2012) showed that increase in particle emissions with temperature depends on the type of the oil. Low emitting

oils showed much less increase in particle concentration compared to the high emitting oils when the oil temperature increased from 130 to 197 °C. The PM_{2.5} emissions changed with temperature for all oils only beyond 150 °C. The increase in particle mode diameter with temperature was also reported by Amouei Torkmahalleh et al. (2012) such that the mode diameter increased on average from 30 nm to 47 nm for seven oils when the temperature increased from 178 °C to 197 °C. The reason for the observed increase in mode diameter with temperature could be due to the higher rate of coagulation at higher temperatures as higher temperatures increase the particle emissions and thereby concentrations. It could be also due to the increased concentrations of organic vapor at higher temperatures and thereby increased rate of condensation on the existing particles. Other studies also reported the increases in particle concentration and mode diameter with temperature during heating cooking oils (Gao et al. 2013), during panfrying of steak, chicken fillets, and pork chops (Yeung and To 2008), and during frying chicken (Zhang et al. 2010).

Surface Area of the Pan/Position of the Pan on a Stove

Amouei Torkmahalleh et al. (2012) demonstrated that the particle emissions increase with the surface area of the oil/pan. Thus, to reduce the particle emissions cooking in pans with smaller surface area is recommended.

Kitchen ventilation systems were found to be more efficient in filtering or venting out the particles during cooking on the rear burner compared to the front burner (Rim et al. 2012). The capture efficiency of a hood during stir-frying was reported to be 4–39% and 70–99% for front and back burners, respectively (Lunden et al. 2015). A similar observation was reported by Singer et al. (2012). However, O’Leary et al. (2019) observed a slight reduction in the concentration of frying particles when the back burner was used compared to the front burner such that this difference was statistically insignificant. They concluded that the observed insignificant difference could be attributed to the good coverage of the hood in their study over the front burner.

Particle Loss (Coagulation, Ventilation, and Deposition)

To reduce exposure of indoor occupants including the cooks to the cooking particles, two main approaches exist. The first approach is to reduce the particle emissions from the source by changing the cooking habit and employing cleaner energy while the second approach is to remove already produced particles from indoor air. The relative importance of these two approaches has not been addressed in the literature.

Factors affecting the emission of cooking particles have been addressed in the previous sections of this chapter. Here we discuss the factors affecting the removal of the cooking particles from indoor air. These factors include coagulation, deposition, and ventilation or air exchange.

The latter includes natural and forced ventilation. Coagulation was reported to be a dominant mechanism compared to the deposition and air exchange (Wallace et al. 2008). Wallace et al. (2008) estimated the coagulation, air change, and deposition rates of cooking particles in the size range of 2 to 64 nm in a test house to be +13 to -7 h^{-1} , $01\text{--}0.3 \text{ h}^{-1}$, and $< 0.5 \text{ h}^{-1}$, respectively. The highest rate of coagulation was registered for particles as small as 5 nm while coagulation rate for particles larger than 20 nm was found to be negligible. Coagulation was a dominant mechanism for concentrations as high as 30,000 particles/cm³. Using HR-TEM images, Cho et al. (2019) showed that ultrafine particles emitted from frying Atlantic salmon coagulated more rapidly than the accumulation mode particles (Rim et al. 2012).

Rim et al. (2012) showed that hood flow rate and particle size are the two factors in UFP removal such that the removal rate increased with particle size at 370 m³/h, while at 680 m³/h, the removal rate was almost the same over the size range of 4 nm to 20 nm.

Reductions in particles by a factor of 3–10 were reported due to ventilations during heating oils (Zhao et al. 2019). The capture efficiency of the ventilation system is a factor in reducing the indoor concentration of cooking particles, which varies with the type of the ventilation and fan speed (Lunden et al. 2015; Wallace et al. 2004a; Howard-Reed et al. 2003). It is possible to reduce the exposure of indoor occupants to cooking particles by using a proper ventilation system and a central fan and air conditioning (Howard-Reed et al. 2003). Particle deposition rates were examined in the presence of central heating and air conditioning (HAC) fan,

electrostatic precipitator (ESP), and fibrous mechanical filters (MECH). The ESP increased the particle deposition rates compared to the MECH and HAC fan (Wallace et al. 2004a; Howard-Reed et al. 2003). HAC fan alone and an in-duct ESP could reduce the indoor cooking particle concentrations by 25–50% and 55–85%, respectively. He et al. (2005) estimated the particle deposition rates in 14 residential houses in Brisbane. The lowest deposition rate was registered for particles in size range from 0.2 to 0.3 mm for both minimum (air exchange rate: $0.61 \pm 0.45 \text{ h}^{-1}$) and normal (air exchange rate $3.00 \pm 1.23 \text{ h}^{-1}$) ventilation conditions. Reductions in UFP concentrations are possible using increased flow rates of range hood. However, this reduction depends on the particle size (Rim et al. 2012). A flow rate of 95 l/s was reported to be necessary but not sufficient for range hoods to obtain a capture efficiency of 75% for the front burner (Singer et al. 2012). A similar observation in nine California homes was made by Singer et al. (2017) such that using a range hood (flow rate: 108 l/s), particle concentration reduced by 80–95%.

Particle Morphology

Understanding the morphology of the cooking particles will help us to estimate the particle transport and toxicity. Few data are available explaining the morphology of cooking emitted PM. The existing evidence suggest that aggregated branched chain-like structure PM accounted for the major morphology of gas and electric stoves frying (Buonanno et al. 2009) although individual nano-sized spheroid particles were observed. Combustion of solid fuel and gas stoves without food produced nano-size spherule primary particles that build submicron soot particles (Shen et al. 2017). Li et al. (2019) investigated the morphology of cooking particles ($\text{PM}_{2.5}$ and PM_{10}) collected in four Chinese restaurants that used different cooking styles, including Cantonese style (GD), Sichuan style (SC), Xibei style (XB), and Hunan style (HN). The cooking oil used in these restaurants was a blend of 94% soybean oil and 6% sunflower seed oil. PM morphology was categorized into six morphological classes in the study conducted by Li et al. (2019) including rectangular, flocculent, flat, irregular, spheroidal, and spherical shapes.

The most abundant particle morphology in PM_{10} was agglomerated rectangular (55%) shape. The flocculent shape accounted for 30% of the particles in PM_{10} . The percentage of flat particles was approximately 5%. Irregular particles showed the same percentages as flat particles. The spheroidal particles accounted for less than 2%.

The lowest of all the categories (~1.5%) was the regular spherical particle. $\text{PM}_{2.5}$ consisted of approximately 75% of rectangular particles. The next common shape was flocculent particles close to 20%.

Li et al. (2017) concluded that cooking style influenced the particle morphology such that rectangular particles were emitted largely from water-based cooking, while oil-based cooking and roasting produced abundantly spherical and spheroidal particles, respectively.

Citizen Science

Cooking is an inevitable activity in homes worldwide, and thus, exposure to cooking fumes in homes is unavoidable. However, the key question is how to cook while reducing the exposure to COFs. Employing ventilation has been demonstrated to be an approach to reduce exposure to cooking fumes. Nevertheless, not all homes are equipped with proper ventilation systems, and not all people use their ventilation systems during cooking. An alternative and novel opportunity to significantly reduce the exposure of home occupants to cooking fumes is to change the cooking habits and processes through controlling the factors influencing the cooking emissions, thereby reducing the emissions from the source as discussed in this chapter. For example, many people have misunderstood the suitability of olive oil in cooking. Olive oils are beneficial for eating as salad dressing or spreads on bread since they have high monounsaturated to polyunsaturated fatty acid ratio and contain powerful antioxidants such as polyphenols (Ktragadda et al. 2010; Velasco and Dobarganes 2002). However, olive oils are not among the best choices for thermal cooking in general and frying in particular with respect to the PM emissions.

It is important to transfer this knowledge and science to the general public using understandable language and popular communication tools. One way to publicize research outcomes in the area of cooking emissions is to involve people particularly women, commercial chefs, and young adults in research activities in this field that also promotes environmental equity. More importantly, social media such as Facebook, Instagram, Twitter, Clubhouse, WhatsApp, and Telegram are available to provide rapid and efficient communication with the public through different posts, lives, stories, and messages. Thus, researchers are encouraged to translate their research outcomes for public audience through such platforms. Existing examples are Instagram (addressed as *@aerosol_science_en* (English language) and *@aerosol_science* (Farsi Language)) and Clubhouse (addressed as *@profmehdi*) pages of the author of this chapter, Mehdi Amouei Torkmahalleh, to disseminate research findings related to the air quality in general and cooking emissions in particular.

Conclusions

While over 700 articles have been published over the past 30 years in the area of cooking aerosol, research on cooking aerosol deserves further attention in the area of health, chemistry, and physics. Few recent studies reported the production of particles smaller than 3 nm so-called “cluster mode particles.” However, doubt exists as to whether the cooking components are the source of these particles. Thus, future research should address the emission, dynamics, and exposure and health effects of sub-3 nm cooking particles. Frying cooking oils triggers the oil chemistry including hydrolysis, oxidation, and thermal alteration that result in the production of VOCs, PAH, and trace elements in the aerosol phases. In addition to the cooking oils, cooking pans could also be the source of the trace elements in the particulate phase.

What we have learned so far shows that opportunities exist to reduce exposure of cooks and indoor occupants to cooking aerosol by changing the cooking habits. Such cooking habits include employing low-emitting cooking oils, addition of salts to the oils at the beginning of cooking, using back burner on the stove, cooking in a low emitting pan, using a smaller pan, and cooking longer at lower temperature. Indoor air scientists particularly those studying cooking emissions are encouraged to include citizen science concepts and employ social media platforms in their research to increase public awareness and promote environmental equity with regard to indoor air quality and exposure to cooking fumes.

Abstract

Indoor air is a complicated matrix. There are various volatile organic compounds (VVOCs) such as formaldehyde and volatile organic compounds (VOCs) such as benzene, toluene, and xylene in indoor air. They are of low concentration and have different polarities. This chapter first introduces the sampling methods, sample treatment, and analysis of VVOCs (mainly carbonyls and ketones) in indoor air. The 2,4-dinitrophenyl-hydrazine (DNPH) derivatization – high-performance liquid chromatography (HPLC) method – is the most commonly used for the determination of VVOCs. Then four sampling methods for VOCs, including active sampling, passive sampling, whole-air sampling, and solid-phase microextraction (SPME), are introduced. Thermal desorption and solvent

extraction are two commonly used methods to pretreat the samples for further analysis. GC combined with MS, FID, ECD, or BID is frequently used for the VVOCs, VOCs, quantitation.

Carbonyl · Concentration · Sampling · Treatment · Measurement

Introduction

Since the 1950s, many manufactured materials such as composite wood, polymeric flooring, plastics, etc. have been widely used as building materials. They may emit harmful organic compounds, including very volatile organic compounds (VVOCs) such as formaldehyde; volatile organic compounds (VOCs) such as benzene, toluene, and xylene; and semivolatile organic compounds (SVOCs) such as phthalate esters and brominated flame-retardants (Weschler 2009). These compounds can cause various adverse health effects, ranging from irritation of the eyes, skin, mucous membranes, and the respiratory tract (WHO 2010; Jones 1999; Billionnet et al. 2011) to the highly toxic effects of reactive organics, such as chronic asthma and cancer (WHO 2010; McGwin et al. 2010; Hulin et al. 2010).

There are different criteria for the classification of VVOCs and VOCs. The original classifications of the WHO (1989) for VVOCs and VOCs cover boiling points from $<0\text{ }^{\circ}\text{C}$ to $50\text{--}100\text{ }^{\circ}\text{C}$, from $50\text{--}100\text{ }^{\circ}\text{C}$ to $240\text{--}260\text{ }^{\circ}\text{C}$, respectively. The US EPA does not differentiate between VOCs and VVOCs and uses various definitions (<http://www.epa.gov/iaq/voc.html>): volatile organic compounds (VOC) mean any compound of carbon, excluding carbon monoxide, carbon dioxide, carbonic acid, metallic carbides or carbonates, and ammonium carbonate, which participates in atmospheric photochemical reactions, except those designated by EPA as having negligible photochemical reactivity. Salthammer (2016) summarized a list of VVOCs with relevance for the indoor environment.

Sampling and analysis of such indoor organic compounds are crucial for evaluating their exposure risks (Miller et al. 2022; Wang et al. 2020). There are two types of analytical methods for VVOCs and VOCs: real-time and off-line methods. The real-time monitoring of indoor organic compounds is introduced in ► Chap. 18, “Real-Time Monitoring of Indoor Organic Compounds.” In this chapter, the off-line sampling methods, sample treatment, and analysis of VVOCs and VOCs in indoor air will be introduced and discussed.

Sampling and Analysis of VVOCs

In organic chemistry, a carbonyl group is a functional group composed of a carbon atom double-bonded to an oxygen atom: C=O. VVOCs often contain a carbonyl group. Thus, most VVOCs are carbonyls. In the indoor environment, the dominant

VVOCs are aldehydes (such as formaldehyde, acetaldehyde, and ketones) (Salthammer 2016). The detailed description of VVOCs can be found in ► Chap. 22, “Source/Sink Characteristics of VVOCs and VOCs.”

Sampling

The sampling methods for airborne carbonyls often use a simultaneous sampling/derivatization process using sorbents or impregnated filters/cartridges coated with the derivatizing agent (Barro et al. 2009). The commonly used method used in indoor monitoring for VVOCs is 2,4-dinitrophenyl-hydrazine (DNPH) (Salthammer et al. 2010; Saito et al. 2006) to form colored dinitrophenylhydrazone suitable for UV detection. There are also other methods such as 5-dimethylaminonaphthalene-1-sulfohydrazide (dansylhydrazine, DNSH) (Pereira et al. 2002), pentafluorophenylhydrazine (PFBH) (Koziel et al. 2001), and 3-methyl-2-benzothiazolinone hydrazine (MBTH) (Xiao et al. 2018). The sampling methods can be used for both active and passive sampling.

For example, the DNPH method is frequently used in many standard methods for the determination of VVOCs. In acidic solution, hydrazone are formed from 2,4-dinitrophenylhydrazine (DNPH) by nucleophilic addition to the carbonyl group, followed by elimination of water (Salthammer et al. 2010). In the sampling process, ambient air is pulled by a pump through cartridges typically containing silica gel and coated with an acid solution of DNPH. After sampling, the cartridge is then eluted with acetonitrile. The eluate can be directly used for HPLC-UV analysis. Some studies improved the DNPH method for carbon isotope analysis of atmospheric acetone (Wen et al. 2006). Solid-phase microextraction (SPME) was used to monitor ten selected VVOCs in newly renovated rooms (Hippelein 2006). Koziel et al. (2001) developed a new sampling and analysis method combining solid-phase microextraction (SPME) and DNPH for formaldehyde in indoor air. To reduce sampling time, Saito et al. (2006) coated DNPH on the surface of a needle to simultaneously achieve the derivatization/collection process of indoor aldehydes and ketones.

The MBTH method is a nonselective colorimetric method for determining aliphatic aldehydes of low molecular weight. The MBTH method only quantifies total aldehydes in ambient air. Furthermore, strong reducing agents can interfere with the determination of aldehydes (Salthammer et al. 2010).

Sampling Treatment

The sampled VVOCs or carbonyls are usually eluted by solvent extraction, except for SPME-based or needle-based methods using direct thermal desorption in the injection port of gas chromatography (GC). Since most procedures for aldehyde analysis imply the use of high-performance liquid chromatography (HPLC), acetonitrile is often used as the solvent (Barro et al. 2009).

Sample Analysis

The ISO 16000-3 standard was developed to provide a method to determine formaldehyde and other carbonyl compounds (ISO 16000-3 2011). Generally, indoor aldehydes and other carbonyls are determined by detecting the fluorescent derivatives formed in the derivatization reactions. If only formaldehyde is the target, the MBTH method can be used and the absorbance of formaldehyde derivative is monitored at 628 nm with a UV spectrophotometer (Xiao et al. 2018). If there are various VVOCs in air, the sampled carbonyls are separated by HPLC, and absorbance or fluorescence changes are used for their detection (Barro et al. 2009). Analytical standard procedures for aldehydes and ketones in ambient air, such as TO-5 (US EPA 1984c) and TO-11A (US EPA 1999a) are often used. Even et al. (2021) adopted the ISO 16000-6 standard method (ISO 16000-6 2011) for VVOCs measurement by GC/MS.

Sampling and Analysis of VOCs

VOCs are emitted from various products and materials used indoors, such as paints, furniture, building materials, glues, and adhesives (Vallecillos et al. 2021). The detailed description of VOCs can be found in ► Chap. 22, “Source/Sink Characteristics of VVOCs and VOCs.”

Sampling

There are four types of sampling methods for VOCs, including active sampling, passive sampling, whole-air sampling, and solid-phase microextraction (SPME).

Active Sampling

Active sampling uses pumps to pull air through a single adsorbent or mixtures of adsorbents, where the airborne VOCs are captured and concentrated. Thus, the essential factors for active samplings are the selections of adsorbents, the amount of adsorbents, and the active pumping airflow rate. Many types of adsorbents have been used for indoor VOCs monitoring, such as silica gel (McGath et al. 2014), activated carbon (Sinha et al. 2006), Tenax (Fang et al. 2019), Carbotrap (De Bortoli et al. 1992), Carbopack (McClenney et al. 2006), Carbosieve (Pallau et al. 2007), and Carboxen (Su et al. 2007). Tenax has been extensively used in the active sampling of indoor VOCs, due to its hydrophobic nature, thermal stability, and rapid desorption kinetics (Fang et al. 2019; Norris et al. 2019; US EPA 1984a; ISO 16000-62,011).

Some studies combined several different adsorbents in one cartridge to capture VOCs of a wide volatility range. Pallau et al. (2007) studied the influence of relative humidity and ozone on the sampling of volatile organic compounds on carbotrap/carbon sieve adsorbents. Ribes et al. (2007) have developed a dynamic

Fig. 1 Schematic diagrams of the triple adsorbent cartridge

method to collect VOCs on multisorbent tubes filled with 70 mg Carbotrap, 100 mg CarbopackX, and 90 g Carboxen. Triple adsorbent cartridges were also utilized to capture VOCs from diluted sidestream tobacco smoke (Ueta et al. 2010). Usually, along with the pump flow, the packing order of different adsorbents in one cartridge should be weak adsorbent to strong adsorbent, as shown in Fig. 1.

Active sampling by pumps requires a trained person to set up air sampling. The sampling times are usually 30 min to 1 h, but low flow pumps can extend sampling times to 24 h (Crump 2001). Active sampling is likely to determine a relatively short-term concentration, such as the peak or worst-case. The pump flow rate will strongly influence the sampling volume of compounds. Before sampling, the pump flow must be calibrated. If using active sampling for relatively long time sampling, such as several hours, the pump flow rate should be examined before and after the sampling. A particle filter is also recommended at a long-term active sampling to avoid particle deposition into the sampling tubes. The reliable active sampling flow range is about 20 to 225 mL/min (Xian et al. 2011). It should be noted that the breakthrough problem must be considered in the active sampling.

Passive Sampling

In passive sampling, the transport of VOCs to the sampling medium is caused by diffusion. Compared with active sampling, passive sampling has increased attention due to its simplicity and has become a widely accepted method (Chandra et al. 2020; Cao et al. 2016a). Passive air sampling using sorbent tubes offers certain advantages over active sampling, including no need for electrical power, simplicity of use, reduction of operational costs, and suitability for personal exposure measurements (Brown et al. 1992; Du et al. 2014b; Ishizaka et al. 2019). However, the uptake rate (UR) of passive sampling needs to be obtained first to describe the equivalent

amount of ambient air collected during exposure, which is the challenge in using passive sampling (Jia and Fu 2017). More details about passive sampling can be found in ► Chap. 17, “Passive Samplers for Indoor Gaseous Pollutants.”

Whole-Air Sampling

Whole air sampling is a simple approach to directly collect air samples in field tests using sampling bags or canisters (Camel and Caude 1995). The collected air can be analyzed by GC, either by direct injection or through preconcentration processes (cold trap or a cryofocusing device) according to US EPA method TO-14A (US EPA 1999a) and TO-15 (US EPA 1999b).

The often-used sampling vessels are plastic bags and stainless-steel canisters. Plastic bags are usually made by Teflon, Tedlar, or aluminized Tedlar to avoid VOCs being adsorbed onto the inner surface. The inevitable problem of plastic-bag sampling is that filling the bags needs the air sample to be pumped in, which will add a potential source of contamination through the pumping system. Stainless-steel canisters such as Summa canisters (US EPA 1999b) have been frequently used in the sampling of indoor VOCs. The canister can be pumped out creating a vacuum before sampling and does not need a pumping system during the sampling. Similar to the plastic-bag method, the inner surface of stainless-steel canisters must be carefully pretreated to avoid VOC adsorption and carryover from prior samples. However, the Summa canister is much more expensive than the plastic bag. In general, it is not convenient to carry many stainless-steel canisters in the field-test studies, which limits the usage of the whole-air sampling.

Solid-Phase Microextraction

Solid-phase microextraction (SPME) was introduced in 1990 (Arthur and Pawliszyn 1990) and is based on solid-phase extraction (SPE). Although SPE method reduces the use of solvents and reduces laboratory costs, SPE cartridges are usually made by plastic, which will adsorb the other compounds and makes the SPE method often suffer from high blank values (Arthur and Pawliszyn 1990). In comparison, SPME is a solid-phase extraction sampling technique that involves the use of a fiber coated with an extracting phase, which extracts specific kinds of analytes from different kinds of media. The SPME method is a solvent-free process without sample preparation and then provides extremely fast chromatography. The coating on the fiber is important for the enrichment of the compounds of interest (Larroque et al. 2006).

SPME should be calibrated when measuring VOC concentrations. Calibration is the main obstacle for applying SPME to indoor air monitoring (Barro et al. 2009). Ouyang and Pawliszyn (2008) reported a detailed review of calibration methods for SPME. In the traditional calibration process, the sampling process ends when the equilibrium between the fiber coating and the target VOC has been reached (Ouyang and Pawliszyn 2008), and a linear relationship for the target VOC between the mass adsorbed by the coating and the concentration in the medium can be quantified (Cao et al. 2017). Cao et al. (2016b) further developed an analytical model to characterize SPME sampling for VOCs and SVOCs by considering the surface mass transfer process. The model can conveniently calculate the chemical concentrations in a

sample matrix. In addition, the model can be used to determine the characteristic parameters (partition coefficient and diffusion coefficient) for the kinetic calibration of SPME samplings. Sample volume plays an extremely important role in analysis by SPME (Górecki 1997). Its effect on the analysis results can be neglected only when it is much larger than the fiber capacity (Górecki et al. 1998). Hippelien (2006) was able to use SPME to measure VVOCs in rooms, such as acetone, methyl acetate, and 2-methylpentane.

Sampling Treatment

After the capture of target compounds by the above four types of sampling methods, it is necessary to release the compounds before the final chemical analysis. Thus, the treatment of samples is essential. Normally, the sampling method, treatment method, and analysis methods should match each other. For example, the Tenax sampling tubes can be treated by thermal desorption and then analyzed by GC or GC/MS (US EPA 1984a).

Thermal desorption techniques are widely used for treating samples collected by solid-phase adsorbents, such as activated carbon, Tenax, and Carbotrap. Usually the desorbed compounds can be directly injected into GC/MS system for further separation and quantification. For example, SPME samples can also be inserted in the injection port of GC and then thermally desorbed due to the high temperature in the injection port. VOCs have been widely extracted from adsorbents by thermal desorption (Kim et al. 2001; Fang et al. 2019; Du et al. 2014b; Du et al. 2014a). An automatic thermal desorption platform combined with a GC/MS system is often used to analyze large batches of samples.

When VOCs are too strongly adsorbed, thermal desorption may not completely desorb the compounds. Another alternative and commonly used treatment method is solvent extraction. Carbon disulfide is one of the most common solvents used for solvent desorption due to its good solubilization properties for many analytes (Barro et al. 2009). There are also other solvents used in the literature, such as methanol, toluene, hexane, or acetone. Chen et al. (2020) used hexane as the solvent to elute compounds from SPE columns.

Sample Analysis

The most commonly used method for determining indoor VOCs is gas chromatography/mass spectrometry combined with (automatic) thermal desorption, (A)TD-GC/MS. US EPA has published the standards for VOC measurement by GC or GC/MS (US EPA 1984a, b, 1999a, b). The standard methods cover the samples from different sampling and treatment methods. The basic function of GC is to separate compounds of a mixture, and then MS will qualitatively and quantitatively identify VOCs. As an alternative to MS, there are other methods to measure VOCs, such as flame ionization detector (FID) (ISO 16000-62,011), photoionization detector (PID)

(Soo et al. 2018), electron capture detector (ECD) (Sakai et al. 2004), and barrier discharge ionization detector (BID) (Antoniadou et al. 2019).

If the sample contains many compounds, it is hard to completely separate all compounds in one-dimensional GC. Liu and Phillips (1991) first developed a multidimensional gas chromatography technique, comprehensive two-dimensional gas chromatography (GCxGC). The GCxGC utilizes two different columns with two different stationary phases. In GCxGC, all of the effluent from the first dimension column is diverted to the second dimension column via a modulator. The modulator quickly traps, then “injects,” the effluent from the first dimension column onto the second dimension. Lewis et al. (2000) used GCxGC technique to successfully separate more than 500 chemical species of VOCs from urban air samples.

For more polar VOCs, the samples can be extracted by liquid solvents, and then the compounds can be determined by HPLC (Hong et al. 2001).

Conclusion

Indoor air is a complicated matrix. VVOCs and VOCs in indoor air are usually of very low concentrations. Thus, the sampling and analysis of VVOCs and VOCs in indoor air are crucial for identifying and evaluating their exposure risk. This chapter briefly summarizes the sampling methods, sample treatment, and analysis of VVOCs and VOCs in indoor air. The sampling method, treatment method, and analysis methods should match each other. Air samples are usually collected by active sampling, passive sampling, whole-air sampling, and solid-phase microextraction (SPME). Thermal desorption and solvent extraction are two commonly used methods to pretreat the samples for further analysis. GC combined with MS, FID, ECD, or BID is frequently used for the VVOCs, VOCs, quantitation. HPLC is often used for the detection of carbonyls and ketones.

Abstract

Semi-volatile organic compounds (SVOCs) are ubiquitous indoor air pollutants and have adverse effects on human health. They partition strongly to interior surfaces, particles, and dust due to their physicochemical properties. This chapter provides an overview of the sampling and analytical methods of SVOCs in indoor environments, including sampling, sample pretreatment, and chemical analysis procedures. First, the general principles and techniques of gaseous and particulate SVOCs sampling, including passive air sampling, active air sampling, and dust sampling, are discussed. Second, common pretreatment methods are reviewed. Four different extraction methods, including Soxhlet extraction, accelerated solvent extraction, ultrasonication extraction, and microwave-assisted extraction, are compared. For cleanup and concentration, filtration, centrifugation, evaporation, and nitrogen blow are discussed. Finally, several widely used chemical analysis techniques are introduced. This chapter reviews the advantages and disadvantages of general methods for sampling and analysis of SVOCs in indoor environments and suggests future research needs.

Keywords

SVOCs · Sampling · Pretreatment · Chemical analysis

Introduction

Semi-volatile organic compounds (SVOCs) are defined as compounds with boiling points ranging from 240—260 °C to 380—400 °C with polar compounds in the high ends of the intervals (Clausen and Kofoed-Sørensen 2009). Another definition demonstrates SVOCs as compounds with saturation vapor pressures ranging from 10^{-2} kPa (10^{-1} torr) to 10^{-8} kPa (10^{-7} torr) (Clausen and Kofoed-Sørensen 2009). Therefore, SVOCs are likely to be distributed between the gas phase and the particle phase in indoor air. Indoor SVOCs include flame retardants, such as the polybrominated diphenyl ethers (PBDEs) and organophosphate esters (OPEs); pesticides, such as chlordane, chlorpyrifos, and diazinon; plasticizers, such as phthalates (PAEs); heat transfer fluids, such as the polychlorinated biphenyls (PCBs); and combustion byproducts, such as polycyclic aromatic hydrocarbons (PAHs), dioxins, and furans (Weschler and Nazaroff 2010). SVOCs are derived from a wide range of indoor sources, including building materials, consumer products, and furnishings, and they have been linked to serious adverse health effects. For example, Heudorf et al. (2007) found that exposure to some phthalates results in profound and irreversible changes in the development of the reproductive tract in males. Vonderheide et al. (2008) demonstrated that exposure to PBDEs may cause impairment of the brain and nerve tissues. As SVOCs are an important class of indoor pollutants that are of great health concern, sampling and analysis of SVOCs in indoor environments is essential to characterizing their concentration, fate, and transport mechanisms, and to avoid potential health effects. The aim of this chapter

is to review and compare different techniques of sampling, pretreatment, and chemical analysis of SVOCs in indoor environments, and to provide readers with recommendations for suitable methods in different situations.

Sampling

Semi-volatile organic compounds (SVOCs) are present not only in indoor air but also on suspended particles, dust, and interior surfaces (Clausen and Kofoed-Sørensen 2009). The objective of this section is to introduce the general principles and techniques regarding SVOC sampling from different environmental media.

Passive Air Sampling

SVOCs can be collected in two ways: passive air sampling and active air sampling. Passive air sampling does not use electrical power; instead, it captures SVOCs by sorbents via diffusion mechanisms. Typically, passive air samplers (PASs), such as a semipermeable membrane device (SPMD), polyurethane foam (PUF) disk, poly-dimethylsiloxane (PDMS), and XAD-2 resin-based passive air samplers (XAD-PASs), are installed at specified sampling sites. After a sampling period, usually several weeks or months for SVOCs, the PASs are collected, and SVOCs captured by the sorbents can be desorbed or extracted for further analysis.

To quantify the air concentration, the relationship between the sampled mass of the analyte in the PAS and its gas-phase concentration at the sampling location should be established. The mass transfer process of chemicals in a PAS can be described as (Bartkow et al. 2005):

$$V_s \frac{\partial C_s}{\partial t} = k_o A_s \left(C_g - \frac{C_s}{K_{sg}} \right) \quad (1)$$

$$\frac{1}{k_o} = \frac{1}{k_g} + \frac{1}{k_s K_{sg}} + \frac{1}{Q/A_s} \quad (2)$$

where V_s [L^3] is the volume of sorbent, C_s [ng/m^3] is the concentration of the analyte in the sorbent, t [s] is the sampling time, k_o [m/s] is the overall mass transfer coefficient from air to the sorbent, A_s [m^2] is the area of sorbent, C_g [ng/m^3] is the concentration of the analyte in gas phase, K_{sg} is the sorbent/air partition coefficient, k_g [m/s] is the mass transfer coefficient for the air-side boundary layer, k_s [m/s] is the mass transfer coefficient for the sorbent-side boundary layer, and Q [m^3/s] is the air flow rate on the surface of the sorbent. When $\frac{C_s}{K_{sg}}$ is much smaller than C_g (the captured amount is far from the equilibrium amount), Eq. (1) can be integrated and the amount of analyte in the PASs (N_s [ng]) can be calculated by:

$$N_s = k_o A_s C_g t = R C_g t \quad (3)$$

where R [m^3/h] is defined as the sampling rate of PASs, $R = k_o A_s$.

The air-side mass transfer coefficient can be expressed as $k_g = D/\delta$, where D [m^2/s] is the air diffusivity of a specific compound and δ [m] is the length of the diffusion path. For PAS sampling, if the mass transfer is air controlled (i.e., $k_o \approx k_g$), the sampling rate (R [m^3/h]) equals $D \cdot A_s/\delta$. The relationship suggests that when PASs are exposed to elevated wind speeds, the sampling rate increases due to the decreased thickness of air boundary layer (Bartkow et al. 2005), and when the flow field near the PAS is unstable during sampling, the thickness of air boundary layer (δ) may also change continuously. As a result, it is difficult to measure the boundary layer thickness and accurately quantify the sampling amount using PASs in field studies.

To obtain the sampling rate, depuration compounds (DCs) are commonly added to PASs prior to field measurements. DCs have similar properties to the analytes but do not exist in the environment. Typically, isotope-labeled compounds are used as DCs and they are added to the PAS before field sampling. Assuming that the mass transfer processes for the uptake of the analytes and loss of DCs are in opposite directions and air-side-controlled, the concentration of DCs is zero in the environment, and the mass transfer rate is not affected by chemicals, the sampling rate of PASs can be derived from Eq. (1) as follows (Moeckel et al. 2009):

$$R = \frac{-\ln \left(\frac{C_{DC}^{corr}}{C_{DC,0}} \right) \cdot K_{PAS-A} \cdot \rho_{PAS} \cdot V}{t} \quad (4)$$

$$C_{DC}^{corr} = \frac{C_{DC}}{C_{DC-stable}/C_{DC-stable,0}} \quad (5)$$

where $C_{DC,0}$ and C_{DC} [ng/sample] are the initial and final concentrations of the DC during the deployment period, respectively, K_{PAS-A} [m^3/g] is the DC's PAS-air partition coefficient, ρ_{PAS} [g/ m^3] is the PAS bulk density, V [m^3] is the volume of the PAS, and t [h] is the deployment period. In Eq. (5), $C_{DC-stable,0}$ and $C_{DC-stable}$ [ng/sample] are the initial and final concentrations of a stable DC during the deployment period, respectively. C_{DC} values are corrected by the recoveries of the stable DC during sampling using C_{DC}^{corr} [ng/sample]. The purpose is to reduce uncertainties associated with the loss of DCs during spiking, collection, and pre-treatment (Moeckel et al. 2009).

Many types of passive samplers have been adopted for SVOC sampling. Table 1 lists their applications in different studies. Details of passive sampler design and a model that allows the optimization of a passive sampling system are discussed in ► Chap. 17, “Passive Samplers for Indoor Gaseous Pollutants,” in this handbook.

Compared to conventional PASs, solid-phase microextraction (SPME) is a recently developed passive sampling device. The SPME sampler consists of a fiber holder and a fiber assembly that contains a 1-cm long SPME fiber. The SPME fiber consists of a thin fused-silica or metal core coated with a thin polymeric film, and the fiber diameter is less than 0.5 mm. For sampling, the fiber is exposed to the air and then quickly inserted into a gas chromatography (GC) injection port for direct analysis (Pawliszyn et al. 1997).

Meng et al. (2020)	PUF disk	Phthalates	Computer rooms, offices, laboratories, classrooms and dormitories	31

A typical sampling profile for an SPME device consists of three parts: linear regime, kinetic regime, and near equilibrium, as shown in Fig. 1 (Ouyang and Pawliszyn 2007), in which t_{50} and t_{95} represent the time when the extracted amount reaches 50% and 95% of the equilibrium amount, respectively. To quantify the sampling amount of the analyte using an SPME, both equilibrium and nonequilibrium methods are used depending on the sampling time (Ouyang and Pawliszyn 2008).

The equilibrium method applies only if the analyte has reached a near equilibrium distribution between the sample matrix and fiber coating. At equilibrium conditions, the extracted amount of analyte (n [ng]) can be expressed as (Pawliszyn 2012):

$$n = \frac{K_{fs} V_f V_s C_0}{K_{fs} V_f + V_s} \quad (6)$$

where K_{fs} is the partition coefficient of analytes between the fiber coating and the sample matrix, V_f [L] is the fiber coating volume, V_s [L] is the volume of sample

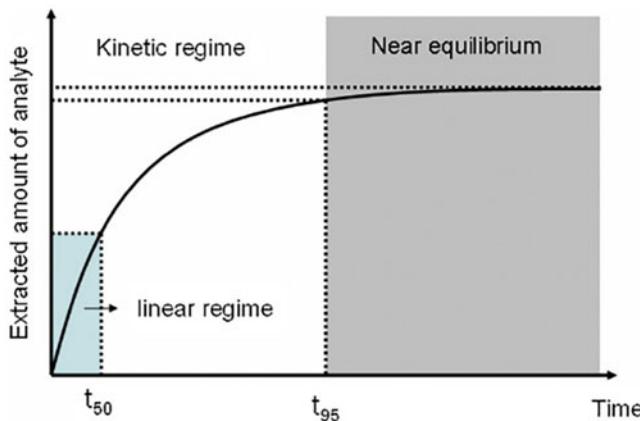

Fig. 1 Typical sampling profile for an SPME. (©With permission of Ouyang and Pawliszyn 2007)

matrix, and C_0 [ng/L] is the initial concentration of analyte in the sample matrix. When the volume of the sample matrix is much larger than the volume of the coating ($V_s \gg V_f$), Eq. (6) can be simplified to:

$$n = K_{fs}V_fC_0 \quad (7)$$

Equation (7) suggests that the amount of the extracted analyte is independent of V_s and the sampling time. As a result, the SPME fiber can be directly exposed to the sample matrix (e.g., air, water, blood) to obtain its concentration (C_0) when equilibrium is reached and K_{fs} is known (Ouyang and Pawliszyn 2008).

The equilibrium method has been used for on-site sampling of many organic pollutants like VOCs (Müller et al. 1999), but it may not be appropriate for SVOCs, since it takes a long time period to reach equilibrium due to the large K_{fs} value (Isetun et al. 2004). Therefore, a nonequilibrium SPME method was developed for SVOC sampling. This method assumes that the sampling rate remains constant throughout the sampling period. Therefore, the whole sampling period should be in the linear regime (i.e., the total sampling time is less than t_{50}). The extracted amount of analytes can then be quantified as $n = R \cdot C_0 \cdot t$, where R is estimated based on air diffusivity and the shape factor of SPME (Ouyang and Pawliszyn 2007). The concentration is then determined by linearly fitting the extracted amount (n) to different sampling times (t). However, the nonequilibrium method may only be suitable in a closed or stable chamber system because small changes of air flow in the field (indoor or outdoor environments) near an SPME may vary the sampling rate significantly. Cao et al. (2016) applied the non-equilibrium method and successfully measured the concentrations of dibutyl phthalate (DnBP) and di(2-ethylhexyl) phthalate (DEHP) in a sealed chamber system. The results were used to analyze the characteristics of phthalate emissions from vinyl flooring.

Active Air Sampling

Active air sampling usually needs three components: a pump, a sampling media, and a flow calibrator. During sampling, the pump generates a fixed flow rate and drives the air through the sampling media as shown in Fig. 2a. The average sampling flow rate is determined by a flow calibrator before, during, and after the sampling. Since the controlled flow rate is significantly higher than the sampling rate of the PAS, the time needed for active air sampling is shorter than passive air sampling, typically hours to days. The air concentration can then be calculated as:

$$C_a = \frac{M}{t \cdot R_s} \quad (8)$$

where C_a [$\mu\text{g}/\text{m}^3$] is the SVOC concentration, M [μg] is the sample mass collected by the sampling media, t [s] is the sampling time, and R_s [m^3/s] is the sampling flow rate. Several aspects should be optimized before sampling, including the type of sorbent used, the sampling time, and the sampling flow rate.

A combination of a filter and sorbent bed is typically used to collect particle- and gas-phase SVOCs (Tuduri et al. 2012). This method traps the particle phase on a quartz or glass fiber filter first (Fig. 2b). The gas phase is sampled downstream on a solid sorbent, such as polyurethane foam (PUF), XAD-2, or Tenax. Instead of a filter, a denuder/impactor can also be used for sampling particle-phase SVOCs (Mader et al. 2001), as depicted in Fig. 2b. In addition, a denuder system is also suitable for air sampling of SVOCs, in which annular denuder tubes (coated with appropriate adsorbents) trap the gas phase while particles pass through the tubes and are collected by the downstream filter. The filter may connect with a backup sorbent cartridge to capture any gas-phase SVOCs desorbed from the particles.

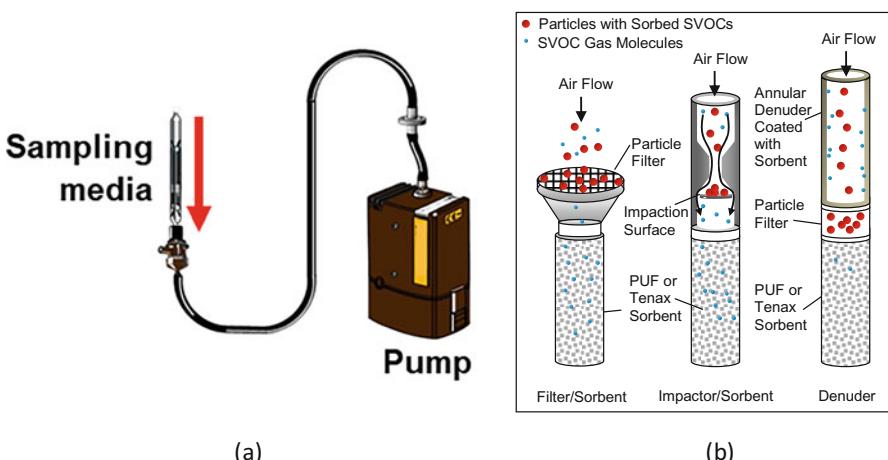

Fig. 2 (a) Active air sampling and (b) methods to measure gas- and particle-phase SVOCs

Generally, the concentration of total airborne SVOCs (the sum of gas- and particle- phase SVOCs) is determined through these methods. However, several studies have also used the results to calculate the partition coefficient between gas and particle phases for SVOCs (Cao et al. 2019; Zhou et al. 2021). However, these sampling systems may induce artifacts that disturb gas/particle partitioning. For example, for the filter/sorbent system, positive artifacts (overestimation of the particle phase) are mainly due to the sorption of gaseous species on the filter, while negative artifacts (underestimation of the particle phase) result from desorption of SVOCs from particles collected on the filter (Cheng et al. 2009). For the denuder system, several artifacts can also bias the measurement of the gas/particle partition coefficient, including incomplete gas phase removal, particle loss in the denuder tube, and SVOC off-gassing from particles when their corresponding gas phase components are removed in the denuder (Cheng et al. 2009).

In general, PUF, XAD, and Tenax are suitable sorbents for most SVOCs. Filters and sorbents such as PUF and XAD-2 are commonly extracted using solvents before GC analysis, while thermal desorption instruments are required to desorb Tenax. XAD-2 usually contains a lot of contaminants and needs extensive cleanup before use. In contrast, PUF and Tenax need to be cleaned up to a certain extent before use, but they may absorb vapors in the air during storage thereby increasing the background levels of blanks, so they must be stored carefully. Depending on method quantification limits, to obtain enough samples for analysis, PUF and XAD samplers must usually collect a larger sample volume than Tenax tubes, as listed in Table 2.

Compared to conventional methods, the needle trap device (NTD) method was recently developed for sampling of SVOCs. The NTD is prepared by packing a sorbent into a needle with a small hole on its side (Fig. 3). It combines the concept of active sampling and SPME (Asl-Hariri et al. 2014). For sampling, air is drawn through the needle by a sampling pump, and both gas- and particle-phase analytes are trapped by the sorbent. Desorption is performed by inserting the needle into a GC injection port with a carrier gas flowing into the needle through the side hole to aid the introduction of desorbed analytes into the GC column. Since the NTD technique integrates sampling, pre-concentration, and sample introduction into a single step, it is superior to conventional sampling techniques, being solvent-free, accurate, sensitive, and cost and time efficient. The NTD approach has been used for VOC and SVOC measurements in ambient air and water (Niri et al. 2009; Ueta et al. 2009). It has also been successfully applied to collect particle-free and particle-bound SVOCs for PAHs (Li et al. 2010) and insecticides (Niri et al. 2009) and has shown high efficiency in capturing particles with a size range of 0.01 μm to 100 μm . Recently, Li et al. (2020) developed a new NTD method for sampling SVOCs, such as phthalates, organophosphates, and polybrominated diphenyl ethers (PBDEs), in experimental chambers and fields. The NTD method shows high sensitivity and reproducibility, and better performance has been observed with the NTD method as compared to traditional methods. Their results indicated that the NTD method is a simple, sensitive, effective, reusable, and inexpensive technique for air sampling of SVOCs at a concentration level between 2 ng/m³ and 100 $\mu\text{g}/\text{m}^3$ (Li et al. 2020). Table 3 lists recent studies on NTD sampling of SVOCs.

Li et al. (2020)	Divinylbenzene (DVB) particles (HayeSep® Q, mesh size 60/80 and surface area 582 m ² g ⁻¹) were chosen as the sorbent materials. Two spring plugs and a small amount of epoxy resin were used to hold the DVB particles inside the NTD.	Phthalates, PBDEs	—	15 ± 1

In summary, both passive and active air sampling methods have strengths and drawbacks. Compared to active sampling, in which a high known volume of air can be sampled within a short time period, passive sampling is time-consuming. In addition, uncertainty associated with quantification of the mass transfer rate reduces the accuracy of the measured SVOC air concentration using the passive method. However, the cost of active sampling is often higher than that of passive sampling due to the use of sampling pumps, electricity, and especially the associated labor. Therefore, active air sampling can be applied to accurately and rapidly quantify SVOC air concentrations (Liang and Xu 2014). In contrast, passive air sampling is suitable for measuring the average air concentration over a long period of time in field studies, especially for those with a large number of sampling sites, or for sampling sites requiring low noise levels or with no electrical output (Shen et al. 2005).

Dust and Surface Sampling

SVOCs partition strongly to household dust (Weschler and Nazaroff 2010). Inadvertent ingestion of house dust is reportedly the largest contributor to SVOC exposure for all life stages (Bamai et al. 2016). Because young children spend a considerable amount of time on the floor, where contaminated particles accumulate, and frequently put their hands and other objects in their mouths, the increased ingestion of dust can lead to significantly higher SVOC exposure than adults. Vacuuming has been commonly used as a sampling method for dust-phase SVOCs. To avoid contamination from the plastic parts of vacuum cleaners, a pre-cleaned cellulose thimble is usually inserted between the cleaner tube extender and the crevice tool. Dust samples are captured by the thimble during vacuuming and are then extracted for further chemical analysis (Stapleton et al. 2012b). Larsson et al. (2017) used filters instead of a thimble to collect dust samples in Swedish preschools. In their study, the filter was fixed in a styrene-acrylonitrile container inside a polypropylene holder that was installed on the nozzle of a vacuum cleaner (Larsson et al. 2017). Compared to thimbles, cellulose filters are thin and flexible, but they are commonly fragile and should be installed in a container with careful pretreatment procedures.

In addition to settled dust, building heating, ventilation and air conditioning (HVAC) filter dust has also become a useful sampling medium to measure SVOC concentrations in airborne particles. HVAC filters can be installed with minimal effort for a particular period of time and capture particles from large volumes of air, resulting in the collection of spatially and temporally integrated concentrations. The large volume of air that passes through the filters simply increases the sensitivity of sampling and analysis. This approach overcomes the limitation of traditional air sampling methods that only provide a “snapshot” of compound concentrations, which can vary significantly with time and within a building. When combined with HVAC system characterization, such as system run-times, volumetric flow rates, and mass of dust collected, HVAC filter dust sampling provides a novel filter forensics methodology to detect and quantify particulate SVOC concentrations in indoor air (Bi et al. 2018). However, HVAC filter dust sampling is limited to regions where centralized HVAC systems are installed in buildings. In addition, seasonal and environmental factors may affect the composition of SVOCs in HVAC filter dust. For example, the average runtime for HVAC systems in winter is 10%, which is much shorter than in summer (31%). This difference may result in lower dust loading and shorter dust age on winter filters (Bi et al. 2018). The impact of dust loading and age on the concentrations of SVOCs in HVAC filter dust remains unclear (Bi et al. 2018).

Available evidence on the accumulation of atmospheric SVOCs on urban surfaces (Liu et al. 2003) suggests that SVOC molecules may also be sorbed onto a wide range of indoor surfaces and even human occupants. For sampling SVOCs on interior surfaces, wiping is a simple and commonly used technique (Lu and Fenske 1999; Cohen Hubal et al. 2006; Persson et al. 2018). Surgical gauze pads soaked with a solvent are applied and wipe across an identified surface area several times (Lu and Fenske 1999). Cotton sponges and PUF foam rollers have also been used in some studies, but because the whole sponge may not be pressed uniformly during

wiping, it may reduce the sampling efficiency (Cohen Hubal et al. 2006). Additionally, surface-phase SVOCs can also be collected through surface press sampling. Cohen Hubal et al. (2006) measured pesticide residue on interior surfaces in classrooms of a child care center. C₁₈-impregnated Teflon extraction disks were used as the sampling medium in that study. During sampling, the sampler was pressed to the sampling surface for 2 min and then extracted for further chemical analysis (Cohen Hubal et al. 2006). However, surface press sampling is likely affected by the pressure on the samplers, which may lead to great uncertainties.

Sample Pretreatment

Collected samples typically require pretreatment before chemical analysis. Extraction, concentration, and cleanup are typical procedures used for pretreatment. In addition, thermal desorbers are a type of pretreatment instrument that can also complete these procedures. The aims of sample pretreatment are to ensure SVOC concentrations above the instrumental detection limit for chemical analysis and to remove impurities from the sample to protect analytical instruments. This section introduces the common sample pretreatment techniques.

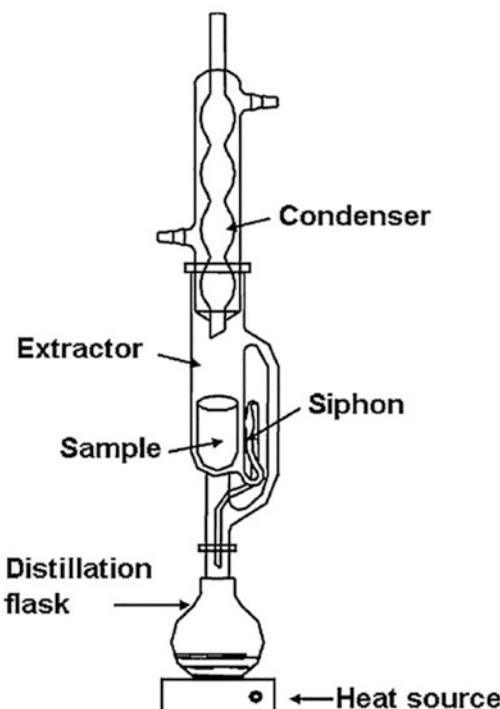

Solvent Extraction

Soxhlet Extraction

Soxhlet extraction has been a standard extraction technique for over a century (Luque de Castro and Priego-Capote 2010). In this system (Fig. 4), solid samples are extracted in a thimble holder filled with a flowing solvent that was continuously evaporated from a distillation flask at the bottom and condensed in a condenser on the top. During extraction, the combination of a heat source and condenser can circulate the solvent in the extractor. The sample is held by the thimble and the analytes are dissolved by the fresh solvent throughout the whole period. A siphon is designed to periodically empty the solvent in the thimble and carry the extracted analytes into the distillation flask. The temperature of the heat source should be set a little bit higher than the solvent's boiling point and significantly lower than the analytes' boiling point so that the solvent can remain circulating in the system while the extracted analytes can be retained in the flask.

The principle of this system is to keep the analytes dissolved in the circulated fresh solvent. It is a simple technique that has a relatively high extraction efficiency and requires inexpensive equipment and little manual work. However, compared to other extraction methods, Soxhlet extraction is particularly time-consuming and uses a large amount of solvents. Disposal of waste solvents is also expensive and is likely to cause environmental problems (Luque de Castro and García-Ayuso 1998). Table 4 lists several studies that used Soxhlet extraction to extract SVOCs from solid samples.

Fig. 4 Schematic of a classical Soxhlet extractor.

Accelerated Solvent Extraction (ASE)

Accelerated solvent extraction (ASE), also known as pressurized solvent extraction (PSE) or pressurized liquid extraction (PLE), is widely used as an alternative to Soxhlet extraction. ASE performs under high temperature and pressure. Samples are heated in an oven and are pressurized by a pump (Richter et al. 1996). In the ASE system, extraction occurs at a higher temperature than Soxhlet extraction or microwave-assisted extraction (MAE), because the solvent's boiling point is elevated in the pressurized extraction cell. As a result, the analytes' solubility is significantly improved due to decreased viscosity and superficial tension of the solvent (Mustafa and Turner 2011). This considerable improvement can also lead to less extraction time and lower solvent consumption. Table 5 lists several studies that applied the ASE method to extract SVOCs.

Ultrasonication Extraction (USE)

Ultrasonication extraction (USE) uses high frequency pulses to provide high shear stress and maintain high extraction efficiency. Ultrasonic baths are the most widely used USE system (e.g., Bi et al. 2018; Tang et al. 2020). As shown in Fig. 5, transducers are used as the source of ultrasound power (Chemal et al. 2017). Samples are placed in a container (e.g., a flask or a beaker) and submerged in

Table 4 Soxhlet extraction methods in different studies

Studies	Samples	Analytes	Extraction time	Solvent	Solvent volume (solvent flow rate)
Hwang and Cutright (2004)	2 g of soil	PAHs	15 h	Dichloromethane (DCM)	25 mL
Cai et al. (2012)	20 g of sewage sludge	PAHs, phthalates, chlorobenzenes, nitroaromatic compounds	24 h	Acetone/DCM (1/1, v/v)	100 mL
Klees et al. (2013)	1–2 g of street dust	PCBs	16 h	Toluene	300 mL
Sun et al. (2013)	20 g of sediments	Phthalates	48 h	DCM	(4–6 cycles/h)
Mi et al. (2019)	10 g of sediments	Phthalates	16 h	DCM	(5 mL/min)
Peng et al. (2020)	25 cm ² of play mat	PBDEs, OPEs	48 h	n-hexane/acetone (1/1, v/v)	200 mL

Table 5 ASE methods in different studies

Studies	Samples	Analytes	Extraction cycle	Solvent	Extraction condition
Stapleton et al. (2009)	0.2–0.5 g of furniture foam and indoor dust	OPEs	3 times	Hexane/DCM (1/1, v/v)	100 °C and 1500 psi
Kalachova et al. (2012)	0.5 g of household and car dust	BFRs	3 times	Hexane/DCM (1/1, v/v)	100 °C and 1500 psi
Klees et al. (2013)	1–2 g of sea sand	PCBs	1 time	Toluene	140 °C and 110 bar (optimized)
Celeiro et al. (2015)	1.5 g of clean sand	Fragrance allergens, musks, phthalates, and preservatives	1 time	Methanol	110 °C and 1500 psi (optimized)
Pil-Bala et al. (2019)	5 g of cheese	Endocrine-disrupting compounds	1 time	Acetone	70 °C and 1000 psi

solvent. During extraction, the container is immersed in pure water in the bath tank, with the water level in the tank higher than the level of solvent inside the container. USE can be operated at room temperature, but ice bags are

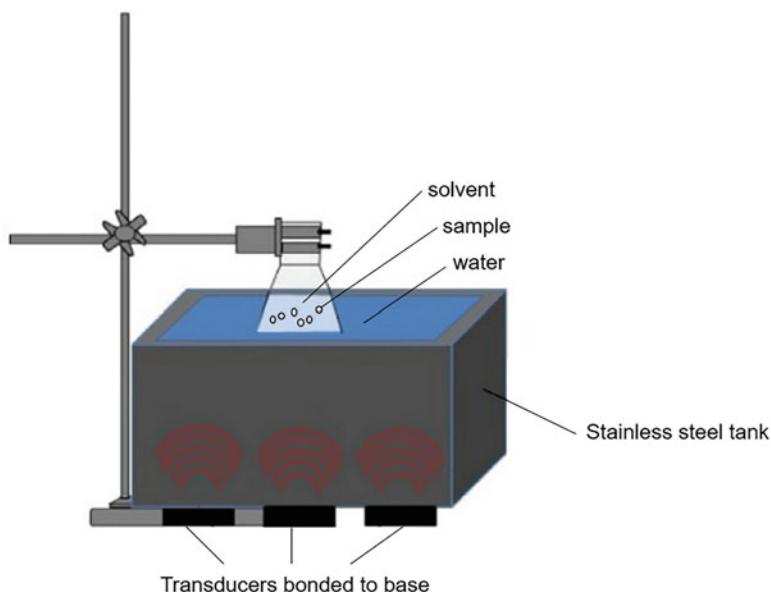

Fig. 5 Schematic of ultrasonic bath system. (©With permission of Chemat et al. 2017)

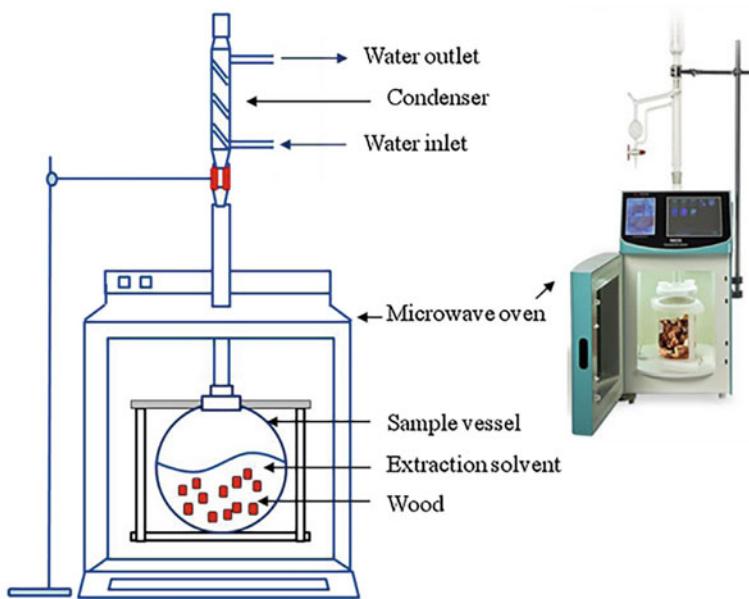

recommended to maintain a low water temperature to prevent unexpected solvent loss (Chemat et al. 2017). Fragile samples such as C₁₈ disks may break under ultrasound power, and therefore a mild extraction technique such as Soxhlet extraction may be more suitable. Similar to Soxhlet extraction, the USE system utilizes a large amount of solvents, but it is inexpensive, time efficient, and easy to operate. It has a very high extraction efficiency and can extract a number of samples in parallel. However, ultrasonication may produce oxidative free radicals that can degrade the sample and produce underreporting of the actual concentrations (Riesz et al. 1985). Therefore, surrogate compounds and recovery checks are strongly suggested. Table 6 lists several studies that have used USE to extract SVOCs from different samples.

Microwave-Assisted Extraction (MAE)

MAE uses microwaves as auxiliary energy for extraction (Bouras et al. 2015). In the system (Fig. 6), a sample vessel containing a solvent and samples is placed in microwave-producing equipment (typically a microwave oven). The mass transfer between the sample and solvent is significantly enhanced due to the high temperature in the vessel (Bouras et al. 2015). Thus, a cooling system is needed for condensation and circulation of the evaporated solvent. The use of microwaves shortens the extraction time and increases the extraction efficiency without extra solvent or cost (Bouras et al. 2015). However, MAE also has several restrictions. Cleanup procedures are needed for solid impurities after the extraction. Additionally, for heat-sensitive bioactive compounds, the use of microwave

Table 6 USE methods in different studies

Studies	Samples	Analytes	Extraction time	Solvent	Solvent volume
Shen et al. (2007)	1 g of cosmetic products	Phthalates and parabens	30 min	Methanol	10 mL
Stapleton et al. (2012a)	0.05 g of foam pieces	Flame retardant additives	15 min	DCM	1 mL
Bi et al. (2018)	HVAC filter and settled dust	Phthalates and OPEs	30 min, repeated 3 times	n-hexane	Not mentioned
Persson et al. (2018)	Indoor dust and window wipes	Phthalates	10 min	n-hexane/acetone (3/1, v/v)	2 mL
Tang et al. (2020)	0.5 g of preschool children's clothing	Phthalates	30 min (the first time), 20 min (the second time)	n-hexane/acetone (1/1, v/v)	40 mL (the first time), 30 mL (the second time)

**Fig. 6** Schematic of the MAE system. (©With permission of Bouras et al. 2015)

will lead to degradation of some target compounds (Bouras et al. 2015). Table 7 lists several studies that have utilized the MAE method. Finally, the advantages and disadvantages of different extraction techniques are summarized in Table 8.

Table 7 MAE methods used in different studies

Studies	Samples	Analytes	Extraction time	Solvent	Extraction temperature
Purcaro et al. (2009)	1/2/3 g of smoked meat	PAHs	5/15/ 30 min	n-hexane, n-hexane/ acetone (3/1, v/v)	60/90/ 115 °C
Liang et al. (2010)	1 g of soil	Phthalates	30 min	5 mL of acetonitrile	100 °C
Sun et al. (2012)	0.5 g of edible vegetable oil	Phthalates	20 min	5 mL of methanol	100 °C
Salazar-Beltrán et al. (2018)	0.5 g of polyethylene terephthalate bottles	Phthalates	30 min	5 mL of acetonitrile	140 °C

Table 8 Comparison of different extraction methods (Eskilsson and Björklund 2000)

	Advantages	Drawbacks
Soxhlet	Low cost No filtration requirement	Low extraction speed Large solvent volume Laborious cleaning work, which typically results in relatively frequent breakage
ASE	Fast extraction speed Low solvent volume High temperature No filtration requirement	High capital cost, but savings in solvent costs, breakage, throughput, and labor
USE	Low cost Fast extraction speed Available for multiple extractions	Large solvent volume Large manual work (repeated extractions are usually needed) Filtration requirement May degrade the sample and produce underreporting of the actual concentrations
MAE	Fast extraction speed Low solvent volume High temperature Available for multiple extractions	Extraction solvent must be able to absorb microwaves Only suitable for polar compounds Filtration requirement

Cleanup

After solvent extraction, the extracted solution normally contains solid impurities. Cleanup procedures are required to remove them and protect analytical instruments. Centrifugation and filtration are the two typical cleanup methods. In a centrifugation process, liquid samples are placed in a centrifuge tube, which spins at a constant speed and temperature for several minutes. Under centrifugal force, suspended

particles in the solution will be separated from the supernatant. In the filtration process, the samples are pushed through a filter. Particles larger than the filter's pore size are trapped on the filter and separated from the solution.

Filtration and centrifugation both have advantages and disadvantages. Only the supernatant of the extracts can be used after centrifugation, while all the extracted solution can be collected after filtration. However, during filtration, particles may form a cake on the filter and block the rest of the solution from passing through the filter, which is called blinding (Soerensen et al. 1997). Therefore, to achieve good filtration efficiency, filters with different pore sizes are used, and the process is usually carried out level by level. Considering the sample loss that occurs during multiple steps, filtration is more complicated than centrifugation and is not suitable for removing large amounts of particles. To achieve a good recovery rate, cleanup was typically carried out before the concentration step (e.g., Bohlin et al. 2014).

Concentration

Concentration is necessary to ensure that the analytes in the extracts can be detected and quantified by analytical instruments, considering that the use of a large amount of solvent may significantly dilute the extracts. Evaporation and nitrogen blowdown are typical methods to reduce solvent volume. Rotary evaporation is commonly used, in which the solvent is evaporated in a vessel partially immersed in hot water and continuously rotated to maintain a large heated area (Erickson et al. 1981). Since it reduces solvent volume very rapidly, rotary evaporation is typically used to remove a large portion of solvent. In contrast, nitrogen blowdown is a gentle and slow concentration method. During the process, the solvent is volatilized by a stream of high purity nitrogen blowing across the surface of the solution. Due to its low concentration speed, it is recommended to perform nitrogen blowdown after rotary evaporation as a further concentration step. Cheng (2003) reported that if only rotary evaporation was used to concentrate the solution to a final volume of less than 1 mL, a large amount of analyte would be lost. Therefore, the combination of rotary evaporation and nitrogen blowdown can provide acceptable recovery ratios and is recommended.

Thermal Desorption (TD)

Thermal desorption (TD) is a technique that extracts SVOCs from sorbents or a solid matrix by heating the sample in a stream of inert gas. The extracted SVOCs are subsequently captured by an electrically cooled cold trap and concentrated there prior to transfer to a GC column for chemical analysis through a heated transfer line. TD is applicable to a wide range of sample types including solids, liquids, and gases. Sorbent tubes are generally used to collect gas samples up to several hundreds of liters. Since the two-stage desorption process (tube desorption and trap desorption) mentioned above focuses the analytes into a narrow band of gas and ensures the

analytes being transferred to the GC quickly by heating the cold trap rapidly, greater sensitivity than that of solvent extraction can be achieved (Clausen and Kofoed-Sørensen 2009). In addition, TD instruments can be programmed to run a series of tubes automatically, and it is more environmentally friendly than solvent extraction. However, compared with other sample pretreatment methods, the cost of TD instruments is normally high. Additionally, the sorbent tubes can only be thermally desorbed once, while the samples from solvent extraction can be stored at low temperature for repeat analysis.

Chemical Analysis

Chromatography

Gas chromatography (GC) and high-performance liquid chromatography (HPLC) are two of the most commonly used chromatography techniques for analyzing indoor SVOCs. Compared to HPLC, GC is easier to operate and has low running expenses, but it is only suitable for SVOCs that are stable at the temperatures used in GCs (generally less than 350 °C) (Clausen and Kofoed-Sørensen 2009). Many SVOCs in indoor environments can be analyzed by GC, including polycyclic aromatic hydrocarbons (Possanzini et al. 2004), phthalates (Babu-Rajendran et al. 2018), polychlorinated biphenyls (Dmitrovic et al. 2002), polybrominated diphenyl ethers (Sapozhnikova et al. 2015), dichlorodiphenyltrichloroethane (DDT) (Sapozhnikova et al. 2015), organophosphate esters (Mihajlović et al. 2011), and per- and polyfluoroalkyl substances (Scott et al. 2006).

HPLC is a more complex and expensive method than GC. There are many parameters that need to be optimized, and solvent consumption is large. It is a widely used method for analyzing less volatile, strongly polar or thermally unstable SVOCs that are not suitable for GC (Clausen and Kofoed-Sørensen 2009). HPLC is often used to quantify human metabolites due to exposure to phthalates, OPEs, parabens, phenols, antibacterial agents, and per- and PFASs (Blount et al. 2000; Hoffman et al. 2018). Other SVOCs such as PAHs, pesticides, PBDEs, polychlorinated dibenzodioxins (PCDDs), and polychlorinated dibenzofurans (PCDFs) can also be analyzed by HPLC (Król et al. 2011; Petry et al. 2014).

Mass Spectrometry (MS)

The most commonly used SVOC detection method in conjunction with chromatography is mass spectrometry (MS). Unlike conventional detectors, such as flame ionization detectors (FID), that can only identify compounds with the aid of standard solutions, MS determines compounds by comparing fragment ions with available commercial mass spectral libraries. Applications of MS are generally divided into targeted and non-targeted analysis. At present, single quadrupole is still the most widely used mass analyzer for targeted approaches because of its low cost, easy

maintenance, and simple operation (Gruber et al. 2020). Recently, triple quadrupole has taken the lead in targeted analysis. In the multi-reaction monitoring (MRM) mode of triple quadrupole, the sensitivity and selectivity are higher than that in single quadrupole's selected ion monitoring (SIM) mode (Gruber et al. 2020).

With the development of high-resolution MS analyzers such as time-of-flight (TOF) and Orbitrap, non-target screening of SVOCs has attracted increasing attention from researchers. Both TOF and Orbitrap can provide high sensitivity, resolution, and mass accuracy to meet the needs of non-targeted analysis (Gómez-Ramos et al. 2019). Compared to Orbitrap, TOF costs less and has a higher acquisition speed, and it is thereby widely applied in environmental research as a non-targeted analysis technique (Chung et al. 2017; Phillips et al. 2018). However, Orbitrap has a higher mass spectral resolution than TOF with advantages of high resolving power (up to 120 K at m/z 200) and mass accuracy lower than 1 ppm (Gómez-Ramos et al. 2019). It is a more powerful but more costly tool for non-targeted analysis of SVOCs (Wang et al. 2019; Phatthalung et al. 2021).

Conclusion

The current review provides information on several techniques for the sampling, pretreatment, and chemical analysis of SVOCs in indoor environments. Understanding the advantages and disadvantages of different methods is important for the selection of suitable techniques for different analytes and situations. However, as existing methods still have some limitations, it is necessary to further optimize the process parameters to improve the performance and efficiency of different methods and develop new technologies.

Abstract

A passive sampler is a device which is capable of preconcentrating an analyte without the help of a pump. Due to its advantages of simple operation, easy portability, and no external power, passive sampling is a promising method for multi-point sampling, remote-area sampling, long-term sampling, and personal sampling compared to active sampling. Over the past decades, numerous passive samplers have been developed and successfully applied for monitoring concentrations of indoor gaseous pollutants, especially volatile organic compounds (VOCs). This chapter provides an overview of the evolution of passive samplers and passive sampling theories since 1970s, and introduces an inverse-problem-based method for the optimal design of passive samplers with the goal of minimal sampling errors.

Introduction

Nowadays man-made chemicals are abundant in various indoor environments (Weschler 2009). Exposure to some of these chemicals, especially certain volatile organic compounds (VOCs), are related with sick building syndrome (e.g., mucous membrane irritation, headache and fatigue) (Destaillets et al. 2008; Kim et al. 2001; Wolkoff 1995), other morbidities (WHO 1983), and even cancer (WHO 2000). Therefore, monitoring VOC concentrations in various environments is essential for the evaluation of their exposure concentrations and the potential associated health risks. Concentrations of VOCs are often quite low in the air (below or around magnitude of $100 \mu\text{g}/\text{m}^3$). Thus, enrichment of the sample is a very important step for their quantitative determination (Du et al. 2013). Generally, two sorbent enrichment technologies are frequently used: active sampling and passive sampling (Du et al. 2013). Passive sampling is defined as any sampling technique based on free mass transfer of analyte molecules from the sampled medium to a collecting medium (due to the difference in chemical potentials of analyte between these two media) (Gorecki and Namiesnik 2002). As a result, a pump and its power supply are eliminated. Because of its simplicity and low cost (both for manufacture and sample analysis), passive sampling is a promising method for multi-point sampling, remote-area sampling, long-term sampling, and personal sampling compared to active sampling (Du et al. 2013; Kot-Wasik et al. 2007).

Over the past several decades, there has been growing demand for environmental monitoring and exposure evaluation. Thus, the design and application of passive sampling have been extensively developed (Brown et al. 1981; Cocheo et al. 1996; Du et al. 2014; Namieśnik et al. 2005). Passive samplers have been successfully applied for monitoring concentrations of pollutants in indoor air, workplace air, ambient air, and other matrixes (Kot-Wasik et al. 2007; Partyka et al. 2007). Passive sampling has been shown to have the same accuracy as active sampling (Bohlin et al. 2014; Du et al. 2013). Nevertheless, the performance of the existing passive samplers for monitoring VOC concentrations still varies among different sampling environments, suggesting the need for improving the sampling stability of passive samplers (Cao et al. 2016a). Thus, this chapter starts with a summary of the representative passive samplers and passive sampling theory reported in the literature since 1970s, and then introduces a method for the optimal design of passive samplers with the goal of minimal sampling error.

Overview of Passive Samplers

Representative Passive Samplers

The start of passive sampling methods dates to 1853 when Swiss chemist Schonbein employed a strip of filter paper saturated with potassium iodide to detect the presence of O₃ in the atmosphere (Namieśnik et al. 2005). The first true passive samplers, which enabled the quantitative determination of analytes, were designed in 1973 producing two different types, (1) tube-type passive sampler for detecting NO₂ concentration in outdoor air, in which the analyte diffused from the sampled air to the sorbent through a static layer of gas (Palmes and Gunnison 1973); and (2) a permeation device for detecting SO₂ concentration in workplace air, in which the analyte permeated from the sampled air to the sorbent through a polymer membrane (Reiszner and West 1973). Since then, different designs of passive samplers have been proposed as prototypes or have been commercially available. Generally speaking, three types of passive samplers can be identified based on their geometry: tube-type samplers, badge-type samplers, and radial samplers as shown in Figs. 1 and 2. Details of representative passive samplers are summarized in Table 1 with an emphasis on the geometry type, barrier type, sorbents, and analytes. Although the radial type samplers were developed more recently, they combined the features of tube and badge samplers, and they tended to be the most appealing passive samplers in common applications (Zabiegala et al. 2010).

Although the details of the implementations varied widely among the different types of passive samplers, most passive samplers include two main parts, the sorbent, and the barrier covering the sorbent as shown in Fig. 3. When a passive sampler is exposed to the measured matrix, the analyte will transfer through the boundary layer around the barrier surface, then diffuse through the barrier, and finally be adsorbed by the sorbent and diffuse in the sorbent (Cao et al. 2016a).

The barrier helps to define a relatively steady sampling rate by eliminating or minimizing effects of environmental factors (especially the fluctuating velocity of the sampled air), which is crucial for quantitative analysis. According to the type of the barrier, most passive samplers can be classified into two main categories: diffusion-based passive sampler (the analyte diffuses through a static layer of air or a porous medium from the sampled air to the sorbent) and permeation-based passive sampler (the analyte permeates through a polymer membrane from the sampled air to the sorbent) (Huang et al. 2018).

For the diffusion-based passive samplers, static air was used as the first type of barriers (Brown et al. 1981; Namieśnik et al. 2005; Palmes and Gunnison 1973), while tiny air tunnels or porous polymer layer were more frequently used as barriers in the newer generation of passive samplers (Cocheo et al. 1996; Kourakis et al. 1993; Olansandan. et al. 1999). This change is because the mass transfer of analyte through the tiny air tunnels or porous polymer is much less responsive to the fluctuation of air velocity. For the permeation-based passive samplers, a dimethyl silicone polymer was firstly employed as the permeation membrane by Reiszner and West (1973). Since then, multiple non-porous polymers were used in the passive

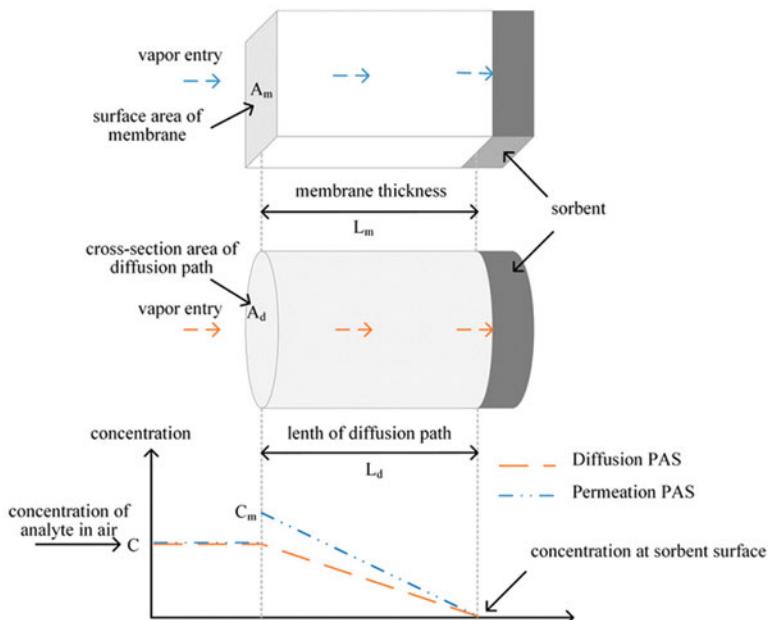

Fig. 3 Concentration profiles for diffusion and permeation passive samplers. (Reprinted with permission from Huang et al. (2018))

samplers, including semi-permeable membrane devices (SPMD), low-density polyethylene (LDPE) tubes, trimethylpentane containing passive samplers (TRIMPS), ionic liquid SPMD (IL-SPMD), and triolein-embedded cellulose acetate membrane (TECAM) as summarized by Esteve-Turrillas et al. (2007). Because the thin non-porous membrane tends to be rather fragile and contains pinholes that allow the direct penetration of air flow, permeation-based passive samplers are generally of badge type.

Analytes are retained in different sorbents by physical or chemical sorption (Harper 2000). For analysis, the analytes retained in sorbents are liberated by thermal desorption or solvent extraction depending on the type and the properties of the sorbents and the analytes.

Passive Sampling Theory

As shown in Fig. 3, the transport of the analyte from the sampled air to the passive samplers can be divided into four steps: (1) transfer through the boundary layer around the barrier surface (from the ambient air to the barrier surface), (2) diffuse/penetrate through the barrier (from the barrier surface to the sorbent-barrier interface), (3) be adsorbed by the sorbent, and (4) diffuse in the sorbent (Huang et al. 2018).

Early in 1973, Palmes and Gunnison (1973) described the mass transfer through the stagnant air gap in Palmes tube by Fick's First Law,

$$\frac{dm}{dt} = D_s A \frac{C_a - C_s}{L} \quad (1)$$

where m (μg) is the mass collected by the sampler, t (s) is the time, dm/dt ($\mu\text{g}/\text{s}$) is the sampling flux, D_s (m^2/s) is the diffusion coefficient of the analyte in the barrier, A (m^2) is the cross-sectional area of the sampler, C_a ($\mu\text{g}/\text{m}^3$) is the concentration of chemical in bulk air, C_s ($\mu\text{g}/\text{m}^3$) is the concentration at the air side of the air-sorbent interface, and L (m) is the diffusion distance (i.e., the length of the stagnant air gap between the sorbent and the ambient air).

Palmes and Gunnison (1973) assumed that the sorbent was an ideal sink for the analyte, and thus, the analyte concentration adjacent to the air-sorbent interface (i.e., C_s) was equal to zero throughout the whole sampling process. Consequently, the mass collected by the sampler (m) can be estimated by,

$$m = SR \cdot C_a \cdot t_s \quad (2)$$

where t_s (s) is the sampling time, and SR (m^3/s) represents the sampling rate of the sampler, which equals $D_s A / L$ according to Eq. (1), i.e.,

$$SR = \frac{D_s A}{L} \quad (3)$$

The diffusion-based model (Eq. (2)) has been widely used for describing the relationship between the sampled mass of the analyte in the diffusion-based passive samplers and C_a .

For permeation passive samplers, permeation is the principal process involving the dissolution of the analyte at the outer surface of the membrane, diffusion of the analyte through the membrane (analogous to diffusion through a liquid) and evaporation of the analyte at the other side of the membrane. In 1973, the permeation of the analyte through a polymer film was firstly mathematically described by Reiszner and West (1973) as,

$$\frac{dm}{dt} = \frac{D_s A (p_1 - p_2)}{S} \quad (4)$$

where p_1 and p_2 (Pa) are the partial pressures of the analyte near the external and internal surfaces of the membrane, respectively; and S (m) is the membrane thickness.

Supposing the partial pressure gradient is linear within the membrane and the collection efficiency of the sorbent is 100% (i.e., the sorbent is an ideal sink for the analyte, $p_2 = 0$), the mass of the analyte collected in the sorbent can be described:

$$m = \frac{D_s A}{S} p_1 t_s \quad (5)$$

Furthermore, the partial pressure of the analyte at a given temperature can be easily converted to its mass concentration in the air using the idea gas law equation,

$$p_1 = cRT \Rightarrow p_1M = (cM)RT = C_aRT \Rightarrow p_1 = \frac{RT}{M}C_a = HC_a \quad (6)$$

where R (J/(mol·K)) is the universal gas constant, T (K) is the temperature, c (mol/m³) is the molar concentration of the analyte, M (μg/mol) is the molecular weight of the analyte, and $H (= RT/M)$ is a constant.

Substituting Eq. (6) into Eq. (5),

$$m = SR \cdot C_a \cdot t \quad (7)$$

where SR is the sampling rate, $SR = \frac{D_s H A}{S}$. Generally, the product of D_s and H is usually called the permeation coefficient P , i.e., $P = D_s H$, and $SR = PA/S$.

According to these two models (Eq. (3) for diffusion-based sampler and Eq. (7) for permeation-based sampler), the sampling rates of both the diffusion-based and permeation-based passive samplers can be easily obtained. That is, the sampling rate is proportional to the diffusion/permeation area and diffusion/permeation coefficient, and inversely proportional to the diffusion/permeation distance. For a passive sampler with a defined geometry and used at a constant temperature, its sampling rate should be a constant for a given analyte. Given these prevailing theories for passive samplers, many passive samplers have been designed and evaluated using these two models (Batterman et al. 2002; Bertoni et al. 2004; Hardy et al. 1979; Pennequin-Cardinal et al. 2005b).

However, the key assumption of these two models (ideal sink) is just satisfied for the uptake of chemicals in strong sorbents. Sampling rates of passive samplers were often observed to decrease as sampling time increased in either laboratory or field experiments (Ballach et al. 1999; Kilic and Ballantine 1998; Pennequin-Cardinal et al. 2005a; Tolnai et al. 2001; Walgraeve et al. 2011). Furthermore, convective mass transfer on the barrier surface was shown to significantly affect sampling rates (Cao et al. 2016b; Gair and Penkett 1995; Plaisance 2011; Soderstrom and Bergqvist 2004). However, this mass transfer is excluded in Eqs. (2) and (7). Therefore, the models based on Eqs. (2) and (7) may not fully describe the uptake of analyte from air, through the barrier, and into sorbents. As summarized in Table 2, several models have been modified to describe the uptake of analytes by passive samplers. However, none of these models fully considered the three steps of analyte transport from ambient air to the sorbent, i.e., transfer through the boundary layer around the barrier surface, diffuse/penetrate through the barrier, and diffuse in the sorbent (and be captured by the sorbent).

Recently, Cao et al. (2016a) developed a transient model that fully considered the mass transfer processes in passive samplers. As illustrated in Fig. 4, the model was developed on the basis of the radial-type diffusion sampler (e.g., Radiello sampler in Fig. 1c) because it had better performance and was commonly used (Du et al. 2013). Several assumption were made in the model: (1) the barrier and sorbent were both made of porous media, (2) the mass transfer of analyte in passive sampler was one-dimensional, i.e., only mass transfer in the radial direction was considered; (3) the analyte in the porous air was assumed to be in equilibrium with the sorbent

Table 2 Evolution of the passive air sampling theory

	Across air boundary	Mass transfer through barrier	Diffusion within sorbent	Sorption/Desorption equilibrium within sorbent	Type of model
Palmes and Gunnison (1973)	×	√	×	×	Steady
Hearl and Manning (1980)	×	×	√	×	Unsteady
Coutant et al. (1985)	×	√ (Diffusion)	√	×	Unsteady
Tolnai et al. (2001)	×	√	√	×	Unsteady
Gorecki and Namiesnik (2002)	×	√	×	×	Steady
Bartkow et al. (2005)	√	×	×	×	Steady
Seethapathy and Gorecki (2010)	×	√ (Permeation)	×	×	Steady
Zhang and Wania (2012)	√	×	√	√	Unsteady

“×” means the item is not included in that model; “√” means the item is included in that model

at each point; (4) the sorption isotherm was linear over the concentration range of interest (Lee et al. 2005; Lewis and Mulik 1985); (5) mass transfer in the barrier was pseudo-steady state (due to the diffusion coefficient in the barrier being significantly larger than that in the sorbent, e.g., 10^{-6} m²/s compared to 10^{-11} m²/s (Lewis and Mulik 1985)); and (6) analyte sorption to the barrier was assumed to be negligible.

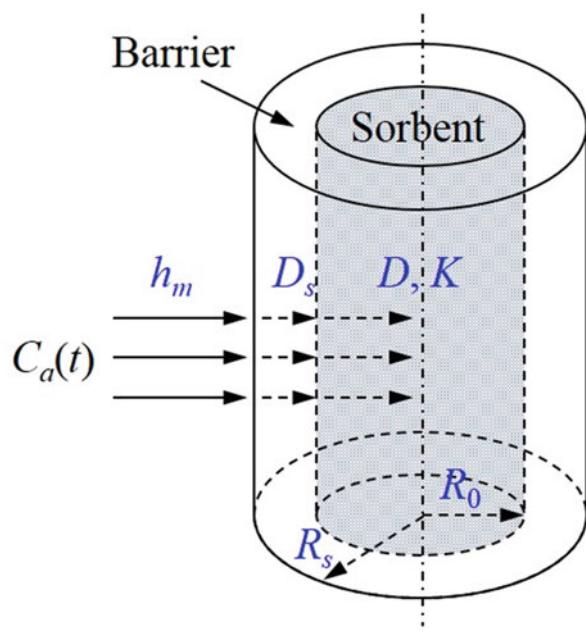

The mass transport of the analyte within the radial sorbent can be treated as the sorption of chemicals by porous media (Lee et al. 2005). The governing equation is expressed as,

$$\frac{\partial C}{\partial t} = D \left(\frac{\partial^2 C}{\partial r^2} + \frac{1}{r} \frac{\partial C}{\partial r} \right) (0 < r < R_0) \quad (8)$$

where C (μg/m³) is the VOC concentration in the sorbent, D (m²/s) is the “effective” diffusivity of the analyte in the sorbent, r (m) is the distance to the cylinder axis of the sorbent, and R_0 (m) is the radius of sorbent cylinder (also the inner radius of the barrier). Here, the surface diffusion of the analyte is negligible as the surface diffusion coefficient is several orders of magnitude lower than the diffusion coefficient in the porous air (Blondeau et al. 2003; Satterfield 1981).

At the cylinder axis of the sorbent (there is no mass flux here), the boundary condition is:

Fig. 4 Schematic of mass transfer of the analyte from ambient air to the sorbent for radial sampler. (Adapted with permission from Cao et al. (2016a). Copyright (2021) American Chemical Society)

$$\left. \frac{\partial C}{\partial r} \right|_{r=0} = 0 \quad (9)$$

At the interface between the sorbent and the barrier, the boundary condition is expressed as:

$$D \left. \frac{\partial C}{\partial r} \right|_{r=R_0} = h_{me} \left(C_a(t) - \frac{C}{K} \right) \quad (10)$$

where K (dimensionless) is the equilibrium partition coefficient of the analyte between the sorbent and the air, and h_{me} (m/s) is the “effective” convective mass transfer coefficient of the analyte from the bulk air to the sorbent-barrier interface. According to the above assumption (5), h_{me} can be calculated as:

$$\frac{1}{h_{me}} = \frac{1}{h_m} + \frac{1}{h_m'} = \frac{1}{h_m} + \frac{\ln(R_s/R_0)}{D_s} \quad (11)$$

where h_m (m/s) is the convective mass transfer coefficient of the analyte above the barrier, which can be calculated by empirical formulas (Bergman et al. 2011), R_s (m) is the outer radius of the barrier, D_s (m^2/s) is the effective diffusion coefficient of the analyte in the barrier, and h_m' (m/s) is the effective mass transfer coefficient, which is obtained by the mass transfer resistance for cylindrical system (one-dimensional diffusion) (Bergman et al. 2011). The parameter, h_{me} , involves

the information of barrier material (D_s), sampler geometry (R_s and R_0), and external condition of the sampling matrix (h_m).

Before sampling, the analyte remained in the passive sampler should be eliminated. Therefore, the initial condition is:

$$t = 0 : C = 0 \quad (0 < r < R_0) \quad (12)$$

The mass of analyte collected by the sampler (m) after t_s can be estimated by,

$$m(t_s) = 2\pi h \int_0^{R_0} r C(r, t_s) dr \quad (13)$$

where t_s (s) is the sampling period, h (m) is the height of the sorbent.

Eqs. 8, 9, 10, 11, and 12 provide the complete model that describes the mass transfer of the analyte from the bulk air to the sorbent of passive sampler. Comparisons between experimental data from the literature (benzene and toluene sampled by Radiello sampler (Oury et al. 2006)) and model outputs have been conducted by Cao et al. (2016a). Good agreement between model predictions and measured data both for benzene and toluene were obtained, implying high accuracy of Eqs. 8, 9, 10, 11, and 12.

Cao et al. (2016a) also developed a similar model for the tube-type diffusion sampler (e.g., Perkin-Elmer sampler in Fig. 1a). As shown in Fig. 5, with the same assumptions made above, the governing equation of mass transfer of the analyte within the sorbent is expressed as,

$$\frac{\partial C}{\partial t} = D \frac{\partial^2 C}{\partial x^2}, \quad (0 < x < L_s) \quad (14)$$

where x (m) is the distance to the end of the sorbent and L_s (m) is the thickness of the sorbent material.

At the end of the sorbent, the boundary condition is:

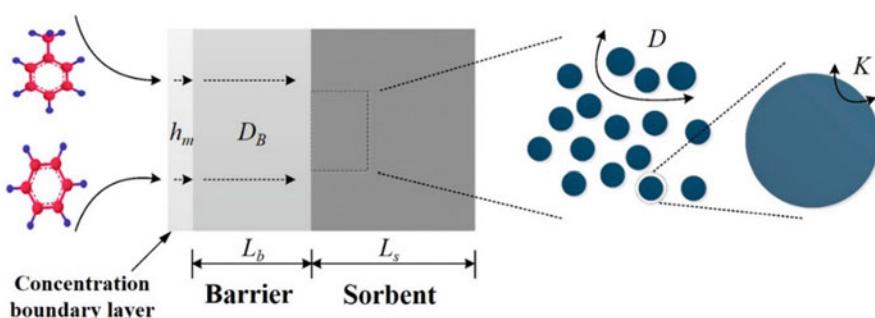

Fig. 5 Schematic of mass transfer process of the analyte in tube-type diffusion sampler. (Reprinted with permission from Cao et al. (2016a). Copyright (2021) American Chemical Society)

$$\left. \frac{\partial C}{\partial x} \right|_{x=0} = 0 \quad (15)$$

At the interface between the sorbent and the barrier, the boundary condition is:

$$D \left. \frac{\partial C}{\partial x} \right|_{x=L_s} = h_{m,e} \left(C_a(t) - \frac{C}{K} \right) \quad (16)$$

where $h_{m,e}$ is also the “equivalent” convective mass transfer coefficient of the analyte from the bulk air to the sorbent-barrier interface, which can be calculated by:

$$\frac{1}{h_{m,e}} = \frac{1}{h_m} + \frac{1}{h_m'} = \frac{1}{h_m} + \frac{L_b}{D_s} \quad (17)$$

where h_m' ($= D_s/L_b$) is the equivalent mass transfer coefficient for analyte diffusion through the barrier, which is obtained by the mass transfer resistance for diffusion through a flat plate (one-dimensional steady-state diffusion) (Bergman et al. 2011). h_m (m/s) is the convective mass transfer coefficient of the analyte at the external surface of the barrier, which also can be calculated using the empirical formula (Bergman et al. 2011).

The initial condition is:

$$t = 0 : C = 0 \quad (0 < x < L_s) \quad (18)$$

Eqs. 14, 15, 16, 17, and 18 form the complete model that describes the mass transfer of the analyte from the bulk air to the sorbent of a tube-type diffusion passive sampler. Comparing Eqs. 14, 15, 16, 17, and 18 to Eqs. 8, 9, 10, 11, and 12, it is easy to show that these two models are very similar.

Optimal Design of Passive Samplers

As mention above, the performance of the existing passive samplers for monitoring VOC concentrations still varies among different sampling environments. For example, significant uncertainties were observed when employing OVM badge samplers to measure concentrations of benzene, toluene and xylenes (BTX) (Du et al. 2013; Pratt et al. 2005). The sampling rates of Perkin-Elmer tube samplers deviated by up to 300% (for benzene) in some studies (Tolnai et al. 2001). Based on experiments, Plaisance et al. (2008) concluded that sampling rate is the main factor influencing the performance (accuracy) of passive samplers, e.g., variation of sampling rate contributes more than 80% of the sampling uncertainty (benzene measured by Radiello sampler).

In general, the traditional method for improving passive samplers employs the idea of “trial and error,” i.e., testing the performance of passive samplers with different combination of sorbent and barrier materials as well as different sizes, and selecting the optimized one with minimum testing error. In this case, abundant test experiments are required resulting in long development periods and high costs. Thus, it can be inconvenient to develop a fully optimized passive sampler that meets the requirements of field test (especially for a wide range of target pollutants). Zhang et al. (2015) proposed an inverse-problem-based method for solving building energy and environment problems. As they have noted, “the objective of an inverse problem is to find the most suitable model parameters to obtain model results that are the most expected (those that tend to be maximal or minimal).” With the principle of Zhang et al.’s method, Cao et al. (2016a) proposed a method for optimizing radial passive samplers by combining the mass transfer model in passive samplers with the goal of minimal sampling error. In this way, substantial time and cost required in the traditional approach can be eliminated.

Method Principle

In the design of passive samplers, the key parameters to be determined are the sorption properties of materials of passive sampler (both barrier and sorbent materials) and geometry of passive sampler. Since the objective of passive sampler is to determine gas-phase concentration of the analyte based on the measured mass of analyte collected by the sampler (m), the expected result of optimizing passive samplers is to minimize the error in the estimated value of m . Prior studies suggested that the error in m originate primarily from three aspects (if the temperature keeps constant): the fluctuation of analyte concentration in the measured environment, the variation of wind velocity in the measured environment, and the error of m introduced by chemical analysis (Pennequin-Cardinal et al. 2005b; Plaisance et al. 2008).

The relative error attributed to the fluctuation of analyte concentration of the measured environment, $\varepsilon(C)$, can be defined as,

$$\varepsilon(C) = \frac{|m - m_C|}{m_C} \quad (19)$$

where m is the mass of the analyte collected by the sampler in time t_s during which the concentration varies (in a real environment, the concentration is C_a), m_C is the mass of the analyte collected by the sampler in time t_s during which the concentration keeps constant (in controlled chamber, the concentration is C_C , $\mu\text{g}/\text{m}^3$). Noting, $\int_0^{t_s} C_C dt$ should be equal to $\int_0^{t_s} C_a dt$.

The relative error caused by the variation of wind velocity in the measured environment, $\varepsilon(V)$, can be defined as:

$$\varepsilon(V) = \max \left(\frac{m_{v,\max}}{m_C} - 1, 1 - \frac{m_{v,\min}}{m_C} \right) \quad (20)$$

where $m_{v,\max}$ is the mass of the analyte collected by the sampler at the maximum wind velocity, $m_{v,\min}$ is the mass of the analyte collected by the sampler at the minimum wind velocity.

The relative error of m from the chemical analysis is related with the method detection limit (MDL), i.e.,

$$\varepsilon(MDL) = MDL/m_C \quad (21)$$

Taking these three factors into consideration, the function of relative error of m (ε) can be defined as:

$$\varepsilon = \sqrt{\varepsilon(C)^2 + \varepsilon(V)^2 + \varepsilon(MDL)^2} \quad (22)$$

As mentioned above, the principle of inverse problem optimization method for passive sampler is to determine the sorption properties of sorbent and barrier materials as well as geometry of passive sampler with minimum ε , based on the mass transfer model in passive samplers, i.e., Eqs. 8, 9, 10, 11, 12, and 13 for the radical-type diffusion sampler.

Eqs. 8, 9, 10, 11, 12, and 13 and 19, 20, 21, and 22 indicate that ε is of the following function form:

$$\varepsilon = f(D, K, h_m', R_0, h, C_a(t), \varepsilon(V), MDL, t_s) \quad (23)$$

Sampling of the VOC concentrations in normal indoor environments was the target case in Cao et al. (2016a). When calculating, a combined standard condition was set at temperature of 20 °C, wind velocity of 0.2 m/s, VOC concentration of 0.05 mg/m³ (common indoor average level of benzene or toluene (Kim et al. 2001; Liu et al. 2013; Sarigiannis et al. 2011; Son et al. 2003)), $R_0 = 2.4$ mm and $h = 6.0$ cm (commonly used for radial-type passive sampler, e.g., Radiello (Cocheo et al. 1996)), and t_s of 24 h. Note: the effects of relative humidity were not considered in Cao et al. (2016a) despite competitive sorption in the sorbents may exist between VOCs and water vapor. The fluctuant VOC concentration in the measured environment was supposed to be:

$$C_a(t) = C_{AVE} + 0.5 \cdot C_{AVE} \cdot \sin \left(\frac{2\pi}{t_T} t + 160^\circ \right) \quad (24)$$

where t_T is the period of concentration change, 24 h; C_{AVE} is the time-weighted average concentration, which is assigned to be 0.05 mg/m³, representative of

common indoor level (Kim et al. 2001; Liu et al. 2013; Sarigiannis et al. 2011; Son et al. 2003). Values in Eq. (24) were determined by fitting the results of a field test in a residential bedroom (more than 3 months after adding decorations, measured by Cao et al. (2016a)). Thus, Eq. (24) was expected to reflect the real characteristic of indoor concentration fluctuations.

The wind velocity covered a wide range of $0.1 \sim 3$ m/s, covering the range of typical indoor common wind speeds and the normal speed of people walking (Baldwin and Maynard 1998; Bao et al. 2000; GB/T 18883 2002). The *MDLs* of benzene, toluene and ethylbenzene analyzed using gas chromatograph-thermal desorption complying with standard method GB 11737-89 (in Chinese) are 50 ng, 100 ng, and 200 ng, respectively, while the *MDL* of toluene (VOCs) for the same method is 5 ng (MDHS 80 1995). Cao et al. (2016a) selected 50 ng as a conservative estimate of the *MDL* for the analysis of VOCs. To numerically solve the model (Eqs. 8, 9, 10, 11, 12, and 13), the sorbent was divided into 30 slices and the barrier was divided into 100 slices. Then the partial differential equations can be discretized into a system of ordinary differential equations.

Considering the above conditions, D , K and h_m' were unknown and were the parameters that required optimization. The properties of sorbent material (determined by D and K) and the barrier material (determined by D_s involved in h_m' according to Eq. (11)) as well as the size of passive sampler can then be determined (determined by R_s involved in h_m' according to Eq. (11)). The effects of some of the model parameters (D , K , and h_m') on the error of M were analyzed by performing sensitivity analysis with the parameterized mass transfer model. The ranges of D , K and h_m' were selected as $1 \times 10^{-15} - 1 \times 10^{-7}$ m²/s, $1 \times 10^2 - 1 \times 10^8$ and $2 \times 10^{-5} - 1 \times 10^{-2}$ m/s, respectively, to cover a broad range of possible cases. The results of sensitivity analysis of D , K , and h_m' are shown in Fig. 6.

Figure 6a shows the variation of the relative errors of m attributed to the fluctuations of VOC concentrations ($\varepsilon(C)$), the variations of wind velocity ($\varepsilon(V)$) and chemical analysis ($\varepsilon(MDL)$) as well as the composite error of m (ε) for various D (when $K = 2.0 \times 10^6$ and $h_m' = 3.6 \times 10^{-4}$, typical values for benzene series (Cao et al. 2016a)). These analyses indicated that as D increases: (1) $\varepsilon(C)$ is decreasing, i.e., the effect of the fluctuation of concentration is weakening; (2) $\varepsilon(V)$ will increase since the effect of external mass transfer resistance (associated with wind velocity) will be more significant for larger D (reducing the internal mass transfer resistance); (3) $\varepsilon(MDL)$ will decrease since the sorption amount of VOC in the sorbent with the same sampling time (i.e., m) will increase for larger D (which reduces the mass transfer resistance of the whole process). This figure also indicates the composite error, ε , will decrease to a constant value as D increases; meanwhile, ε is insensitive to the variation of D .

Figure 6b shows sensitivity analysis results of K (when $D = 9.0 \times 10^{-12}$ and $h_m' = 3.6 \times 10^{-4}$). Similarly to results of D , $\varepsilon(V)$ will increase as K increases, while $\varepsilon(C)$ and $\varepsilon(MDL)$ will decrease. The composite error, ε , will decrease to a constant as K increases, and the effect of K on ε is quite significant for K with small values. Figure 6c shows that ε is very sensitive to changes in h_m' , the value

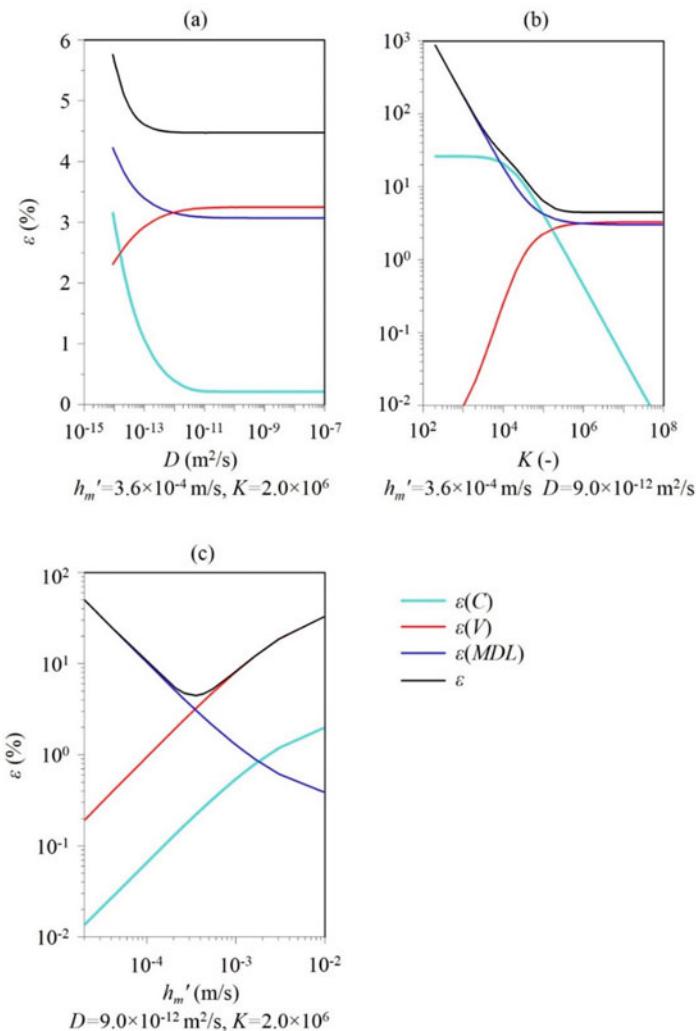

Fig. 6 Sensitivity analysis of model parameters for the relative error of m (ε). (a) D ; (b) K ; and (c) h_m' . (Reprinted with permission from Cao et al. (2016a). Copyright (2021) American Chemical Society)

of ε will decrease firstly and then increase as h_m' increases. The sensitivity analysis results have significance for determining the optimized parameters of passive sampler with the minimum ε . Thus, when searching for the optimized parameters, we can increase the values of D , K and h_m' from certain values (i.e., lower boundary of the range of each parameter), and then stop the calculation when ε approached the minimum value (constant for D and K , while beginning to increase h_m').

Table 3 Optimized parameters of radial passive samplers for benzene and formaldehyde in a normal indoor environment

Chemicals	$D (\times 10^{12} \text{ m}^2/\text{s})$	$K (\times 10^7)$	$h_m' (\times 10^{-4} \text{ m/s})$	$\varepsilon (\%)$
Benzene	0.70	0.60	3.6	4.5
Formaldehyde	6.0	3.0	4.4	3.7

Illustration of Optimization Outputs

In the analysis of Cao et al. (2016a), optimization of radial passive samplers for benzene and formaldehyde in a normal indoor environment was conducted based on the above method, the optimized parameters and minimum values of ε are listed in Table 3. It can be seen that the minimum ε are just 4.5% and 3.7% for sampling of benzene and formaldehyde, respectively. Figure 7 shows the calculated results of ε for various D and K when h_m' is equal to the value listed in Table 3, which indicates that the value of ε is decreasing as K and D increases (in consistent with the above sensitivity analysis results).

Due to the limitation of existing sorbents (i.e., unlikely to find the sorbent meeting the optimized values of D and K), Fig. 7 is useful for selecting the appropriate sorbent by plotting ε of existing sorbents in the figure. Fig. 7 compares the calculated ε of six commonly used sorbents, i.e., Carbograph 4 (used by Radiello sampler), active alumina, active carbon, active manganese oxide, silica gel, and silica zeolite. The results show that for passive sampling of benzene, active alumina, active carbon, Carbograph 4, and silica zeolite are the appropriate sorbents with minimum ε (calculated); while for formaldehyde, active alumina and active manganese oxide are most suitable. However, Carbograph 4, silica gel, and silica zeolite are also acceptable. Although the calculated ε should not be interpreted as the measurement uncertainty in field test, the modeled results are expected to reflect the uncertainty and the performance of passive samplers to a reasonable extent.

In the practical selection of sorbent, the physical and chemical properties of the sorbent need to be considered. Since active manganese oxide may react with VOCs when the temperature is sufficiently high, it is not suitable to be selected as the sorbent if the samples are to be analyzed by thermal desorption-GC-MS. Due to abundant pores in active carbon, desorption of VOCs from this sorbent requires a long period of time and the desorption efficiency is relatively low leading to low throughput because of long analysis times (Du et al. 2013). Water vapor is easily adsorbed by silica gel, which may result in uncertain sampling of VOCs (e.g., formaldehyde). Furthermore, when optimizing passive samplers, the cost should also be considered, and Carbograph 4 is much more expensive than silica zeolite (Du et al. 2013). Therefore, silica zeolite, which is low cost, hydrophobic, and having good desorption efficiency was suggested to be the most appropriate sorbent among the aforementioned sorbents for sampling of benzene (the modeled $\varepsilon < 5\%$) and formaldehyde (the modeled $\varepsilon < 15\%$) by Cao et al. (2016a).

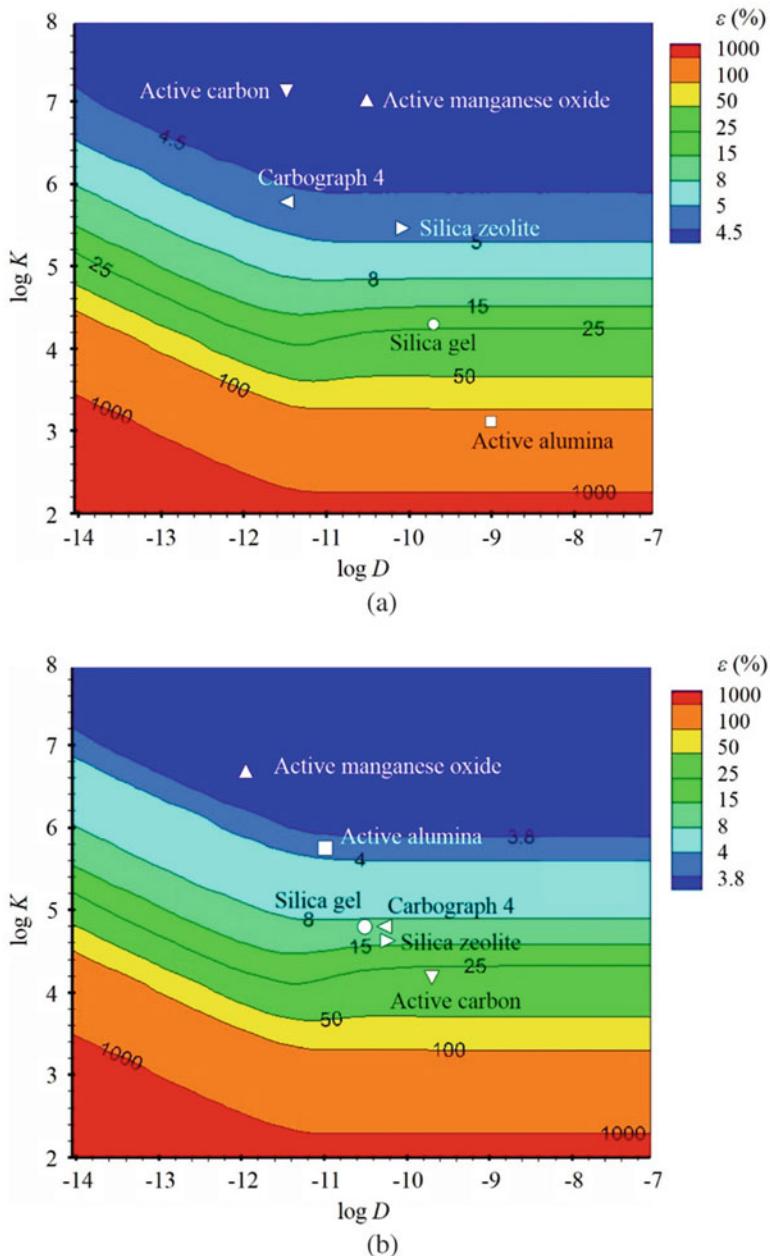

Fig. 7 Variation of ε for various D (m^2/s) and K when: (a) $h_m' = 3.6 \times 10^{-4} \text{ m/s}$ for benzene, (b) $h_m' = 4.4 \times 10^{-4} \text{ m/s}$ for formaldehyde. (Reprinted with permission from Cao et al. (2016a). Copyright (2021) American Chemical Society)

The radius of the sorbent, R_0 , was assumed to be 2.4 mm in the above analysis. The radius can be optimized after selecting the suitable sorbent, i.e., silica zeolite. According to Eq. (23), if D and K of silica zeolite are measured, h_m' and R_0 are the two remaining parameters requiring to be optimized for sampling of VOC concentration in a normal indoor environment. By referring to the method and experimental system developed by Xu et al. (2011), D and K of silica zeolite were measured to be 7.5×10^{-11} m²/s and 3.1×10^5 for benzene by Cao et al. (2016a). Similarly to the method (just mentioned above) for determining D , K and h_m' , the optimized h_m' and R_0 are determined to be 2.45×10^{-4} m/s and 2.15 mm, respectively, for sampling of benzene in a normal indoor environment with the minimum ε to be 4.8%, while the value of ε for a commonly used sampler (i.e., Radiello (Cocheo et al. 1996)) under the same condition is calculated to be 28%.

Application and Discussions

Benzene has been identified as the predominant risk compound in the indoor air compared with other VOCs (e.g., formaldehyde) (Loh et al. 2007). Therefore, a novel radial diffusive sampler, named Tsinghua Passive Diffusive Sampler (THPDS), for indoor benzene measurement was developed according to the above optimization results. Specifically, silica zeolite (FX-2021, Shanghai Fuxu Molecular Sieve Ltd.) was selected as the sorbent with a radius of 2.15 mm (the mass is about 60 mg), the effective mass transfer coefficient (h_m') was set as 2.45×10^{-4} m/s (which is determined by the size and material of the barrier). In design of THPDS, a stainless-steel powder sintered porous cylinder, which is low cost and with weak sorption capacity of benzene (Du et al. 2013), was selected as the barrier with the length of 30 mm, inner diameter of 4.3 mm (i.e., $2R_0$), external diameter of 10.3 mm

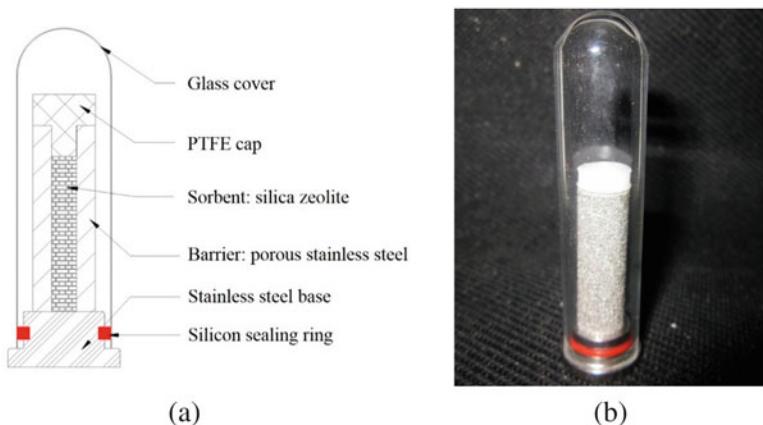

Fig. 8 Tsinghua passive diffusive sampler (THPDS): (a) structure illustration; (b) photo. (Reprinted with permission from Cao et al. (2016a). Copyright (2021) American Chemical Society)

(i.e., $2R_s$), and porosity of 37–38%. Other components and structure of THPDS are illustrated in Fig. 8. As assumed above that sorption of VOC to the barrier should be ignored, the adsorptivity of porous stainless-steel for benzene was tested by exposing the THPDS without sorbent (i.e., just the porous stainless-steel) to $10 \mu\text{g}/\text{m}^3$ gas-phase benzene for 30 days. After that, the sorption amount of benzene in the barrier was lower than the detection limit of the corresponding chemical analysis method (which is the same method for analyzing THPDS, see detailed in Du et al. (2013)), implying that it is reasonable to neglect the sorption of benzene to the barrier. Similar results were obtained for benzene series compounds, i.e., toluene and xylene.

The performance of newly designed THPDS was then evaluated through experimental measurement. The detailed experimental setup and testing results has been reported by Du et al. (2013), including evaluation of the desorption efficiency, background, effect of wind velocity, effects of temperature and relative humidity, and comparison with other sampling methods. According to their evaluation, the uncertainties (at 95% confidence) of THPDS for benzene, toluene, and xylene were 22%, 23%, and 17%, respectively. Compared to several commercial passive samplers, the uncertainties of THPDS were lower than most cases as illustrated in Fig. 9.

However, it should be noted that the measured ε (22%) is quite larger than the modeled ε (4.8%) for benzene, possibly because the errors introduced by other

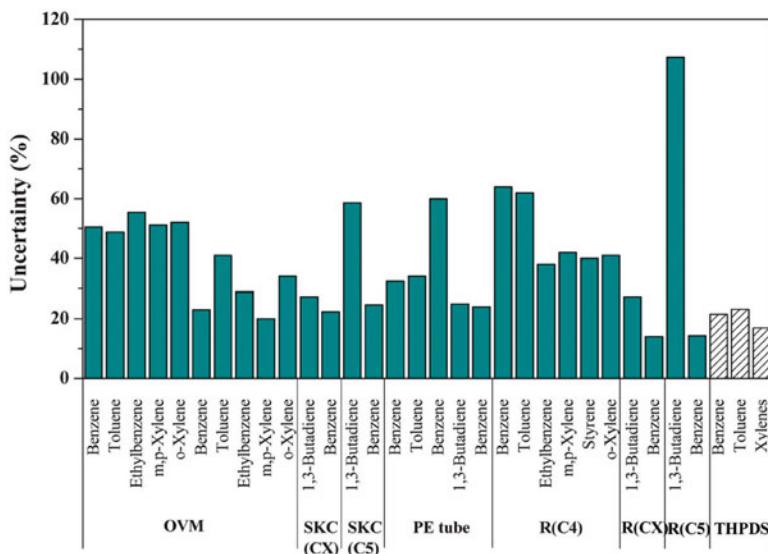

Fig. 9 Uncertainties of VOC determinations by different diffusive samplers against a reference method under field tests. SKC (CX): SKC samplers filled with Carbopack X, SKC (C5): SKC samplers filled with Carbograph 5, R (C4): Radiello samplers filled with Carbograph 4, R (CX): Radiello samplers filled with Carbopack X, R (C5): Radiello samplers filled with Carbograph 5. (Reprinted with permission from Du et al. (2013))

factors, such as temperature variation, humidity, desorption efficiency and storage time of samplers are not considered when modeling the composite error (i.e., Eq. (22)). Further study considering these factors when optimizing and designing passive samplers is requisite. Application of the above method to other series of VOCs, e.g., aldehydes and hydrochloric ethers, also warrants further investigation. In addition, assumption 3) of the above model may not suitable for sorption of formaldehyde (chemical reaction may occur), applicability of this assumption or errors introduced by it for modelling of formaldehyde in passive samplers require more extensive research. Furthermore, the optimized results are focused on one specific compound (e.g., benzene or formaldehyde), optimization of passive samplers that can simultaneously monitor the concentrations of different VOCs can be very challenging. As mentioned above, it is unlikely to find the sorbent that meets the optimized values of D and K , development of new sorbents may be helpful for the optimization of passive samplers. Finally, further study focusing on the optimization of passive sampler of semi-volatile organic compounds (SVOCs) is valuable (Zhang and Wania 2012), which may require to eliminate the barrier layer due to low volatility of SVOCs (Weschler and Nazaroff 2008). Several studies demonstrated that solid-phase micro-extraction (SPME) can be used as passive sampler of SVOCs in laboratory experiments (Cao et al. 2016b, 2017); however, further study is needed to evaluate whether it is applicable in the field test. Details about the passive sampling of SVOCs can be found in another chapter of this handbook (► Chap. 16, “Sampling and Analysis of Semi-volatile Organic Compounds (SVOCs) in Indoor Environments”) and a recent critical review by Wania and Shunthirasingham (2020).

Conclusions

Over the decades, numerous efforts have focused on the development of reliable passive samplers. Tube-type samplers, badge-type samplers, and radial samplers appeared in succession. Meanwhile, many passive sampling theories have been investigated. This chapter provided a brief summary of representative passive samplers and passive sampling theories reported in the literature, with emphasis on the passive sampling of indoor VOCs. Then, an optimization method (for minimizing the sampling error) based on a relatively comprehensive passive sampling model was introduced in this chapter. However, the actual performance of the designed sampler was found to be considerably deviated from the designed performance, indicating the requirement for further investigation of passive sampling models and optimized design of passive samplers.

Abstract

Online measurement techniques of airborne organic compounds have been greatly improved over the past several decades, and they are increasingly applied to indoor air research. Some instruments are designed to accurately measure a specific organic pollutant. Herein we review online measurement techniques for formaldehyde and highlight two recently developed portable devices that are accurate enough for indoor applications. Other instruments can measure many organic compounds simultaneously. The available techniques can be classified into two categories: chemical ionization mass spectrometry (CIMS) and automated gas chromatography (GC) systems. CIMS has high sensitivity and fast response, but often has limited chemical specificity. There are about ten types of

CIMS available, among which proton transfer reaction mass spectrometry (PTR-MS) is most widely used and can measure a large variety of volatile organic compounds. GC-based instruments can have better chemical specificity than CIMS, but the time resolution is lower. Herein we describe operation principles of common CIMS and GC-based instruments, and summarize how these instruments have been applied for indoor air monitoring to gain new insights about the dynamics, emission, chemistry, and exposure of indoor organic compounds. The limited number of indoor applications using these online instruments already demonstrate the great potential of these new tools to advance our understanding of indoor organic chemicals.

Keywords

Online · VOC · SVOC · CIMS · PTR-MS

Introduction

Organic compounds constituent an important class of indoor air pollutants. The indoor air concentrations of many organic compounds are often a few times or several orders of magnitude higher than the outdoor levels, due to direct emission and secondary formation from building and furnishing materials, from occupants, as well as from occupant activities. Indoor exposure to some organic pollutants has been associated to adverse health effects, while for many other organic compounds, the health risks are still being understood. It is thus important to understand the speciation, exposure level, source characteristics, and dynamic behavior of indoor organic compounds.

Concentrations of organic compounds in any given indoor space can vary with the source characteristics, ventilation rates, and temperature among other factors (Parts 2, “Indoor Air Chemicals,” and 5, “Source/Sink Characteristics”). Real-time monitoring of organic compounds can directly characterize their dynamic behavior and time-resolved exposure patterns. Combining the dynamic behavior of organic compounds and simultaneous measurements of environmental parameters, we can better understand the underlying processes controlling the concentrations. Making real-time measurements of organic compounds is, however, nontrivial. First of all, the instruments need to be highly sensitive. The indoor air concentrations of organic compounds, although often higher than outdoors, are typically in the range of tens of ng/m^3 to a few hundred $\mu\text{g}/\text{m}^3$. Secondly, it is challenging to separately measure the large variety of organic compounds present in the indoor air. There are alkanes, alkenes, aromatics, alcohols, aldehydes, ketones, organic acids, peroxides, furans, siloxanes, furanoids, chlorides among others, as well as compounds with multiple functional groups. Some airborne organic compounds are volatile and only present in the gas phase, some others partition between gas phase and particle phase, and the other low-volatility compounds predominantly reside on the particles. The differing phase state requires different sampling methods.

Despite of the challenges, great progress has been made on online measurement techniques for airborne organic compounds over the past several decades. Some real-time instruments are designed to accurately measure a specific organic pollutant. In indoor air research, a particular focus is formaldehyde ([► Chap. 2, “Very Volatile Organic Compounds \(VVOCs\)”\). In the next section, the available online techniques for formaldehyde measurement are summarized and two recently developed portable devices are highlighted. Other instruments aim to measure many organic compounds simultaneously. For measurements of organic compounds at least partially present in the gas phase, including volatile organic compounds \(VOCs\) and semi-volatile organic compounds \(SVOCs\), the available techniques can be classified into two categories: \(1\) chemical ionization mass spectrometry \(CIMS\) and \(2\) automated gas-chromatography \(GC\) systems. The following two sections review the operation principles and indoor applications of these two categories of techniques, respectively. In the section about CIMS, the proton transfer reaction mass spectrometry \(PTR-MS\), which has been widely used for online VOC measurements, is the major focus. In the section about GC-based techniques, two types of instruments respectively designed for the measurement of VOCs and SVOCs are introduced. There are also specialized online techniques to measure particle-bound organic compounds. These techniques are not discussed in this chapter since they are presented in the chapter about particle composition measurement \(\[► Chap. 19, “Measuring Particle Concentrations and Composition in Indoor Air”\]\(#\)\).](#)

Real-Time Monitoring of Formaldehyde

Formaldehyde (HCHO) is one of the most pervasive pollutants in the indoor environment. Airborne formaldehyde concentrations range from tens to hundreds of ppb indoors, while the ambient levels are in the range of hundreds of ppt to several tens of ppb (Salthammer et al. [2010](#)). The common procedure for analyzing formaldehyde in the indoor air is trapping formaldehyde in absorbers or on impregnated cartridges through reaction with derivative agents and then analyzing the resulting chromophore offline by chromatography and/or spectroscopy. The most widely used two derivation methods are the 2,4-dinitrophenylhydrazine (DNPH) method and the acetylacetone method (also called Hantzsch method), which are followed by HPLC analysis and UV/vis spectroscopy or fluorimetry, respectively. These offline methods are reliable and accepted as international or national standards, but can only provide time-integrated or snap-shot formaldehyde concentration.

Sophisticated chemical, spectrometric, and spectroscopic methods have been developed for in situ measurements of gas-phase formaldehyde. Traditional real-time measurement technology employs Hantzsch fluorimetry. This wet-chemistry-based technique is accurate but labor and resource intensive. PTR-MS, which will be discussed in detail in the next section, can also detect formaldehyde. The formaldehyde response in PTR-MS is, however, sensitive to humidity and subject to interference from many other organic compounds which fragment as CH_3O^+ . Highly sensitive spectroscopic techniques have been developed for ambient HCHO measurement, such as laser-

induced fluorescence (LIF) and quantum cascade laser spectroscopy (QCLS). These instruments can provide high-quality scientific data with high time resolution (in seconds). All the abovementioned instruments are bulky, expensive, and often difficult to operate and to maintain. They have been used for outdoor formaldehyde measurements, but their indoor application is limited (Huangfu et al. 2019).

Alternatively, small, cheap formaldehyde sensors using either electrochemical or photoelectric photometry technologies are also available. These sensors often have poor detection limits or are subject to interferences from many other common species in the indoor air. They are mainly used for commercial purposes (e.g., home air quality monitor) and rarely for scientific research.

Here we highlight two recently developed and commercially available HCHO measurement devices, which have sufficient detection limits for indoor measurements, yet are portable and easy to operate. These techniques fall between the two extremes of measurement techniques described earlier, in term of measurement accuracy, cost, and ease of use. They are promising for monitoring formaldehyde concentrations in real time in normally occupied indoor spaces.

Formaldehyde Multimode Monitor

The formaldehyde multimode monitor (FM-801, Graywolf Sensing Solution) measures formaldehyde through colorimetric reaction. The sensor element is made of porous glass impregnated with both β -diketone and ammonium ions, which is initially colorless, turns yellow after reaction with formaldehyde (Maruo et al. 2008). The yellowing is proportional to the formaldehyde concentration and the duration of exposure, and is measured via photoelectric photometry. This device utilizes passive diffusion sampling and is normally operated at 30-min exposure times. The size is small, just slightly bigger and thicker than a smartphone.

The stated measurement accuracy of this formaldehyde monitor is ± 4 ppb for <40 ppb and $\pm 10\%$ of reading for ≥ 40 ppb for 30-min exposures. By re-zeroing between readings, the sensor cartridge is reusable within certain HCHO exposure (approximately 150×30 min tests at 80 ppb HCHO and 1000 tests at <10 ppb HCHO) and can be used for continuous monitoring for several days in normal indoor environments. The standard software for this device reports readings below 10 ppb as “ $<\text{LOD}$,” but the actual limit of detection (LOD) is down to <5 ppb. Carter et al. (2014) determined that the LOD (2σ) was 2 ppb through tests conducted in a controlled environment. As a related note, modified software is available to access readings below the nominal detection limit of 10 ppb (Singer et al. 2020).

Cross-sensitivity of this formaldehyde monitor to many other common indoor air pollutants has been systematically evaluated (Maruo et al. 2010). Interferences from most of the compounds are negligible at concentration levels well above the typical concentrations anticipated in the residential settings. The only exception is the presence of high NO₂ from use of gas cooking burner (Singer et al. 2020).

Online formaldehyde measurements using this portal device were compared with offline measurements using the DNPH methods in the laboratory settings (Carter et al. 2014), as well as in real indoor environments (Maruo et al. 2010; Nirlo et al. 2015). The reported concentrations agree within the stated accuracy in all the studies, and the correlation coefficients (R^2) were within 0.94–0.99.

MIRA Pico Formaldehyde Analyzer

MIRA Pico formaldehyde analyzer (Aries Technologies, USA) utilizes laser absorption spectroscopy to measure formaldehyde. Quantification is based on a distinct, mid-infrared “fingerprint” of formaldehyde at 2831.64 cm^{-1} . The device employs a two-inlet design and three-way valve system that allows for the measurement and subtraction of a zero during data collection. For zero measurement, the air flow is directed into the zero inlet containing an inline DNPH cartridge that filters out more than 99% HCHO. Utilizing an Aeris miniature laser-based sensor engine, the analyzer is only $30\text{ cm} \times 20\text{ cm} \times 10\text{ cm}$ in size, including a built-in pump and battery.

The stated LOD (1σ) of the device is 1 ppb for 1-s integration time. Shutter et al. (2019) evaluated its performance in reference to more established LIF instrumentation. The Aeris device displays linear behavior ($R^2 > 0.940$) when compared with both the LIF instrument from Harvard and that of NASA Goddard. The 3σ LOD for 2, 15, and 60 min integration time are 2.2, 0.7, and 0.4 ppbv HCHO, respectively. The accuracy was found to be $\pm(10\% + 0.3)$ ppbv when compared against LIF instrumentation.

Shutter et al. (2019) collocated this device and a Harvard LIF instrument in Cambridge, MA, to sample outdoor air for several days via a shared inlet line. Formaldehyde concentrations were within 1–8 ppb. The readings of the two instruments differed by less than 10%, which is consistent with the laboratory test. So far, the Aeris device has not been evaluated for indoor formaldehyde measurements yet.

Proton-Transfer-Reaction Mass Spectrometry and Other CIMS

Chemical ionization mass spectrometry (CIMS) ionizes a sample of molecules by gas-phase ion/molecular reactions and then detects the formed ions using mass spectrometry. Chemical ionization is relatively “soft,” leading to limited fragmentation. The exact masses of the product ions thus preserve the molecular composition of their parent compounds to some extent. CIMS allows for measurements of organic compounds in the air with high time response (seconds to minutes) and high sensitivity (sub-ppt to tens of ppt) and without the need for sample treatment. The specific organic species detectable by CIMS mainly depends on the reagent ion used.

Proton-transfer-reaction mass spectrometry (PTR-MS), which ionizes molecules through proton transfer reactions with the hydronium ions (H_3O^+), is the most widely used CIMS for real-time measurement of VOCs in the atmosphere. In recent

years, PTR-MS has been increasingly applied to indoor air research. This section provides a brief introduction of the PTR-MS technique and other CIMS and discusses how the CIMS technique has been used to gain new insights of the speciation, sources, chemistry, emission characteristics, and dynamic behaviors of indoor VOCs. More technical information about PTR-MS can be found in some comprehensive review articles (de Gouw and Warneke 2007; Yuan et al. 2017).

Basics of PTR-MS and Other CIMS

As illustrated in Fig. 1, the PTR-MS instrument consists of three parts: ion source, drift tube, and mass analyzer. Hydronium ions are continuously produced in the ion source and ionize organic molecules (R) in the sample air in the drift tube via proton transfer reaction:

The product ion RH^+ is then detected using a mass analyzer at the end of drift tube. Three features of Reaction (R1) make PTR-MS the most widely used CIMS technique for VOC measurements. Firstly, the reaction is thermodynamically spontaneous for any organic molecules having proton affinity greater than water (691 kJ/mol), allowing for detection of a broad range of VOCs including unsaturated hydrocarbons (except ethene) and VOCs containing oxygen, nitrogen, sulfur, halogens, and silicon, among others. Secondly, the exothermicity of the proton transfer reactions is low enough that the extent of product ion fragmentation is limited. Thus, it is possible to recognize the parent molecular species from the measured product ions. Thirdly, for most VOCs, the reaction proceeds at a rate close to the collision rate, allowing for estimating the mixing ratio of parent species from measured

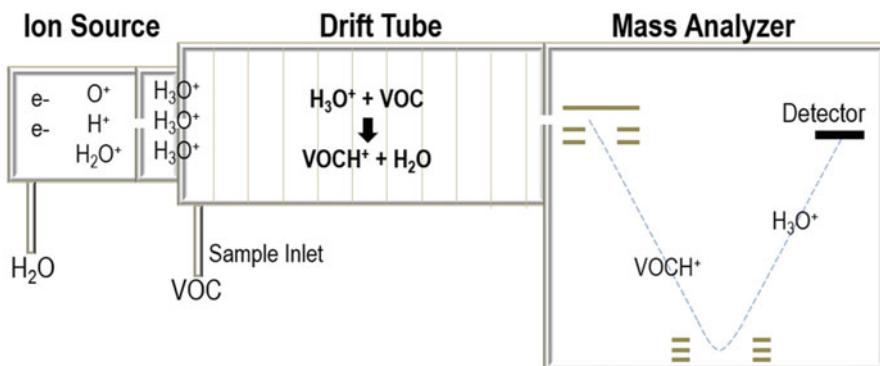

Fig. 1 Schematics of a proton transfer reaction mass spectrometer (PTR-MS) equipped with a time-of-flight detector

product ions even in the absence of standards. In PTR-MS, the reagent ions are generally present in much greater abundance than the analyte, so that we can assume the signal of produced ions is proportional to the mixing ratio of the parent compound in the sampled air.

PTR-MS was initially developed in late 1990s by Lindinger and co-workers at the University of Innsbruck in Austria, and its performance has been gradually improved over the years. There are more than ten models of PTR-MS available from several manufactures, with differing sensitivity, mass resolution, and price. One major difference among these models is the included mass spectrometer. The first-generation PTR-MS uses quadrupole mass analyzer (Lindinger et al. 1998). It only determines the mass of product ion at unit mass resolution and is thus unable to distinguish isobaric compounds (such as $\text{C}_2\text{H}_6\text{O}$ and CH_2O_2). In the late 2000s, time-of-flight (TOF) detectors, which has much higher mass resolution ($m/\Delta m > 4000$), were applied to PTR-MS, enabling resolving molecules with the same nominal mass but containing different elements (Jordan et al. 2009). More recently, long TOF detectors with even higher mass resolution ($m/\Delta m$ can reach $\sim 10,000$) are used in some advanced models (Breitenlechner et al. 2017; Krechmer et al. 2018), further improving the separation of isobaric ions. Another major improvement occurred to ion transmission efficiency from the drift tube to the mass analyzer. Ion transmission in this part strongly affects the sensitivity of the instrument. For example, the PTR-QiTof (Ionicon) using quadrupole ion guide enabled an average increase of sensitivity by a factor of 25, compared to the PTR-TOF 8000 (Ionicon) using the conventional lens system (Sulzer et al. 2014). As another improvement, new designs of the gas inlet and reaction chamber with less wall interaction have recently emerged, extending the measurable compounds from VOCs to SVOCs (Breitenlechner et al. 2017; Krechmer et al. 2018).

PTR-MS is a powerful instrument for VOC measurements, but also have some limitations. PTR-MS only obtains the mass-to-charge ratio (m/z) of the product ions. Although the combination of TOF detector and high-resolution fitting can help translate strong peaks in the mass spectra to chemical formulas without ambiguity, the chemical formula alone is a useful but by no means a unique indicator of the VOC's identity. Moreover, the interpretation of mass spectra can be further complicated by fragmentation of the product ions and formation of cluster ions. It is typically a steep learning curve to grasp data processing and interpretation of high-resolution PTR-MS spectra.

Some other CIMS instruments are also available for online measurements of organic species in the air. The positive reagent ions in addition to H_3O^+ include NH_4^+ , NO^+ , and O_2^+ . The commonly used negative reagent ions include nitrate (NO_3^-), iodide (I^-), and acetate (CH_3COO^-). Compared with H_3O^+ , most of the other reagent ions are more selective and can only ionize a subset of organic compounds with certain functional groups. O_2^+ is more energetic than H_3O^+ , but also leads to more fragmentation. Table 1 lists the analyte compound classes of individual reagent ions and references in which they are applied for real-time monitoring of indoor air.

Table 1 Common types of CIMS and compounds

Reagent ion	Analyte compound classes	Indoor application
H_3O^+	Small oxygenated compounds, polar molecules, alkenes, aromatics	See the main text
NO^+	Alcohols, substituted aromatics, cyclic and branched alkanes, long-chain semi-volatile alkanes, aldehydes and ketone (differentiating the isomers)	N.A.
O_2^+	Alkanes, carbon disulfide, ammonia, halogenated compounds	N.A.
NH_4^+	Highly functionalized VOCs, oxygenated compounds, peroxides	N.A.
NO_3^-	Polar low-volatility oxygenated compounds, strong acids (e.g., H_2SO_4)	See footnote ^a
CH_3COO^-	Carboxylic acids (except acetic acid), nitrophenols, peroxy acids, and benzoyl peroxide	See footnote ^b
I^-	Polar VOC (such as organic acid, peroxides), inorganic chlorinated compounds	See footnote ^c

Application on Real-Time Monitoring of Indoor Air

PTR-MS has been applied for time-resolved observations of speciated VOCs in a variety of indoor environments in the past 10 years. The majority of the reported observations were conducted in normally occupied public indoor spaces including a football stadium (Veres et al. 2013), a cinema (Williams et al. 2016; Stönnér et al. 2018), two classrooms (Tang et al. 2015, 2016; Liu et al. 2016), a museum (Pagonis et al. 2019; Price et al. 2019), and an athletic center (Finewax et al. 2021). Some other work extended to residential environments where people often spend most of their time. Multi-week observation campaigns were conducted in two normally occupied houses in California, USA, in 2016–2018 (Liu et al. 2019, 2021; Lunderberg et al. 2021b). More recently, similar observations were performed in two new apartment buildings in Beijing, China, for five apartments in each (Qiu et al. 2021). Moreover, extensive field experiments with scripted occupant activities were conducted in a test house in Texas, USA (Farmer et al. 2019), as well as in a rented apartment in Hong Kong, China (Lyu et al. 2021). The former study, called the House Observations of Microbial and Environmental Chemistry (HOMEChem) study, involves a large collaborative research team and an unprecedentedly large suite of online instruments.

Application of CIMS other than PTR-MS to indoor air monitoring is less. Liu et al. (2017) monitored gas-phase carboxylic acids in a university classroom using an acetate-CIMS in addition to a PTR-MS. Wong et al. (2017) and Finewax et al. (2021) observed the chemistry of chlorine-containing compounds associated with cleaning activities using iodide-CIMS in a lab and in an athletic center, respectively. In HOMEChem, several types of CIMS were deployed. These

existing studies demonstrate the feasibility and potential of using CIMS techniques for real-time monitoring in the indoor environment. On the ground of these studies, we will first summarize key technical consideration of deploying PTR-MS or other CIMS in the real indoor environment, and then discuss how the data obtained by CIMS have been analyzed to expand our understanding of organic compounds in the indoor air.

Technical Considerations of CIMS Deployment in the Indoor Environment

Space is often a key limiting factor when deploying a PTR-MS and other CIMS in the real indoor environments. A CIMS instrument and its associated gas-handling/calibration system typically occupy an area of a few square meters. The instrument often has high power consumption and generates a considerable amount of heat and its pumping system is constantly making noise. Researchers need to access the instruments periodically for calibration and maintenance. The place to house the instrument needs, therefore, to be sheltered, with stable power supply and thermal comfort for the instrument, reasonably close to the studied indoor space, and accessible by the operators without intervening the monitored indoor environment from its normal operational state. To find such an instrument location is often not easy and requires some special arrangement as well as great supports from the owner and occupants of the properties. For example, the UC Berkeley team deployed their PTR-TOF in an uncoupled garage of the first house H1 they studied (Liu et al. 2019), and then built an air-conditioned instrument shed next to the second house H2 (Lunderberg et al. 2021b). The Peking University team deployed PTR-QiTof in an unoccupied apartment to study the indoor air of some other apartments on the same building (Qiu et al. 2021). For HOMEChem, four instrument trailers were set up outside of the test house.

Depending on where the instrument locates, long sampling tubes of tens of meters are sometimes needed to draw air from the studied indoor space to the instrument. In these cases, the tubing wall effects have to be considered. For common VOCs, the degree of delay through a chemically inert PFA tube varies proportionally with tubing length and inversely with flow rate and its saturation concentration (Pagonis et al. 2017). Taking the medium-volatility VOC nonanal ($C_9H_{18}O$; with saturation concentration $C^* = 3 \times 10^6 \mu\text{g}/\text{m}^3$ at 25°C) for example, the delay through a 30-m sampling tube (1/4" OD) is estimated to be 2.4 min at flow rate of 1 L/min. Note that the tubing delay is defined as the amount of time required for the signal to achieve 90% of the total change through a tube in response to a step-function change in sample concentration. One commonly adopted approach to minimize the tubing wall effect is increasing the total flow rate through the tube. For example, air was constantly drawn through each inlet tube at a controlled flow rate of 2 L/min in addition to the sampling flow rates by the instruments (Liu et al. 2019; Qiu et al. 2021). In the case that the sampling tubing runs from the studied indoor space to outdoors then to the indoor space housing the instrument, we also need to consider temperature gradient the sample air might experience and the associated problems. For example, large temperature drop outdoors at night might lead to

enhanced wall effects and even condensation. Heating and insulating the outdoor sections of the sampling tubes can help to avoid these issues.

A useful sampling strategy of PTR-MS in indoor air research is partially transforming its strength of fast time response to gain information of spatial variability. This can be achieved by setting up multiple inlets to differing locations and automatically switching between them. The most widely used is two-inlet setup, i.e., alternatively sampling from room air and supply/outdoor air. Six-inlet setup is also reported. In the study of California houses, PTR-TOF sequentially sampled from the kitchen, bedroom area, basement, crawl space, attic, and outdoors in 30-min cycles, with each location for 5 min (Liu et al. 2019). In the study of apartments in Beijing, air was sequentially sampled from 4 to 5 apartments (1 or 2 locations in each apartment) of the same building and outdoors in 30-min cycles (Qiu et al. 2021). In these cases, the time resolution at each measurement location dropped to 30 min, but the number of measured places greatly expanded.

Data Analysis Providing New Scientific Understanding

The data obtained by PTR-MS are featured of good chemical specificity and high time resolution. They can also be spatially resolved depending on the experimental design. The data set from a single instrument is often already 2- or 3-dimensional “big data.” There can be many different ways to extract new scientific understandings from the big data. Below we will present some directions to explore the data based on the existing literature.

VOC speciation. The high-resolution PTR-MS spectra using TOF detector or long TOF detector contain rich information of VOC speciation. From the hundreds of VOC signals detected simultaneously, it is possible to identify some important VOC species that are not normally considered. For example, Tang et al. (2015) noticed clusters of ions present at high intensity in the range of 300–500 m/z on their PTR-TOF spectra measured in a university classroom (abundant ions were not expected to appear in this mass range based on prior outdoor VOC measurements). They eventually attributed these ions to cyclic volatile methylsiloxanes. Their finding that siloxanes were the most abundant VOCs emitted from engineering students in the classroom aroused wide attention to chemical emissions from personal care products. More recently, Qiu et al. (2021) observed unexpected high signals of $C_xH_{2x-1}O_4^+$ and $C_xH_{2x-3}O_3^+$ ions ($x = 6–9$) in three out of ten new apartments in Beijing (note that organic compounds containing three or four oxygen typically fragment extensively in PTR-MS). By trial and error, the authors eventually attributed these signals to dimethyl esters (DBEs), a solvent mixture of dimethyl esters of succinic, glutaric, and adipic acids ($C_xH_{2x-2}O_4$, where $x = 6–9$). DBEs have been increasingly used in the coating industry, but are rarely known for their occurrence in the indoor air. In the study, the measured indoor DBE concentrations in all three apartments exceeded the screening level recommended by the Michigan Department of Environmental Quality, USA, suggesting that DBEs might emerge as potential indoor pollutants that merit further attention.

While most existing analyses of PTR-MS data focus on selected abundant ions (compounds), some work tried to perform full-spectrum, non-targeted analyses to

make maximum use of obtained VOC speciation information (Tang et al. 2016; Liu et al. 2019; Lunderberg et al. 2021b). Liu et al. (2019) reported that 656 mass peaks were detected in the PTR-TOF spectra of normally occupied house H1 in California in the summer campaign and 661 in the winter campaign. They eventually extracted 218 VOC signals (organic ion formulas) to represent measured VOC speciation in the summer and 171 in the winter after extensive quality control procedures. These procedures included removing background ions predominantly arising from the instrument and from tubing, assigning chemical formulas based on exact masses of the ions, combining isotopic ions and identified fragment ions, removing interference ions, tracer ions, sticky ions, and inorganic ions, and applying an abundance threshold of >5 ppt. Although substantial amount of time and effort is needed to do this kind of full spectra analysis, the obtained VOC speciation information, in addition to their temporal and spatial variation, forms basis of comprehensive analysis of overall feature of VOC emission and exposure which have never been conducted before (Liu et al. 2019; Lunderberg et al. 2021a, b).

Temporal variation of observed VOC signals. High time resolution is a key advantage of PTR-MS and other CIMS instruments. Temporal variation of the mixing ratios of organic species is often indicative of their emission sources. The first few studies using PTR-MS for real-time monitoring were conducted in built environments regularly occupied by large numbers of people, such as football stadiums, cinema, and classrooms. These studies highlight the magnitude of various impacts human beings have on the VOC composition in their immediate environment. Veres et al. (2013) reported that the mixing ratios of many VOCs increased by more than two times inside Coface Arena in Mainz, Germany, during a football match in the presence of $\sim 31,000$ attendees. The temporal pattern of these VOCs generally followed enhancement of CO₂ concentration attributable to human exhaled breath. Based on the detailed temporal pattern, several distinct source categories were identified, including human respiration, ozonolysis of skin oils, and cigarette smoke/combustion. Liu et al. (2016) applied positive matrix factorization to the unit-resolution mass spectral data of PTR-MS observed in a university classroom, and detected a “human influence” component that varied with level of occupancy and with ventilation in a manner analogous to CO₂. They found that this factor contributed to 40% of the measured daytime VOC concentration in the classroom. Williams et al. (2016) carefully examined the high time resolution (30 s) data measured in a cinema, found that many VOCs in cinema air varied distinctively and reproducibly with time for a particular film, suggesting that the chemical composition of breath emission of cinema audience vary in response to audiovisual cues.

In the non-targeted VOC analysis in normally occupied residence H1, Liu et al. (2019) summarized that the time series of observed VOCs in the living zone was generally characterized by clear short-term enhancements (spikes) on top of more slowly varying baseline levels. The short-term spikes were associated with occupants and their activities. Figure 2 illustrates the time series of kitchen concentrations for selected compounds on one particular day along with recorded occupant activities. Different VOC species spiked as the occupants toasted bread and made coffee

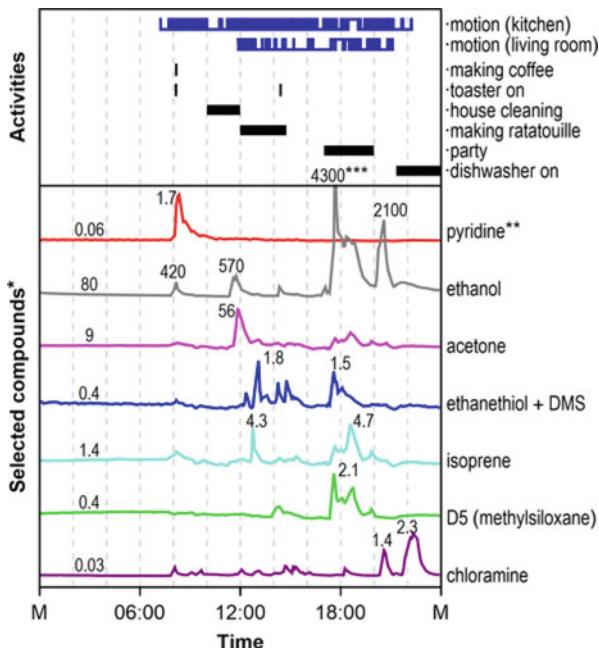

Fig. 2 Time series on a selected day of (top) activities recorded by sensors and occupants and (bottom) kitchen concentrations of selected compounds. Selected compounds (associated major ions) include pyridine ($C_5H_5N^+$), ethanol ($C_2H_5O^+$), acetone ($C_3H_7O^+$), ethanethiol + dimethyl sulfide (DMS; $C_2H_7S^+$), isoprene ($C_5H_9^+$), methylsiloxane D5 ($C_{10}H_{31}O_5Si_5^+$), and chloramine (H_3NCl^+). *Background and peak concentrations (in ppb) of each compound are noted. **Pyridine appeared sticky in our inlet system and consequently the peak signal represents a lowerbound estimate. ***Peak value out of plot range. (Adopted from Liu et al. 2019)

for breakfast, cleaned the floor and made ratatouille during the day, hosted a party in the evening, and then washed the dishes at night. Based on these features, the authors developed further statistical analysis to identify prominent VOC-emitting activities as well as VOC species dominantly contributed by activity emissions. They counted the number of spiked VOC signals in each hour and examined the averaged diel variation during the summer and winter campaigns, respectively. The number of spiked signals peaked at breakfast and at dinner time in both campaigns and the diel pattern resembles remarkably that of stove burner use, which serves as a proxy indicator for cooking activities. This spike analysis strongly suggests that cooking activities made a major contribution to occupant-associated intermittent VOC emissions at least in the studied house. Based on the observation that the presence of spikes in a concentration time series can increase the mean across the whole observational period, but has less effect on the median, the authors took the mean-to-median concentration ratio as a quantitative indicator of the relative importance of occupant-related emissions for a given compound. The analysis identified a range of

compounds with major (dominant) contributions from occupant activities, such as ethanol (beer and wine, toasting bread and other cooking, cleaning), monoterpenes (citrus fruits, cooking, cleaning), pyrrole (making coffee, cooking), D5 and D6 (use of personal care products). More importantly, the analysis suggests that for the majority of VOCs, intermittent event emissions were not their major source. Based on supplementary spatial distribution of VOC signals, the dominant sources were instead continuous emissions into the living space from building material and furnishing.

In addition to the observational studies in normally occupied spaces, experimental studies were also conducted to directly examine how various scripted occupant activities impact indoor VOC composition in a test house in the USA and a rented apartment in Hong Kong (Farmer et al. 2019; Lyu et al. 2021). Investigated activities include cooking, cleaning, incense/candle burning, smoking, painting, and enhanced ventilation. A particularly noteworthy finding is regarding the dynamic gas-surface partitioning of organic species. As a part of HOMEChem, Wang et al. (2020) explored the dynamic response of 19 common indoor air contaminants in sequential enhanced-ventilation experiments using PTR-TOF and some other CIMS. Figure 3 shows the observed time series of selected compounds. By fitting exponential growth curves to the time series data, they determined for each compound the dynamic response time length needed to reestablish steady-state conditions after ventilation perturbations. The derived time constants for all small acids and for phenol were similar, on average, between 700 and 1000 s, much smaller than the reciprocal of air exchange rate (~ 3600 s). This observation, combined with the consistently high response signals, for the first time suggests that there are large weakly polar and polar absorptive surface reservoirs in the studied indoor environment.

Spatial variation of observed VOC signals. When PTR-MS was used to alternatively measure indoor and outdoor/supply air, we can tell directly from the indoor-to-outdoor (I/O) ratio whether an organic species is mainly of indoor or outdoor origin. For >75% of the ~200 measured VOC signals in a house in northern California, the average living-zone concentrations were more than 5 times higher than outdoors ($I/O > 5$) (Liu et al. 2019). For about half of the VOC signals, the difference was at least one order of magnitude ($I/O > 10$). The implication is that the major sources of VOCs in the living zone were emissions directly into the living zone.

More detailed spatial information of VOC species might help better constrain the sources. For the abovementioned house, the authors found that the I/O ratio of some VOC signals in the attic can be 4–10 times higher than the transport-focused predictions, suggesting strong direct emission sources into the attic (Liu et al. 2019). Given that the attic was unoccupied and unfinished, the emission was attributed to emission from wooden building materials. Based on the chemical speciation information of VOCs featured of elevated attic I/O ratio, the authors further hypothesized that these compounds are at least partly volatile products from wood decomposition.

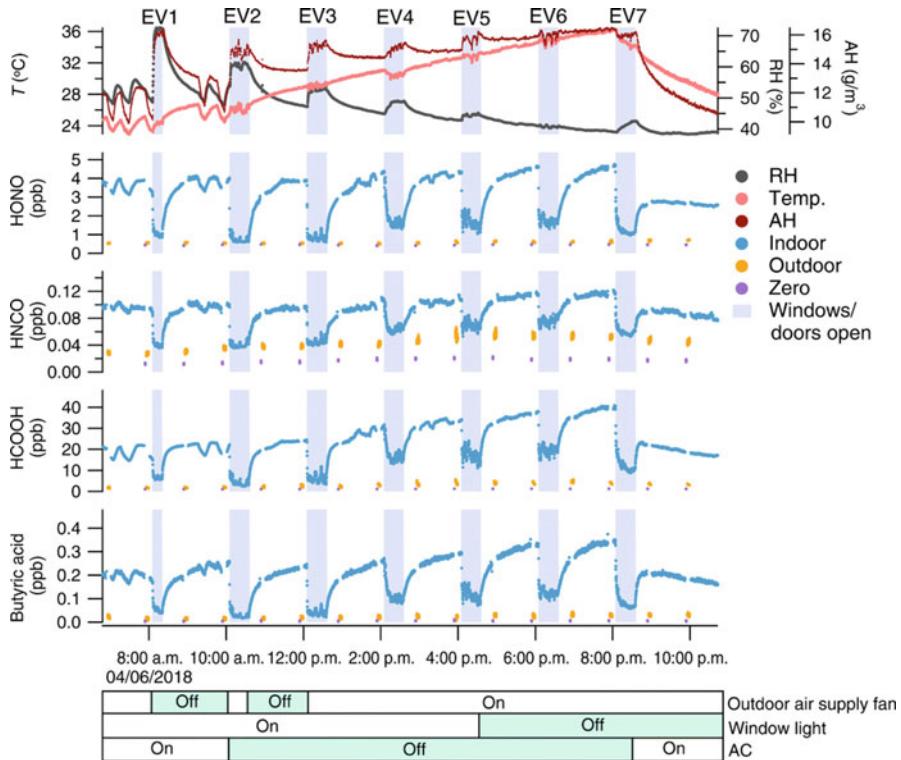

Fig. 3 Indoor mixing ratios of several acids during extensive ventilation experiments during HOMEChem campaigns. The top panel shows the measured house temperature (T ; left axis), relative humidity (RH; right axis), and absolute humidity (AH; second right axis). The shaded areas indicate when doors and windows were open to increase the ventilation rate of the house. The hourly 2-min background measurement (measuring zero air) is shown with purple dots, followed by a 5-min outdoor measurement (orange dots). The average air exchange rate (AER) when the house is closed was about 0.5 h. The color bars at the bottom of the plot show the state of outdoor air supply fan (on/off), window light (with/without), and air conditioning (AC) (on/off) during the experiment, with the green shaded periods showing when the fan, window light, and AC were off. (Adopted from Wang et al. 2020)

Temporal variation of indoor source rate of VOCs. Temporal variation of VOC concentrations reflects the dynamic behavior of its source strength, but is also subject to variation of the air exchange rate among other factors. To obtain more quantitative understanding of VOC source characteristics, we can determine time-resolved indoor source strength from measured time evolution of indoor and outdoor concentrations based on a mass balance analysis. Assuming that the internal volume of an indoor space can be effectively considered as well-mixed, the indoor mass balance of a VOC can be represented by the following equation

$$\frac{dC_{in}}{dt} V = \frac{E}{\rho} - A \cdot (C_{in} - C_{out}) \cdot V \quad (1)$$

where $C_{\text{in}} = C_{\text{in}}(t)$ and $C_{\text{out}} = C_{\text{out}}(t)$ are the concentrations indoors and outdoors (ppb; part per billion by volume); V is the volume of the living zone (m^3); $E = E(t)$ is the net indoor source rate (mg/h); ρ is the gas density for the compound (mg/mm^3); and $A = A(t)$ is the air exchange rate (h^{-1}). Treating $A(t)$ and $E(t)$ as constant over each interval of Δt [$t, t + \Delta t$], we obtain the following approximation for E by integrating Eq. (1):

$$E = \rho V \left(\frac{C_{\text{in}}(t + \Delta t) - C_{\text{in}}(t)}{\Delta t} + A \cdot (\overline{C_{\text{in}}} - \overline{C_{\text{out}}}) \right), \quad (2)$$

where $\overline{C_{\text{in}}}$ and $\overline{C_{\text{out}}}$ are the time averages over $[t, t + \Delta t]$ of C_{in} and C_{out} , respectively. Note that this equation is a simplified representation, the determined E is a net value, incorporating not only indoor emissions and chemical production but also indoor wall interactions and possible indoor losses from chemical reactions.

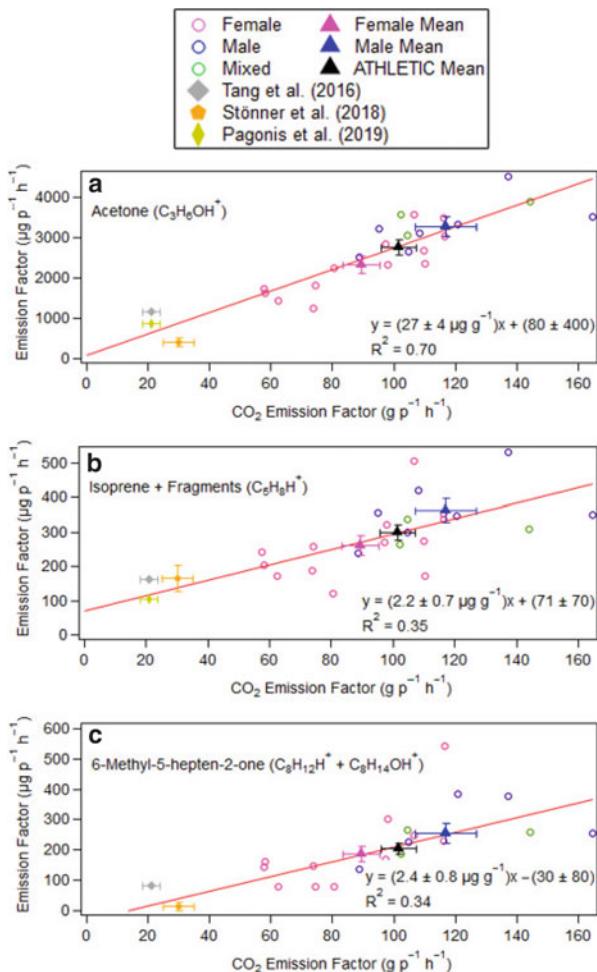

In use of Eq. (2), we need to take a Δt value at least a few times larger than the time resolution of C_{in} and C_{out} measurements. We also need to know $A(t)$. A constant value can be assumed for air exchange rate in the case of public indoor space with dominant mechanical ventilation. In naturally ventilated space, air exchange rates can vary greatly with time and have been to be determined in real time. In this regard, a tracer methods based on selected deuterated alkenes, which are measurable by PTR-TOF, has been developed to quantify air exchange rate in normally occupied indoor spaces (Liu et al. 2018).

For indoor spaces that are intermittently occupied by a large number of people, per-person emission factors ($\mu\text{g}/\text{p/h}$) for human-derived VOCs can be estimated by taking the difference of emission rate when occupied (E_{occ}) and that when vacant (E_{vac}) and then dividing by the occupancy level. Per-person emission factors for a range of VOCs such as isoprene, acetone, and 6-methyl-5-hepen-2-one (6-MHO) have been calculated in this way in a classroom, a cinema, a museum, and an athletic center (Tang et al. 2016; Stönnér et al. 2018; Pagonis et al. 2019; Finewax et al. 2021). As shown in Fig. 4, Finewax et al. found that the emission factors of many compounds increase with the level of physical exercise, indicated by the emission factor of CO_2 . The obtained emission factors can be useful parameters to model occupants' influence to indoor air quality.

The observation-derived source rate has also been used to quantitatively understand indoor ozone chemistry (Liu et al. 2021). As shown in Fig. 5, source strength of the featured skin oil oxidation product 6-MHO exhibited a high correlation with indoor ozone concentration in a house normally occupied by a couple, the fitted intercept (baseline emission) was small compared with the range of fitted slope times indoor ozone (ozone-dependent production), confirming that ozone reaction was indeed the major source of 6-MHO. In addition, the source strength in the episodic presence of a larger number of occupants appeared above the trend line, consistent with the expectation that human skin oil is the precursor. An unexpected observation in this study presents ozone chemistry during vacancy. The author analyzed a subset of data from Fig. 5a with indoor ozone concentration restricted to a small range of 2–4 ppb, as shown in Fig. 5b. They found that the source strength did not exhibit

Fig. 4 VOC vs. CO₂ emission factors for individual exercise sessions (open circles) in an athletic center. From top to bottom shows acetone (C₃H₆OH⁺) and 6-methyl-5-hepten-2-one (6-MHO, C₈H₁₂H⁺ + C₈H₁₄OH⁺), respectively. Open circle markers in pink represent exercise events with at least 75% females, blue open circle markers were exercise events with at least 75% males, and green data points contain less than 75% females or males. The ATHLETIC mean is the mean for all campaign data points. Error bars are standard errors for each dataset.

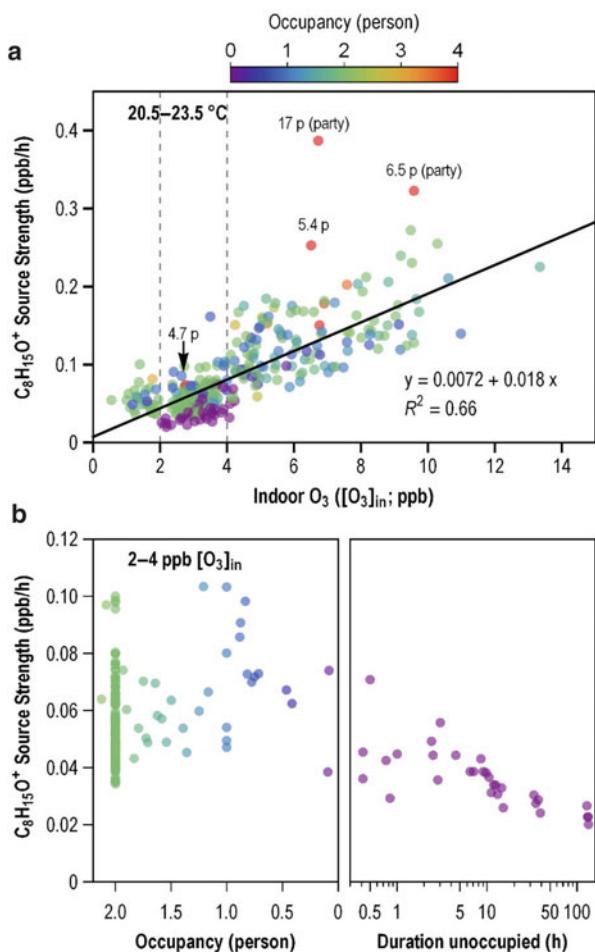

(Adopted from Finewax et al. 2021)

discernable change with the occupancy level ($0 < \text{occupancy} \leq 2$ persons), and diminished only by about half from when the house was unoccupied for ~ 130 h. Given that the reaction between ozone and 6-MHO is fast and there are low baseline emissions (i.e., small intercept in Fig. 5a), it is unlikely that surface reservoirs were a substantial source of 6-MHO during the unoccupied period. Instead the more probable explanation is that ozone reacted with squalene in skin flakes and skin oils that had accumulated on exposed surfaces in the home. The inferred contribution of off-body skin oil/flakes to 6-MHO source strength during normal occupancy (0.045 ppb/h) was substantially larger than the contribution from the body envelopes of the occupants (~ 0.011 ppb/h).

As a further note, based on the same set of data, Liu et al. (2019) found that the emission rates of VOC species that have a dominant contribution from building-related

Fig. 5 Dependence of $C_8H_{15}O^+$ (6-MHO) source strength on (a) indoor ozone concentration and (b) occupancy. (a) Shows all available data using 2-h resolution and restricted to an indoor temperature range of 20.5–23.5 °C. (b) Uses a subset of data in a (bounded by dashed lines, with indoor ozone of 2–4 ppb) and plots $C_8H_{15}O^+$ source strength versus occupancy for $2 \geq \text{occupancy} > 0$ (Left) and versus unoccupied time duration for occupancy = 0 (Right), respectively. In a, the black line shows a linear fit of data after excluding outliers of $C_8H_{15}O^+$ source strength (greater than upper quartile plus $3 \times$ interquartile range); exact occupancy level was labeled for occupancy > 4 . Occupancy level represents the average for the 2-h integration period and so can be a noninteger value when occupants are present for only part of the interval. (Adapted from Liu et al. 2021)

sources exhibited strong temperature dependence. The summed emission rate of all the species increased with temperature in each season as well as across the two seasons. The value at 23 °C was about twice of that at 16 °C. Similar temperature dependencies were evident for most individual ions/groups of ions, such as acetic acid.

Exposure assessment. Human exposure to VOCs has been difficult to characterize, because both VOC concentrations and indoor occupancy vary rapidly. The CIMS instruments make high-resolution exposure assessment of VOCs possible. Lunderberg et al. (2021b) report time-resolved exposures from multi-season sampling of more than 200 VOCs in two California residences. Chemical-specific source apportionment revealed that time-averaged exposures for most VOCs were mainly attributable to continuous indoor emissions from buildings and their static contents.

Also contributing to exposures were occupant-related activities, such as cooking, and outdoor-to-indoor transport. Health risk assessments are possible for a subset of the observed VOCs. Acrolein, acetaldehyde, and acrylic acid concentrations were above chronic advisory health guidelines, whereas exposures for other assessable species were typically well below the guideline levels. In a separate paper, Lunderberg et al. (2021a) evaluated residential intake fractions (iF, mass inhaled by an individual per unit mass emitted) for indoor VOC releases. Despite that emission patterns varied between compounds, all VOC-specific iF estimates were clustered near the values of the living space tracer gases ($iF \sim 0.3\% = 3000 \text{ ppm}$). These experimental observations substantiate the theoretical expectation that iF values are largely independent of analyte characteristics, a useful simplification for exposure assessments.

Automated GC

Automated gas-chromatography systems are also available for real-time measurements of organic species. The analysis typically begins with a sample collection and pre-concentration step, followed by rapid heating of the sample, and detection by standard gas chromatographic methods. Limited by the time length required for gas chromatography analysis, the time resolution of these instruments ranges typically from 30 min to 1 h. Compared with CIMS, the time resolution of GC-based online instruments is much lower, but the chemical specificity can be better.

Many research groups have assembled their own automated GC systems for VOC measurements, and a variety of such systems are also commercially available. Major differences among the various automated GC systems lie in the pre-concentration techniques and the columns and detectors. The commonly used pre-concentration techniques include cryogenic trapping, sorbent enrichment, and a combination of these two methods. Solid adsorbents have been proven reliable for concentrating certain compounds, but for some other compounds, there can be substantial artifact formation and compound losses during the sample enrichment and desorption processes (Apel et al. 2003). Liquid nitrogen is often used for cryogenic trapping in the laboratory setting, but its application is limited in field studies by the use and availability of large volumes of liquid nitrogen. Cryogen-free cooling devices that can create liquid-nitrogen equivalent trapping condition have also been developed for pre-concentration (Sive et al. 2005; Wang et al. 2014). These devices utilize multicomponent mixed refrigerant in a cascade refrigeration cycle, which is closely related to the refrigeration system of a home refrigerator. Many automated GC systems employ multiple sets of separation columns and detectors to expand the range of compounds measurable by the instrument. For example, Sive et al. (2005) used two flame ionization detectors (FID), one electron capture detector (ECD), and one mass spectrometers to measure C3–C7 and C5–C10 nonmethane hydrocarbons, halocarbons, alkyl nitrates, and oxygenated VOCs in 40-min time resolution. Each detector was connected to a separate column optimized for measurements of a set of compounds. The four columns were housed in the same GC oven and ran in parallel.

Abeleira et al. (2017) employed 3 FIDs and 1 ECD to measure 46 individual VOCs including C₂–C₈ nonmethane hydrocarbons, C₁–C₂ halocarbons, C₁–C₅ alkyl nitrates, and several OVOCs with hourly time resolution. These online GC systems have been widely used in atmospheric research, but their application in the indoor air study is limited. To our knowledge, the only reported deployment is during HOMEChem (Farmer et al. 2019).

An automatic GC system for SVOC measurements, semi-volatile thermal desorption aerosol gas chromatograph (SV-TAG), has also been developed (Zhao et al. 2013). The key component of SV-TAG is a high-surface-area passivated stainless steel fiber filter that quantitatively collects both gas- and particle-phase organic compounds less volatile than tetradecane (C₁₄H₃₀). A separation between gas- and particle-phase collection can be determined through a difference method by periodically sampling ambient air through a multichannel charcoal denuder that efficiently removes gas-phase compounds. Samples collected on the filter are desorbed with a ramped temperature into helium saturated with a trimethylsilylation agent *N*-methyl-*N*-(trimethylsilyl) trifluoroacetamide (MSTFA), allowing for online derivatization of the otherwise non-elutable organic chemicals with hydroxyl groups (Isaacman et al. 2014). SV-TAG employs an automatic injection system which can introduce liquid stands to the collection cell reproducibly and thereby achieve in situ calibration (Isaacman et al. 2011). Moreover, in SV-TAG, a valveless sample introduction interface replaces the traditional multiport valve, offering the advantage of long-term reliability and stable sample transfer efficiency under high operation temperature (Kreisberg et al. 2014). Although SV-TAG is more recently developed compared with the GC system for VOC measurements, it has been applied to the observation campaign in a single-family house H2 in north California (Kristensen et al. 2019), as well as to the HOMEChem campaign (Lunderberg et al. 2020).

Kristensen et al. (2019) provides an overview of SV-TAG measurements in H2. Figure 6 shows TIC chromatograms from typical SV-TAG gas-plus-particle sample analyses for several representative cases: outdoor air, indoor air during normal occupancy with no activity, indoor air during cleaning, and indoor air during a cooking event. A large difference both in chemical complexity and in the abundance of SVOCs is consistently observed between indoor and outdoor air, even without contributions from occupant activities. In addition, relative to the baseline indoor condition, both cleaning and cooking activities enhanced the signal intensity. The enhancement is more substantial during cooking, with many new compounds appearing at longer retention time (i.e., with lower volatility), such as straight-chained saturated and unsaturated fatty acids, monoglycerides, and sterols. In comparison, cleaning activities is featured of more volatile compounds such as nonanal and terpineol.

Kristensen also explored the overall features of SVOC dynamics and gas/particle partitioning in the studied house. For the majority of the campaign, gas-phase SVOCs accounted for more than 90% of the total airborne (gas-plus-particle) SVOC concentrations in this residence. However, measurement of the SVOC gas/particle distributions revealed higher contributions of low volatility particle-bound organics during

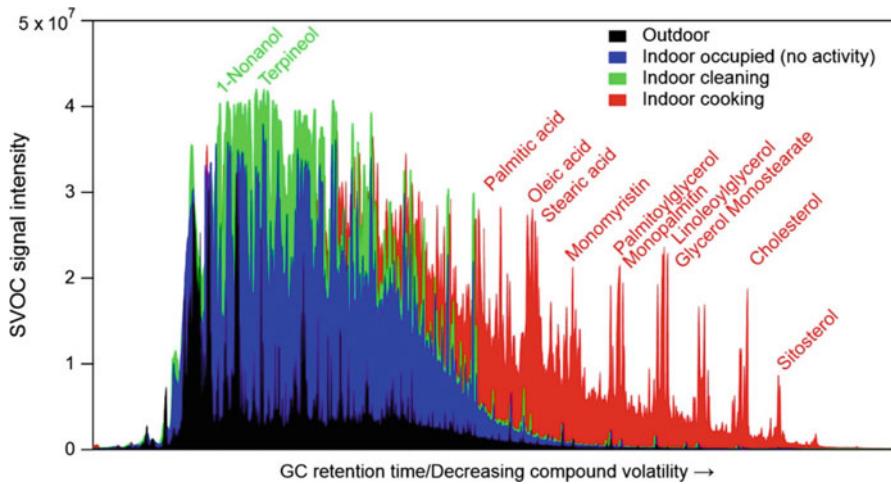

Fig. 6 Total ion chromatograms from SV-TAG analysis of gas-plus-particle samples from outdoor (black), indoor occupied (no activity, blue), cleaning (green), and cooking (red). Compounds associated with the biweekly cleaning (1-nonanol, terpineol) are labeled as well as carboxylic acids (palmitic acid, oleic acid, steric acid), glycerols (linoleoyl glycerol, palmitoyl glycerol, monomyristin, monopalmitin, monostearin), and sterols (cholesterol and sitosterol) identified in the indoor air during cooking activities. (Adopted from Kristensen et al. 2019)

cooking events along with evidence of cooking-associated enhancement of the partitioning into the particle phase of many semi-volatile species responding to the increased indoor particle mass concentrations. The total airborne SVOC concentration shows a positive temperature dependence during both occupied and vacant periods, suggesting that temperature-modulated emissions and/or partitioning with indoor surfaces is a key component of indoor SVOC dynamics.

Based on the same data set, Lunderberg et al. (2019) looked into the dynamic behavior of a specific class of SVOCs, phthalate diesters. They found that concentrations of higher vapor pressure phthalates correlated well with indoor temperature, with little discernible influence from direct occupant activity. Conversely, occupant activities substantially influenced the concentrations and dynamics of a lower vapor pressure compound, diethylhexyl phthalate (DEHP), mainly through production of particulate matter during cooking events.

Lunderberg et al. (2020) further combined the data set from the H2 campaign and that from HOMEChem campaign to show that surface emissions modulate indoor SVOC concentrations through volatility-dependent partitioning. For SVOCs with vapor pressures in the range of C13–C23 alkanes, airborne concentrations in H2 were observed to be correlated with indoor air temperature. Observed temperature dependencies were quantitatively similar to theoretical predictions that assumed a surface-air boundary layer with equilibrium partitioning maintained at the air-surface interface. For SVOCs with vapor pressures corresponding to C25–C31 alkanes, airborne concentrations correlated with airborne particle mass concentration. During

HOMEChem, lower-volatility siloxanes exhibited ongoing emissions after a high emission event associated with oven use in the “Thanksgiving” experiment. In particular, the airborne concentration siloxanes became elevated during the cooking events without oven use on the next day. The suggestion is that the siloxanes emitted from a primary source can be deposited throughout a residence and then reemitted during subsequent particle loading events.

Conclusions

In summary, research-grade online instruments are now available to realize real-time monitoring of volatile and semi-volatile organic compounds in the indoor environment. The pioneering efforts towards this direction in the past decade have demonstrated that the time-resolved measurement data are very useful for investigating the dynamic behaviors of organic compounds in the indoor air and the underlying mechanisms. There is still much more we can learn from the real-time measurements and the resultant big data. Meanwhile, since the available online instruments are expensive, there is also a need for more cost-effective instruments that would permit more widespread measurements to be made.

Abstract

This chapter focuses on methods to measure the mass concentrations of airborne particulate matter, its chemical composition, and the particle number concentrations and the size distributions in indoor air. Particulate matter (PM) is a complex mixture of inorganic and organic compounds with semivolatile components making accurate determinations of its properties difficult. Many of the methods are derived from measurements in the ambient air, but with the simplification that the indoor environment is protected from precipitation and generally from large variations in temperature and relative humidity. PM measurements first collected integral filters that were weighed to obtain the mass of material separated from a known volume of air to obtain the PM mass concentration typically in units of $\mu\text{g}/\text{m}^3$. These samples can be subjected to separation and analysis methods to determine its chemical constituents including elements, ions, collective carbonaceous species, and individual organic compounds. Continuous PM mass measurement systems have been developed based on beta attenuation, oscillating microbalances, and light scattering. There have been major recent developments of low-cost light scattering monitors that permit the use of multiple monitors to simultaneously obtain more detailed data from multiple locations. Particle counting methods date to the late nineteenth century, but have been refined to permit detection of particles as small as 1 nm. These units can be combined with electrical mobility separation to provide particle size distributions. Particle size is important since it determines the penetration and deposition into the human respiratory and the aerosol dynamics in the indoor space. A number of studies employing these methods have been summarized to provide access to the literature to determine the details of how individual studies were conducted. Such information will help in the design of future studies of particle in indoor air.

Particulate matter · Particles · Particle number concentration · Particulate compositions · Measurement methods

Introduction

The largest environmental cause of morbidity and mortality is small particles, $\leq 2.5 \mu\text{m}$ in aerodynamic diameter (PM_{2.5}). Ambient particles are emitted by industrial processes, vehicles, and fires and formed through atmospheric oxidative processes of emitted gases like SO₂, NO_x, and volatile organic compounds (VOCs). Indoors they are emitted mainly by combustion (smoking, cooking, heating, candle burning). The Global Burden of Disease (2020) estimated 6.67 million deaths in 2019 from “air pollution,” which includes both outdoor and indoor fine particles. For indoor air pollution only, other sources estimate 1.6 million or 1.8 million deaths in 2017 (Ritchie 2013; Lee et al. 2020). The toll from fine particles indoors is mainly

from using biomass for both cooking and heating in poor countries without access to an electric grid or clean cooking fuels. Although there is overall improvement, the number of children under 5 dying from household air pollution is still very high at about 200,000. The health impacts from indoor particulate matter are presented in ► “The Health Effects of Indoor Air Pollution” of this Handbook.

Particles Mass Measurements

Measurement Methods

The leading textbook for particle measurement methods is *Aerosol Measurement* (third edition) (Kulkarni et al. 2011). The following discussion highlights a limited number of measurement methods and instruments that have been widely used in indoor studies.

The recognized gold standard for measuring particle mass is to collect the particles on a weighed filter and weigh it after sampling and conditioning to remove particle-bound water. The conditioning process is performed before and after sampling. The basic approach is to equilibrate the filters for at least 24 h at a fixed temperature and relative humidity to remove water from filter and the particulate deposit on the exposed filter. Any particle with water soluble constituents will be hygroscopic meaning it will absorb water vapor from the air at a relative humidity below 100%. The US EPA method uses $23 \pm 1^\circ\text{C}$ and $35 \pm 5\%$ RH. More often higher RH values (40–50%) are employed. However, prior work has shown that most particles require RH to be below 30% to fully dry the particles (Khlystov et al. 2005).

Initially, ambient air sampling focused on total suspended particles (TSP). An open face filter housed in a rain shelter was connected to a vacuum cleaner motor so that TSP could be collected. Subsequently, it was recognized that larger particles were not typically inhalable except under heavier working conditions and ambient PM samplers shifted to having size selective inlets. The first of these were designed to have a 50% collection efficiency (cutpoint) at $10 \mu\text{m}$ aerodynamic diameter to accompany the 1987 US National Ambient Air Quality Standard (NAAQS) for PM_{10} . In 1997, the US Environmental Protection Agency promulgated a NAAQS for PM with aerodynamic diameters $\leq 2.5 \mu\text{m}$ ($\text{PM}_{2.5}$). The size selection comes from the use of impactors (Le et al. 2019) or cyclones (Kenny et al. 2000, 2004). Standard PM samplers for ambient PM typically operate at flow rates of 16.7 LPM or greater. Thus, PM ambient sampling is conducted for TSP, PM_{10} , and/or $\text{PM}_{2.5}$ depending on the exposure assessment that is to be done.

However, different size definitions are employed for PM sampling in occupational settings. Because when working hard and needing more air flow into the lungs, people switch from nose breathing to mouth breathing. Inhalation through the oral cavity allows larger particles into the respiratory tract. Thus, industrial hygienists define “inhalable particles” with aerodynamic diameters up to $100 \mu\text{m}$. Particles that can penetrate into the tracheobronchial tree are terms “thoracic particles.”

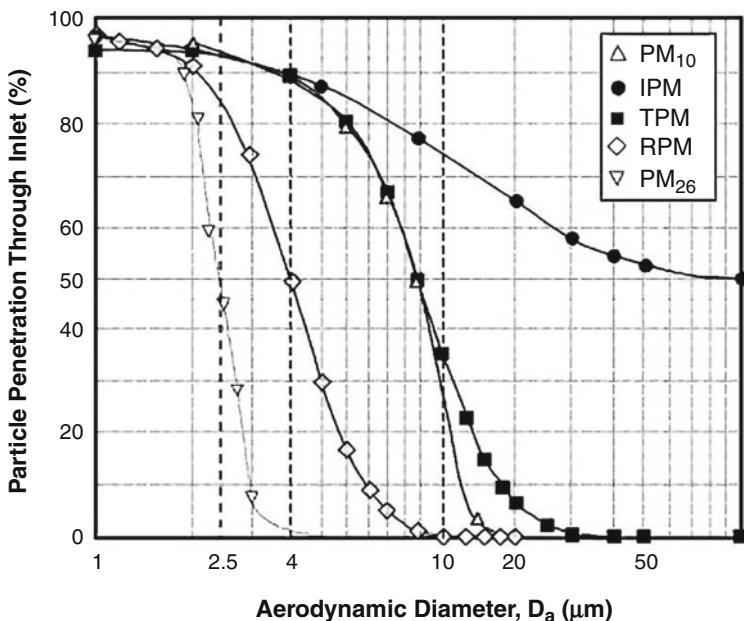

Fig. 1 Comparison of penetration curves for ambient and industrial hygiene sampling of airborne PM. (Figure taken from (USEPA 2004))

This particle size range is very similar to that of PM_{10} . Finally, particles that can penetrate further into the respiratory tract are termed “respirable particles” that have a cutpoint at $4 \mu\text{m}$, or somewhat larger than $\text{PM}_{2.5}$. These size definitions were formalized as the international workplace sampling conventions (ISO 1995). These two sets of collection efficiency curves are compared in Fig. 1.

There is no corresponding network for measuring indoor concentrations although people spend 87% of their time indoors (Klepeis et al. 1996, 2001). Multiple studies have compared outdoor and indoor measurements to try to estimate the total exposure of residents to indoor and outdoor particles. Measurement methods available for indoor particles include gravimetric methods employing portable pumps to collect particles on filters that are usually weighed in a laboratory off site. However, sampling PM indoors creates additional challenges compared to ambient PM sampling because of the limited volume of air in an indoor environment. If the flow rate through the sampler is too high, the sampler becomes an air filtration system substantially changing the concentration in the monitored space. Thus, the volumetric flows cannot be as high as in ambient sampler and are typically $\leq 10 \text{ LPM}$ and generally of the order of 4 or 5 LPM. The total mass flux into the sampler is of the order of 25% of a low volume ambient sampler, thereby making the measurement of the chemical composition of the collected PM sample more difficult. Thus, an integrated sampling/analysis protocol needs to be developed for any particular indoor PM compositional measurement program.

Fixed Location Samplers

Sampling can be at fixed locations or it can move with the individual by using a personal sampler and portable pump. Fixed site samplers usually use line power and can then operate for extended time periods. There are several samplers that can be used for this purpose. Marple et al. (1987) developed the MS&T Area Sampler. This sampler is widely referred to as the Harvard Impactor (HI) that is capable of collecting either PM_{2.5} or PM₁₀ particles on a filter over a time period ranging from 8 h to a week (Turner et al. 2000). Flow rates of 4, 10, and 20 LPM and size cuts of 1, 2.5, and 10 microns (μm) were laboratory tested and penetration curves were determined. For the past 20 years, HIs have been employed in many studies of indoor airborne particles.

A widely used, commercially available, low volume sampler is the MiniVol (Airmetrics, Inc. Springfield, OR, USA). The sampler was jointly patented by the US Environmental Protection Agency (USEPA) and the Lane Oregon Regional Air Pollution Authority (Lane et al. 2001). It operates at 5 LPM and comes with either a PM_{2.5} or PM₁₀ inlet. It is relatively portable and can be either battery or line powered so it has flexibility in where it can be placed.

Another commercially available system is the Ecotech MicroVol 1100 Low Volume Air Sampler. It operates at flow rates between 1.0 and 4.5 LPM through TSP/PM₁₀ size selective inlets and has an optional PM_{2.5} inlet. It operates on line power, battery, or a solar panel with battery. Catrambone et al. (2019) developed a Very Low Volume Sampler (VLVS) using the Smart Sampler (FAI Instruments, Fonte Nuova, Rome, IT) (<http://www.fai-instruments.com/>). Other studies have made use of locally constructed PM samplers (e.g., (Kim et al. 2004; Zhu et al. 2011)) using commercially available inlet cyclones, an inline filter holder, and a small pump.

A subclass of the gravimetric methods is the cascade impactor (Dzubay et al. 1976). In these samplers, multiple samples are collected on stages that represent different size fractions. The substrate from each stage is weighed to determine the contributions of the different size fractions to the total PM mass. Size is important in determining the deposition in the various lung regions, since large particles penetrate only to the thoracic region, whereas small particles can go deeper, reaching the alveolar region where they can be transferred to the blood. The Personal Cascade Impactor Sampler (PCIS), a 5-stage, 9 LPM cascade impactor was developed by Misra et al. (2002) and tested by Singh et al. (2003). It has been commercialized as the Sioutas Personal Cascade Impactor (<https://www.skcltd.com/products2/sampling-heads/sioutas-personal-cascade-impactor.html>). A 10-stage, 2 LPM personal cascade impactor has been reported by Chen et al. (2018). The commercial version of this sampler is mini-MOUDI impactor (<https://tsi.com/products/cascade-impactors/moudi-non-rotating-impactors/mini-moudi-impactors/>) and comes in 6-, 8-, and 10-stage models.

Portable and/or Personal Samplers

Other research personal samples have been developed such as the Harvard School of Public Health Personal Exposure Monitor (H-PEM) (Demokritou et al. 2001) and

commercialized by BGI, Inc (bgi-mesalabs.com). These samplers use an impactor and is similar to the Personal Environmental Monitor (PEM) developed at the University of Minnesota (Marple et al. 1987) that is available from SKC, Inc. (<https://www.skcltd.com>). Both of these designs can have different particle size cuts (2.5, 4, 5, or 10 μm) operating at 2,4, or 10 LPM depending on the model. With an impactor, the sample can be collected on a variety of substrates including filters or thin solid surfaces. Impactors have the additional value of having lower losses of semivolatile species.

RTI International has also developed a portable monitor/sampler called the microPEM (Du et al. 2019) (<https://www.rti.org/impact/micropem-sensor-measuring-exposure-air-pollution>). This unit provides a direct real-time measurement of PM₁₀ and PM_{2.5} and collects the particles on a filter that can then be weighed to provide data for the calibration of the real-time sensor and for subsequent chemical characterization.

Besides PM mass measurements, PM chemical components, such as elements (e.g., sulfur, lead), black carbon (BC), organic carbon (OC), chemical constituents (sulfates, nitrates, ammonia, acidity, secondary organic aerosols (SOA) are sometimes included. The next section of this chapter provides more information on composition measurement methods.

PM Composition Measurements

Analytical Strategy

The commonly applied approach to ambient aerosol chemical characterization typically relies on sample collection on three different types of filters (Solomon et al. 2014). A Teflon filter is analyzed for mass and elemental analysis. A nylon filter behind a diffusion denuder is analyzed for ions and a quartz filter is analyzed for organic and elemental carbon. Indoor air and personal sampling generally only provides a single filter so a strategy needs to be developed to provide the chemical speciation information required to meet the project objectives. The most commonly used filter is a Teflon filter to permit good mass measurements. Quartz filters have also been used, but care must be taken with them since quartz fibers can break resulting in mass loss from the sample.

Light Absorption

Light absorption is an old method and was the basis for the PM concentrations measured during the December 1952 London Fog episode and was reported as “black smoke” or “British smoke.” It is the carbonaceous matter in PM that will often absorb light and provide information that can be used in source identification and apportionment studies. The most commonly measured feature is “black carbon” (BC). There is no uniformly agreed upon definition of “black carbon.” Atmospheric BC often called “soot” is formed via high temperature combustion where it is formed near the flame as the material moves into a cooler area. It has a

low hydrogen to carbon ratio, but is not pure graphite. The measurements based on light absorption do not determine the amount of light absorbing carbonaceous matter. The BC mass is estimated based on a mass absorption coefficient that provides an estimate of the mass of carbon per unit light absorption at some given wavelength.

Its absorptivity varies by wavelength by roughly λ^{-1} with a range of $\lambda^{-0.8}$ to $\lambda^{-1.1}$ (Schnaiter et al. 2003, 2005). Alternatively, compounds with multiple fused aromatic ring structures will more strongly absorb light in the ultraviolet and lower end of the visible light wavelength range (350–470 nm). The particulate carbonaceous material with this type of light absorption is typically termed “brown carbon” (BrC). It is formed in lower temperature combustion that produces humic-like substances (HULIS) (Li et al. 2019). BC and BrC are discussed in detail by Andreae and Gelencsér (2006). Major sources of BrC are solid fuel (biomass and coal) burning and to a lesser extent, secondary aerosol formation. BC is non-volatile while BrC is semi-volatile. Thus, it is important to store samples under refrigeration and better to freeze them prior to analysis to avoid the loss of the more volatile components.

Black smoke was measured by white light reflection (Coulson and Ellison 1963; Davies and Aylward 1951) and systems to make these measurements are still available as the EEL Model 43D smoke stain reflectometer (Diffusion Systems, Ltd. London). The presence of “graphitic” carbon in urban aerosol samples was extensively studied by Hansen et al. (1982) using transmission of 630 nm light. Ultimately, 880 nm light has become the standard wavelength at which BC is measured since at that wavelength, the particulate absorption is dominated by the BC component because light absorbed by other particulate components is significantly less (Sandradewi et al. 2008). However, Sandradewi et al. (2008) use 950 nm absorption in their analytical scheme. Light absorption at 370 and 470 nm has been used to estimate the relative amounts of BC and BrC (Sandradewi et al. 2008; Wang et al. 2011).

BC is typically associated with vehicular emissions while the BrC is assigned to biomass burning. Wang et al. (2011) determined that the difference between BrC (370 nm) and BC (880 nm) that they termed Delta-C was highly correlated with levoglucosan ($r^2 = 0.89$ in winter), a well-known tracer of biomass burning particles (Simoneit et al. 1999). Delta-C has been used to provide a better source separation of biomass burning aerosol in ambient samples (Wang et al. 2012). It could also be useful in identifying cigarette smoke in indoor air (Lawless et al. 2004). To make these measurements, commercially available systems like the Magee OT21 can provide transmission measurements at 2 wavelengths comparable to those made in an aethalometer. Another transmission through a filter system is the Particle Soot Absorption Photometer (PSAP; Radiance Research, Seattle, WA). It is really designed to be a semicontinuous instrument similar to an aethalometer, but it can be used for individual filter measurements. Originally it used a 567 nm LED as the light source (Bond et al. 1999). A 3-wavelength PSAP operates with 467, 530 and 660 nm light sources. Diffusions Systems Ltd. continues to sell the ELL Model 43D.

Elemental Analyses

A commonly used approach for elemental analyses on Teflon filters is x-ray fluorescence (XRF) (Landsberger and Creatchman 1999) that measures the areal density (ng/cm^2) of each measurable element. Thus, sensitivity can be increased by using a smaller diameter filter. XRF requires the sample to be a uniform thin layer and thus, sampling on Teflon or other membrane filters provide appropriate samples. It has a nominal range of detectable elements from Na to U, but realistically, around 15 can be adequately detected. It has good sensitivity for the major crustal elements (Al, Si, Ca, Fe) and several other major elements like S. XRF has the advantage of being “non-destructive.” For most elements, the analysis does not disturb the sample composition. However, since many XRF systems operate in a vacuum, any semi-volatile material will be lost from the filter such as organic compounds and ammonium nitrate. Thus, it is important to perform the light absorption analysis first in order to properly determine the BrC components.

It is not feasible to do quantitative XRF analyses on quartz filter since the particles penetrate into the matte of the quartz fibers with losses of the fluoresced x-rays as they move toward the detector. To analyze elements in the PM on quartz filters, it is necessary to use inductively coupled plasma (ICP) with an appropriate detector after acid digestion of the sample. However, acid-digestion should be conducted after water leaching of the filter for ion analyses if those species are of interest. More details on ICP based methods are presented below.

Analysis of Water-Soluble Ions

It is possible to analyze water soluble ions using ion chromatography (IC). To obtain the samples for analysis, the filter is leached with high purity ($18 \text{ M}\Omega$) water. Teflon filters require wetting with a small amount of high purity ethanol. Both cations and anions can be determined but they require different separation columns and thus, multiple runs are required after modifying the instrument are needed. Cations typically determined include NH_4^+ , Na^+ , Mg_2^+ , K^+ and Ca_2^+ . The commonly determined anions include NO_3^- , SO_4^{2-} , Cl^- , and PO_4^{3-} . These are typically measured using commonly employed column and eluants. By changing the chromatographic conditions, short chain organic mono- and di-acidic ions (formate, acetate, propionate, oxalate, and malonate) can also be determined (Sunder Raman and Hopke 2006). If a quartz filter was used, then aliquots of the water leachate need to be analyzed for elements using the ICP-based analysis.

Inductively Coupled Plasma Methods

Inductively coupled plasma methods employ radiofrequency radiation to convert a flowing stream of argon gas into a plasma at high temperatures (5500 to 6500°K) in a quartz vessel. The water solution containing the elements to be ionized is introduced into the plasma with a nebulizer that breaks the stream into droplets that evaporate to provide the solid material that is vaporized and ionized. The amount of the elements present can be determined by measuring the atomic radiation coming from the excited atoms called atomic emission spectroscopy (ICP/AES) or by extracting the

elemental ions into a mass spectrometer (ICP/MS). For most elements, ICP/MS is more sensitive and is more commonly employed.

To provide the solution of analytes, the filter is acid digested. There are various approaches to the choice of acid(s) depending on how thoroughly the filter is to be digested. Some groups use ultrapure HNO₃ followed by HF (Querol et al. 1996) to obtain a total digestion including the quartz filter if they were used to collect the sample. This procedure produces a sample with significant quantities of Si that are corrected by subtraction of blank filter values. It is more typical to use just ultrapure HNO₃. This procedure will not dissolve Si and several other elements such as Ti. Other procedures may include HCl. However, Cl can combine with Ar to form an ion called an isobaric interference that has the same mass as As. Although the addition of HCl would improve the dissolution of some elements, it should not be used if the analysis is being done using ICP/MS. It would not affect ICP/AES analyses. ICP-based analyses can typically provide a wider array of elemental concentrations ranging from Li to U. However, it is a destructive and more expensive analysis. Thus, the choice of analytical method for elements depends on the elements needed for the subsequent data analyses and the availability of resources to perform the necessary procedures.

Organic and Elemental Carbon

Light absorption does not measure the mass of carbonaceous species. It is estimated based on known or estimated mass absorption coefficients. To directly measure the mass of carbon on a filter, thermal-optical methods are typically used (Birch and Cary 1996). These methods provide an empirical separation between “organic” and “elemental” carbon. The underlying assumption is that the organic compounds that comprise the organic carbon (OC) have some degree of volatility and thus, can be separated from the filter by heating it. Alternatively, the elemental carbon (EC) is thermally refractory and will remain on the filter until removed by oxidation. Thus, instruments have been developed that use a sequence of increasing temperatures to heat a small portion of the filter. To avoid oxidizing the material, a helium atmosphere is used. Because some of the larger carbon molecules and molecules with a number of oxygens have low vapor pressures, relative high temperatures (>500 °C) are required. These steps provide the measurement of OC. Given the use of high temperatures, samples need to be collected on quartz filters or high melting point metal impactor foils (not Al). The evolved organic compounds are catalytically oxidized to CO₂. The CO₂ measured so the system provides measurement of carbon and not carbonaceous material mass. Once the initial sequence of temperatures has been completed, the atmosphere is changed to helium containing a few percent of oxygen to oxidize the carbon remaining on the filter and a second sequence of increasing temperatures is applied to the sample to measure the EC.

There is no standard protocol that defines the temperatures and time-at-temperature for each step. The major protocols are NIOSH (Birch and Cary 1996), IMPROVE-A (Chow et al. 2007), and EUSAAR-2 (Cavalli et al. 2010). Each protocol produces different measures of OC and EC. Only the total amount of carbon is reproducible among the protocols. Thus, these quantities are defined by

the method used to make the measurements. There are typically relationships between EC and BC, but they can vary depending on the source of the carbonaceous particles (Salako et al. 2012).

Organic Compound Analysis

Generally, the determination of organic compounds in indoor air samples is difficult because of the relatively small mass of PM that is collected. The basic approach is to separate and identify the compounds using gas chromatography coupled with mass spectrometry (GC/MS). To transfer the organic material into the GC, there are two approaches: extraction and thermal desorption.

The remaining portion of the quartz filter after using the punch for the OC/EC analysis are then extracted for the analysis of polar and non-polar compounds. These compounds include source tracers termed molecular markers that include species like levoglucosan (biomass burning), cholesterol (meat cooking), etc. Prior to extraction, the filter is spiked with a set of perdeuterated surrogate standard compounds covering a wide range of a molecular weights, volatility and functional groups to quantify the extraction efficiency. The substrates are extracted using as Soxhlet extractor or instruments like the Dionex Accelerated Solvent Extractor (ASE350). Extracts are concentrated and then split into two aliquots. One aliquot is directly analyzed for non-polar species by GC/MS. The second fraction is derivatized to reduce the polarity with a material such as bis (trimethylsilyl) tri-fluoroacetamide (BSTFA) plus 1% trimethylchlorosilane (TMCS) as a catalyst (Pashynska et al. 2002). Using procedures like that described by Edney et al. (2005), the derivatized samples are then analyzed by GC/MS.

In thermal desorption/gas chromatography/mass spectrometry (TD/GC/MS), the filter is heated and evolved gas is directly introduced in the GC and then analyzed (Falkovich and Rudich 2001). Sheesley et al. (2015) subsequently developed a modified TD/GC/MS system that employs an in-situ derivatization that adds tri-methylsilyl groups to alcohol functional groups on simple carbohydrates, like levoglucosan and sterols. Thus, both non-polar and polar compounds can be analyzed directly without extraction and concentration. Both approaches have been used to determine organic compounds in airborne particle samples (Meng et al. 2005).

PM Source Identification and Apportionment

The PM compositional data can then be used in source apportionment studies using tools like the chemical mass balance (CMB) or positive matrix factorization (PMF) (Hopke 2016). There have been studies where measurements have been made in multiple environments (indoor, outdoor, and personal) and the data used to determine the indoor and ambient sources of PM. The first major study of personal exposure to PM was the 1991 Particle Total Exposure Assessment Methodology (PTEAM) study in Riverside, CA (Özkaynak et al. 1996). Personal exposure monitors were worn by the study subjects with 2 samples per person and 178 individual participants. The filters were weighed and elemental concentrations were

determined using X-ray fluorescence (XRF). In addition, indoor and outdoor samples were collected separately and analyzed in a similar manner. Yakovleva et al. (1999) performed a 3-way analysis using a trilinear model and identified 7 source types. Three soil factors with similar profiles, but different time dependence and distribution between indoor, outdoor, and personal samples were determined. Particles from the third soil source only appeared in personal samples leading to the assumption that those particles were resuspended by various personal activities. A “Personal Activities” source appeared in the indoor and personal samples. The “Personal Activities” contribution showed an excellent correlation with number of smokers in the house and smoking during the monitoring period. Those particles were associated with everyday indoor personal activities, such as cooking, smoking, using personal hygiene sprays, etc. Other sources included oil combustion, sea-salt, secondary sulfate, motor vehicle exhaust contributed to the outdoor PM. Cooking and vacuuming were also associated with “Indoor Soil” and “Personal Activities.”

Subsequently, other studies of multiple source types (indoor, outdoor, and personal) were reported by Hopke et al. (2003) and Zhao et al. (2006, 2007). In these studies, a model was developed to explicitly separate indoor and outdoor source types. This model provide a better separation of indoor and outdoor sources than simply applying the normal bilinear model to a combined indoor/outdoor data set that is done in a number of studies.

Continuous PM Monitors

It is desirable to have highly time resolved measurements given short duration, high emission events like cooking, smoking, and other particle generating activities. Mechanisms for continuous PM monitoring used for ambient PM monitoring have been adapted to indoor systems including light scattering, beta attenuation monitors (BAMs), and tapered element oscillating microbalance (TEOM) that can provide highly accurate measurement but at relatively high cost per unit. There are portable BAM (e-BAM) (Kim et al. 2016; Schweizer et al. 2016) and TEOM (Cantrell et al. 1996, 1997). The e-BAM has been used in field studies of indoor spaces such as subway stations (Kim et al. 2016). The portable TEOM was designed to be a continuous personal dust monitor for the exposure assessment of miners (Kissell et al. 2002) and has not been reported as being used in indoor air monitoring.

Particle Monitors

Aerodynamic Particle Sizers

Since the size of a particle is such an important consideration, determining for example how quickly it can be removed from the indoor air by striking a surface such as the floor or ceiling, techniques to measure the particle size are required. Aerodynamic particle sizers use an accelerated flow to separate particles according to their inertia. The time of flight between two sensors can then determine the inertia

and ultimately the size. An example is the APS 3321 model (TSI, Shoreview, MN) which can differentiate between about 52 sizes between 0.5 and 20 μm .

Optical Particle Monitors

A large class of instruments widely used in indoor particle studies are optical particle monitors. These monitors employ a light source to scatter light from particles passing through a sensing chamber. The light source may be visible or infrared and often use lasers or LEDs. The scattered light is collected by detectors surrounding the sensing chamber and can be analyzed using Mie theory to determine particle size. Pulse height or other measure can provide a count of the number of particles. The particle mass (e.g., PM_{2.5}) can then be estimated by calculating the total volume (assuming spherical particles) and assigning an average density. Optical monitors are often calibrated by the manufacturer to a particle mixture of known density such as Arizona Road Dust (specific gravity 2.6). A drawback of all optical particle monitors is that they must be recalibrated to whatever particle mixture is being studied. The recalibration is done using gravimetric sampling.

One widely used research-grade optical monitor is the SidePak (TSI, Shoreview, MN). The SidePak is a small portable sampler with a flow rate of around 1 LPM (0.7–1.8 LPM). It is calibrated to Arizona Road Dust or a related test aerosol, including secondhand tobacco smoke (Jiang et al. 2011). A more recent example of recalibrating the SidePak to an aerosol mixture created by combusting or vaping marijuana is provided by Zhao et al. (2020). The calibration factors (CF) for four types of marijuana sources (glass pipe, joint, bong, and vaping pen) were 0.31 (SE = 0.02), 0.39 (SE = 0.02), 0.40 (SE = 0.01), and 0.44 (SE = 0.03), respectively. These CF values were then used in subsequent studies to determine emission rates of the four sources (Ott et al. 2021) and estimates of exposure from vaping marijuana (Wallace et al. 2020).

A second widely-used optical monitor is the DustTrak (TSI, Shoreview, MN). Several of these optical instruments were compared with gravimetric mass measurements by Wang et al. (2016). Often the data from these instruments need to be adjusted with a correction factor (CF) (Susz et al. 2020). The DustTrak has the advantage of provision of a place for a filter to be installed for later weighing in the laboratory allowing direct determination of the CF as well as analysis of the composition. In Wang et al. study, the bias of a TSI DustTrak relative to gravimetric measurements of environmental tobacco smoke (ETS) ranged from 2% to 15% when a photometric calibration factor (PCF) of 0.38 was applied. Li and Hopke (1993) reported that side stream cigarette smoke generated with a smoking machine was unimodal and lognormally distributed with a geometric mean diameter of 140.7 nm and a geometric standard deviation of 1.53 so the DustTrak would be useful for ETS type measurements with proper correction. Rivas et al. (2017) reported other issues with the DustTrak DRX in which sudden artifact jumps in PM concentration occurred. They suggest that the measured data should be handled with care and meticulously reviewed and revised before being considered valid.

Wallace et al. (2011) compared DustTrak (Model 8520) and personal DataRAM (pDR) (ThermoScientific, Waltham, MA, USA) for PM_{2.5} against each other and

against simultaneously collected gravimetric samples (Wheeler et al. 2011). The DustTrak and pDR were in reasonable agreement ($R^2 = 0.90$ and 0.70, respectively) with the gravimetric PM_{2.5} values. The instrumental limits of detection were approximately 5 µg/m³. Both units had multiplicative biases of about 2.5 and 1.6, respectively, relative to the gravimetric samples. However, proper correction provided values with an average bias-corrected precision of ~10%. Thus, appropriate bias corrections provided very good agreement with standard gravimetric methods. Some instruments such as the Grimm model 1.108 (Cheng, 2008) have a built-in filter holder to permit collection of an integrated gravimetric sample over the course of the measurement period.

In general, calibration work for such devices by taking some parallel gravimetric measurements of the PM that is to be monitored is advised. Li et al. (2019) provides a useful framework for in-field calibrations to provide more accurate use of such devices. They suggest collocation with reference quality instruments to provide a number of data points to build the model. Since particle hygroscopicity is an important factor in changing the amount of scattered light because the absorption of water vapor increases the particle size and modifies the refractive index. Thus, they suggest developing regression models that include relative humidity (RH).

Semicontinuous Composition Measurements

Over the past 20 years, there has been an extensive development of instruments for the semicontinuous characterization of the composition of airborne PM. most of these instruments are available for compositional measurements, but they have generally been designed to sample the ambient aerosol and typically are quite expensive. There have been only a few instances of their use to characterize indoor PM (Ji et al. 2010; Patel et al. 2020). However, one of the measured earliest species was black carbon (BC) or light absorbing carbon (LAC) using an aethalometer whose principle was presented by Hansen et al. (1984). Subsequently, an instrument was developed in which PM is collected on a filter tape and the light transmission is determined. Initially a single wavelength of 990 nm was used, but now multiple wavelength units are available. Portable units are now available for personal or indoor BC monitoring (Cai et al. 2014). Multiple wavelength units could be useful in measuring the emissions from various source types that produce black or brown carbon particles.

Low-Cost Monitors

However, these better-quality light scattering systems still cost thousands of dollars so using many of them for exposure studies is not always feasible. Thus, in recent years, there has been a substantial growth in the use of low-cost PM monitors. This development has exciting implications for investigators of particle exposures near or even inside homes and also epidemiological studies. Epidemiology has long had only one source of particle measurements (the regulatory ambient monitoring carried out by governments). In studying health effects in large populations, epidemiologists are forced to use the regulatory data as their only input in estimating human exposure. Yet we know that most exposure occurs indoors or at work. We also know that indoor exposures are not simply a multiple of outdoor concentrations.

Therefore, obtaining direct continuous long-term records of individual home concentrations will be a great boon to epidemiology.

These monitors evolved from the light scattering sensors originally developed for use in smoke detectors to eliminate the use of radioactivity that had been the basis for the earlier designs. Litton (2002a, b) recognized that these sensors could be used to measure particle concentrations in occupational setting with a low cost device that could be replicated to monitor in multiple locations. Litton et al. (2004) then developed these detectors into a monitor that was used for monitoring cooking emissions in developing countries (e.g., (Smith et al. 2007)). A variety of low-cost sensors for consumers have been developed over the past decade to permit people to monitor air quality in their own home environments. The initial units continued to use the sensors from smoke detectors that typically use an LED with a wavelength of $\sim 1 \mu\text{m}$ and thus, the lower cutoff size that can be efficiently detected was around 500 nm.

Evaluations of these early units found a wide range of performance when compared to higher quality light scattering or reference devices (Williams et al. 2014). An early comparison of four monitor types (Speck, Dylos, Air Assure, and UB AirSense) was performed at Clarkson University using cigarette smoke and Arizona Test Dust (Manikonda et al. 2016). All four types were found adequate for indoor use. Subsequently, there has been development of more sophisticated sensors using lower wavelength lasers that increased the light intensity and reduced the lower size cut-off. These units also require careful analysis of the accuracy and precision of the monitors. There has been sufficient interest in these monitors that the South Coast Air Quality Management District of California has established a testing facility to permit uniform, high quality evaluation of the available monitors (AQ-SPEC 2016). Calibration systems have been developed for these monitors (Holstius et al. 2014; Sayahi et al. 2019a). Other tests for accuracy and precision have been made (Delp and Singer 2020; Williams et al. 2014). These systems generally provide particle counts as the individual particle scatter light and produce a pulse. The count data then need to be converted into mass concentrations. Brattich et al. (2020) provide information on these conversions although the details for any specific commercial monitor are proprietary. A variety of methods have been used to develop calibrations of low-cost monitors (e.g., (Si et al. 2020)). The US EPA (2017) has developed a guidance document for using these monitors.

A few models have performed well, some within a factor of two accuracy with research grade instruments depending on the nature of the aerosol. Monitors cost between \$100 and several thousand dollars. There are currently several $\sim \$200$ monitors based on Plantower PMS5003 laser-based sensors. It has a 50% counting efficiency for 300 nm particles and uses a $\sim 650 \text{ nm}$ wavelength. In the United States, a popular low-cost monitor is provided to buyers by PurpleAir.com, a Utah-based company. The company offers to register the monitors so that the data are continuously uploaded to the Web. At present, more than 16,000 monitors are operating worldwide and their data are freely available to anyone. Most are used outdoors near homes. However, a fair number are being used indoors (about 2000 monitors in California alone). The Plantower sensor is used in the PurpleAir and other monitors

(Chen et al. 2017; Gupta et al. 2018; Jiao et al. 2016; Kelly et al. 2017; Morawska et al. 2018; Ardon-Dryer et al. 2020; Badura et al. 2018, 2019; Barkjohn et al. 2020; Becnel et al. 2019; Bi et al. 2020; Bulot et al. 2019; Delp and Singer 2020; Feenstra et al. 2019; Francis et al. 2019; He et al. 2020; Holder et al. 2020; Kaduwela et al. 2019; Karagulian et al. 2019; Kim et al. 2019; Kuula et al. 2017, 2020; Levy Zamora et al. 2018; Li et al. 2020; Magi et al. 2020; Masic et al. 2019; Masic A et al. 2020; Sayahi et al. 2019b; Singer and Delp 2018; Stavroulas et al. 2020; Tryner et al. 2019a, b, 2020; Wang et al. 2019, 2020; Zheng et al. 2018; Zou et al. 2020, 2021). Findings of these studies are highlighted in Table 1. However, monitor technology has been changing rapidly and newer, more accurate systems are likely to come onto the market (AQ-SPEC 2016).

The difference between estimated exposure using only ambient measurements and true exposure (the sum of outdoor-penetrated and indoor-generated exposure) is *exposure error*. Recently a study has estimated the extent of exposure error for a group of 91 California homes near 91 outdoor monitors (Bi et al. 2021). The error is largest at low outdoor concentrations, due to the increased relative importance of indoor-generated concentrations at these low (but much more common) outdoor concentrations (Fig. 2).

Ultrafine Particles

Health Effects

Ultrafine particles (UFP) are defined as particles below 100 nm or 0.1 μm in diameter. They may cause health effects, including mortality (Bräuner et al. 2007, 2008; HEI 2013; Ohlwein et al. 2019; Stölzel et al. 2007; Utell and Frampton 2000; Wichmann et al. 2000). These effects are not likely due to the particulate mass, since they contribute a tiny fraction of the mass of almost any aerosol. However, they are known to be able to cross cell membranes, and often accumulate near the cell's ATP energy producers. Their toxicity may be more related to their surface area and chemistry rather than other physical parameters (Oberdörster et al. 2005). They may also cross the blood-brain barrier (Oberdörster et al. 2005). Multiple toxicological studies have found effects on cell lines and animal models (Donaldson et al. 2005). Interestingly, effects are not strong for respiratory function, but effects on the heart (e.g., heart rate variability) are more pronounced (Ohlrein 2019). Thus, measurement of this size range is important to provide more complete particulate exposure estimates.

Measurement Methods

Condensation Particle Counters

Neither gravitational nor optical methods are applicable to UFP, since they do not contribute to mass and they are too small to effectively scatter light. The most widely

Table 1 Studies using low-cost monitors

Reference	Year	Model PMS-	Number monitors	Location	Time span	Comment
Manikonda et al. (2016)	2016	N/A	1–3 each of four types	Clarkson Univ test chamber	N/A	Four monitors (Speck, Dylos, TSI AirAssure, UB AirSense) tested using cigarette smoke & Arizona Test Dust. All found adequate for indoor use.

Wallace et al. (2020)	2020	5003	4	Santa Rosa, CA Redwood city, CA	14 months (124 experiments)	Indoor measurements of aerosol from vaping marijuana liquids. Purple Air monitors were collocated with research-grade monitors. Precision and COV were comparable across all monitor types. Calibration factor estimate was about 3.0.
Wang et al. (2020)	2020	1003 3003 5003	9	Berkeley, CA	1 month	3 different monitors incorporating the three models listed. All performed reasonably well (within a factor of two) with multiple different aerosols containing particles $>0.25\text{ }\mu\text{m}$.
Zou et al. (2020)	2020	N/A		Ohio		Chamber study. 8 brands investigated. No effect of temperature. RH accounted for about 11% of residual error but could be corrected for
Zusman et al. (2020)	2020	A003	80	Seattle, 6 other cities	30-95 weeks	PM _{2.5} precision $r = 0.99$, accuracy $R^2 = 0.96$, RMSE $1.15\text{ }\mu\text{g/m}^3$. Region-specific models in 6 other cities $R^2 = 0.74\text{-}0.95$, RMSE $0.84\text{-}2.46\text{ }\mu\text{g/m}^3$. Seattle model applied to other 6 cities: $R^2 = 0.67\text{-}0.84$, RMSE $1.67\text{-}3.41\text{ }\mu\text{g/m}^3$.
Wallace et al. (2021)	2021	5003	33	California	November 2018 to June 30 2020	A new method of calculating PM1 and PM2.5 that does not depend on the hidden Plantower algorithm was developed and applied to determine a calibration factor based on 33 outdoor Purple air monitors near 27 EPA FEM outdoor monitors.

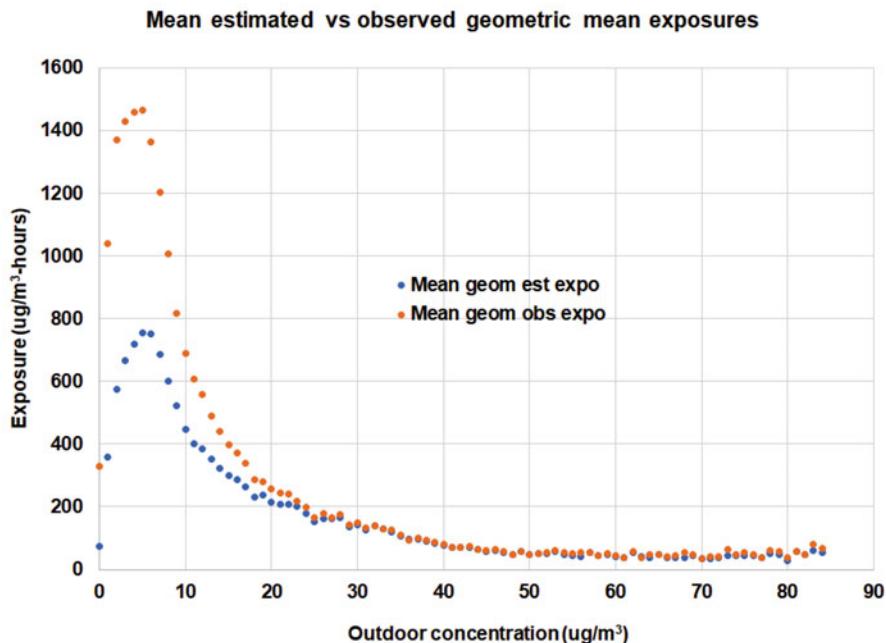

Fig. 2 Exposure error is the difference between the measured indoor exposure (orange) and that calculated from outdoor-penetrated air (blue). (Data source Ref. (Bi et al., 2021))

used method of measuring UFP is the condensation particle counter (CPC). CPCs were originally developed by Aitken (Aitken 1888) and developed into a portable system (Aitken 1892). A model of this device has been recently calibrated (Leigh-Manuell et al. 2020). The history of the development of the CPC is presented by McMurry (McMurry 2000). Current continuous devices employ two regions held at widely different temperatures. In one region is a supersaturated vapor. The particles enter this region and moving in to a cooler region, the vapor condenses around them, increasing their diameter to about 10 micrometers (μm). At this size, they scatter light from a laser beam and are counted. The lower size limit of detection for these devices were typically around 5–10 nm.

For many years, the supersaturated vapor consisted of an alcohol such as butanol. Later, a water-based CPC was developed that operates in a reverse approach (Hering et al. 2005) with the particles first passes through a cold dry region followed by a warm moist region. Water has some advantages over butanol, including non-flammability, lack of odor, and no toxicity. Also, for hydrophilic particles, the water-based CPC (commercially available from TSI) has an improved lower limit of detection approaching 2.5 nm.

The upper limit of detection for CPCs is typically 1–3 μm . However, since UFP typically form 90–95% of all particles $<1 \mu\text{m}$, the counts returned by a CPC are generally considered to be reasonable estimates of UFP number concentrations.

Two portable CPCs have been used in some of the studies reviewed below: the P-Trak, and the Model 3007, both manufactured by TSI. The P-Trak counts particles >20 nm with an upper number concentration limit of $500,000 \text{ cm}^{-3}$. The Model 3007 can “see” smaller particles (10 nm) but with a nominal upper limit of $100,000 \text{ cm}^{-3}$. The term “nominal” is used because although particle coincidence does begin to occur at $100,000 \text{ cm}^{-3}$, it is possible to correct the Model 3007 to obtain reasonable readings up to about $300,000 \text{ cm}^{-3}$ (Hameri et al. 2002). The Model 3007 is the more precise instrument (to within 20%), with a sensor to regulate airflow that is lacking in the P-Trak.

Particle Size Distributions

To obtain the size distribution of the UFP instead just the total number concentrations, a differential mobility analyzer (DMA) is typically employed in conjunction with a CPC. This instrument takes advantage of the electrical mobility of particles by charging the particles with either a radioactive source or soft x-rays and then subjecting them to an electric field. In the most commonly used DMA, the particles enter between two concentric cylinders held at different electric potential. The particles then bend toward the cylinder at the lower potential. Smaller particles will bend more rapidly and strike the cylinder at a different point along the axis than larger particles. A gap in the cylinder allows particles of a given diameter to escape, where they are typically directed into a CPC and counted. By varying the voltage, particles of any given diameter can be selected. To obtain a full size distribution of the particles, the voltage can be varied in a systematic manner. The instrument using this approach combines a DMA and a CPC; the most common commercial version is called a Scanning Mobility Particle Sizer (SMPS) (TSI, Shoreview, MN). A typical scan may take 2.5–5 min to produce a range of about 100 sizes, equally spaced on a logarithmic scale.

Until about 2000, commercial versions of the SMPS had a lower limit of detection of about 10 nm. Then, Chen et al. (Chen et al. 1998) developed an instrument capable of measuring down to about 2.5 nm. This instrument (Model 3908, TSI) employs a nano-DMA with a range of about 3.2–105 nm, or 2.6–65 nm when modified to reach the smallest possible size. Scan time has been reduced to about 1 min. An extensive review of ultrafine particles (measurement methods and observed indoor size distributions) was produced for Environment Canada (Wallace 2009).

“1-nm” Instruments

The history of particle instrumentation has been toward being able to measure smaller and smaller yet particles. Optical particle monitors could only go down to 0.3 μm (300 nm). Early differential mobility instruments could measure down to about 10 nm. Around 2000, Chen et al. (1998) developed a new design that could reach 2.5 nm. Although this does not sound like such a large improvement, in fact early users of the instrument discovered that for some sources such as gas and electric stoves and power tools 90% of the particles produced were between 2.5 and 10 nm.

Although not driven by considerations of indoor particles, a more recent development has succeeded in pushing the lower bound down close to 1 nm (Kangasluoma et al. 2015). This size is approximately the size of a large molecule or atomic cluster. The development has been driven by considerations of chemical reactions, which are important in causing gas-to-particle nucleation. Nucleation “bursts” creating UFPs over hundreds of square kilometers have been noted. The reactions leading to nucleation require instruments capable of observing the growth of the particles from their inception as molecular clusters.

UFP Emission Sources

Gas Burning Appliance Emissions

Wallace et al. (2004) provided initial studies of the size distribution of particles from a gas stove. Wallace et al. (2008) extended the earlier studies of gas stoves using the nano-DMA to investigate particles between 2 and 10 nm. It was found that 95% of the particles produced by the gas stovetop burners lie in this previously unstudied region (Fig. 3). The particle sizes are centered around 5–6 nm, and had an average peak concentration in the bedroom of $200,000 \text{ cm}^{-3}$. For comparison, this is 10 times the typical urban outdoor UFP concentration of about $20,000 \text{ cm}^{-3}$. Gas dryers also emit ultrafine particles (Wallace 2005).

Electric Stove Emissions

Electric stoves, present in 60% of US homes, may be the most important source of UFP. Dennekamp et al. (2001) performed several cooking tests on electric stoves, finding an increase of $90,000\text{--}110,000 \text{ cm}^{-3}$ for heating 1–4 rings to maximum temperature. However, they found that boiling water or stir-frying did not increase the number of particles. Frying bacon produced an increase of $159,000 \text{ cm}^{-3}$. Grilling toast produced an increase of $130,000 \text{ cm}^{-3}$, and grilling bacon produced

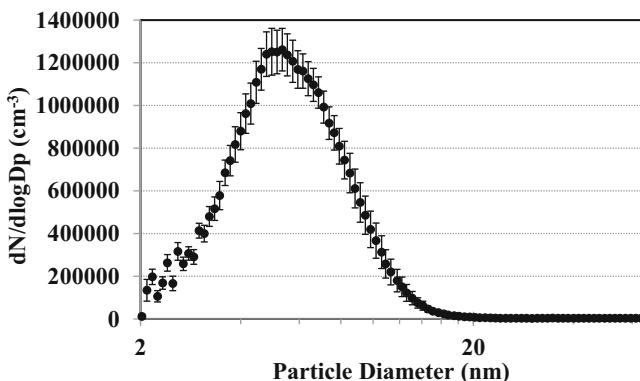

Fig. 3 Particle size distribution observed in bedroom of NIST test house due to use of gas stovetop burner in kitchen for 10 min ($N = 11$ experiments)

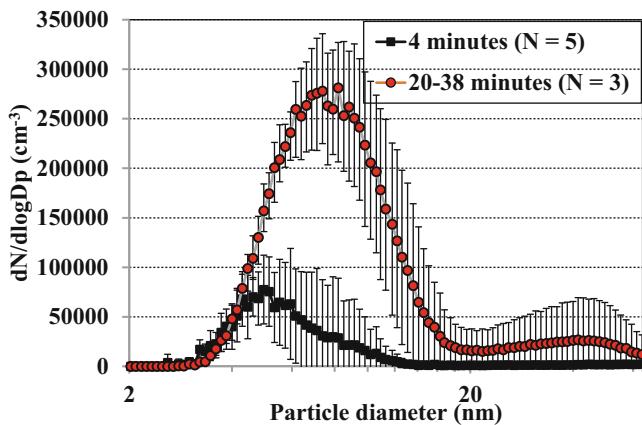

Fig. 4 Particle size distributions observed in bedroom of NIST test house due to use of electric stovetop for short and long periods

an increase of 530,000 cm⁻³. These results were extended to smaller particles (down to 2 nm) by Wallace et al. (2008). As with gas stoves, it was found that electric stovetop coils also emit mostly small particles <10 nm (Fig. 4).

Electric Motors

Appliances with electric motors are widespread, including blenders, mixers, shavers, power tools, etc. Again, not many tests have been done, but they show that all those named can produce UFP, sometimes in large quantities. In this case, the process for producing UFP occurs in the brushes and armature of the electric motor (Smczak et al. 2007). The particle composition may include graphite from the brushes or copper from the wiring.

Other Electric Appliances

However, many common appliances make use of electric heating: hair dryers, electric toasters and toaster ovens, coffee makers, etc. Hair dryers, toasters and toaster ovens do in fact produce copious quantities of UFP, but coffee makers have not been shown to produce UFP. The process of producing UFP from electric appliances is now known to be due to material (probably SVOCs) accumulating over time on the burners (Wallace et al. 2015, 2017).

Candle Burning

A third major indoor source of UFP is candle burning. Bekö et al. (2013) studied 56 homes in Denmark and concluded that candle burning was about as strong a source as cooking.

Source Identification and Apportionment

Given the differences in the emitted size distributions, it is possible to use particle size distributions to conduct source identification and apportionment

studies. Ogulei et al. (2006) used particle size measurements made using an SMPS and an APS. Using positive matrix factorization, they identified nine particle sources including two sources associated with gas burner use: boiling water and frying tortillas. Boiling water for tea or coffee was found to be associated only with the smallest particles, with a number mode close to the detection limit of the SMPS (i.e., 10 nm). Frying tortillas produced particles with a number mode at about 90 nm while broiling fish produced particles with a number mode at about 50 nm. A citronella candle was often burned during the study period, and this practice was found to produce a 200 nm modal number distribution. Other indoor particle sources identified included sweeping/vacuuming (volume mode at 2 μm); use of the electric toaster oven (number mode at 30 nm); and pouring of kitty litter (volume mode $>10 \mu\text{m}$). Two outdoor sources were also resolved: traffic (number mode at about 150 nm) and wood smoke (major number mode at about 70 nm).

Emission Rates

A study of multiple sources of UFP involving either combustion or heating elements was carried out by Wallace and Ott (2010). A Model 3007 CPC (TSI, Shoreview, MN) was used to measure such sources as gas stoves, electric stoves, electric toaster ovens, steam irons, gas clothes dryers, and more than a dozen more common appliances.

Only a few field studies have attempted to estimate UFP emission rates of indoor sources. Emission rates of $0.35\text{--}7.34 \times 10^{11} \text{ min}^{-1}$ were reported for multiple types of cooking in 15 homes in Brisbane, for UFP $>15 \text{ nm}$ (He et al. 2020). Wallace et al. (2004) found a mean emission rate of UFP $>10 \text{ nm}$ for 24 cooking episodes of $3.3 \times 10^{12} \text{ min}^{-1}$. This rate is sufficient to attain a peak concentration of about $100,000 \text{ cm}^{-3}$ in a typical home of 350 m^3 (1500 sq ft.)

Using the nano-DMA, Wallace et al. (2008) extended measurement of emission rates of indoor sources down to 2 nm. For both gas stovetop burners and electric stovetop coils, large quantities of UFP were produced in the previously unstudied region between 2 and 10 nm. Both sources produced particles that peaked at about 5–7 nm, and often 90% of all UFP produced were $<10 \text{ nm}$. Emission rates sometimes exceeded 10^{13} min^{-1} , and worst-case concentrations exceeding 10^6 cm^{-3} were observed. This finding suggests that previous reports of UFP concentrations produced by indoor sources may have been substantially underestimated. However, these sources of $<10 \text{ nm}$ particles were limited to the stovetops; ovens in both types of stoves and also toaster ovens produced mainly particles $>10 \text{ nm}$. Since the fundamental source (gas and electricity) is the same in the ovens as in the stovetops, it is probable that many particles $<10 \text{ nm}$ are being created but coagulate rapidly in the enclosed spaces and thus are not observed in the kitchen or household. A third major indoor source of UFP is candle burning. Wallace et al. (2019) studied the dynamic behavior (UFP number emission rate and deposition rate) of burning candles in a residence. A number of the studies that measured UFP indoors are listed in Tables 2 and 3.

Table 2 Ultrafine particle emission rates from indoor sources

Appliance	Event	N	Range of emission rates ($\times 10^{12}$) (particles min $^{-1}$)	Mean emission rate ($\times 10^{12}$) (particles min $^{-1}$)	SD ($\times 10^{12}$) (particles min $^{-1}$)	SE ($\times 10^{12}$) (particles min $^{-1}$)	Range of 1-h averages ($\times 10^3$) (particles cm $^{-3}$)

Table 3 (continued)

Morawska et al. (2001)	2001	Indoor-outdoor	Homes	16		SMPS, CPC >7	15–685, >7	Median I/O was 0.97. Range 0.44–2.46. Rather high values due to open windows, indoor sources. Under minimum ventilation, median I/O (CPC) = 0.56, range = 0.21–1.99
Levy et al. (2002)	2002	Levels	Non-residential	6	29	P-Trak	20– 1000	UFP in the apt., coffee shop, hospital, library, and mall = 0.6, 0.3, 0.1, 0.2, and 0.1 × outdoors, resp. Food court 150,000 indoors compared to 40,000 out.
Sarnat et al. (2002)	2002	Sulfur as a marker for infiltration	HOmes	6	36	SMPS	20–500	I/O ratios for S well correlated with those for particles in the 60–500 nm range, supporting use of S as marker for PM2.5 infiltration.
Wallace (2000)	2000	Indoor sources	Home	1	18 mo	SMPS	10–950	Indoor sources were active 22% of the time. Fraction of indoor concentration due to indoor sources was 0.82 for the 10–18 nm category; 0.68 for 18–50 nm, and 0.5 for 50–100 nm

Franck et al. (2003)	2003	Penetration	Laboratory, gatehouse	Room	1500 I/O samples	DMPS	15–800	Simultaneous indoor-outdoor sampling in two rooms-indoor activities low. I/O ratios 0.01 at 17 nm, increasing to 0.6 at 150 nm, dropping to 0.2 at 600 nm
Rundell (2003)	2003	Effect of ice resurfacing machines	Ice arena	10 arenas	28 days total	P-Trak	20–1000	104,000 indoors; 4000 outdoors. Pre-resurfacing: 35000–45,000. Post-resurfacing: 120,000–160,000.
Cyrys (Stözel et al. 2007)	2004	Indoor-outdoor	Hospital	two rooms	two 8-week periods summer & winter	CPC	7–3000	Median I/O ratio 0.42. Windows closed: 0.33; open: 0.78
Hameri et al. (2004)	2004	Fine and UFP	Helsinki locations					
He et al. (2004)	2004	Emission rates, penetration	Homes	15	2 days per home	SMPS, CPC	15–685; 7–808	Standardized 10-min cooking test (frying in oil) emitted median value of 10^{12} min^{-1} . Normal cooking ($N = 106$) emitted $1–7 \times 10^{11} \text{ min}^{-1}$. Smoking ($N = 6$) emitted $1.9 \times 10^{11} \text{ min}^{-1}$.
Wallace et al. (2004)	2004	Cooking emission rates	Home	1	44	SMPS	10–450	Cooking with gas stove created about 10 times as many UFP as observed in noncooking periods. Emission rates on the order of 10^{14} h^{-1} .

(continued)

Table 3 (continued)

Wallace et al. (2004)	2004	Effect of filters on deposition rates	Home	1	18 mo	SMPS	10–950	Deposition rates calculated for four conditions: fan off, fan on, fibrous filter, electrostatic precipitator.
Afshari et al. (2005)	2005	Indoor sources	Laboratory	Room-size chamber	NR (137)	P-Trak	20–1000	"U"-shaped distribution with the minimum occurring near 0.1 μm , as predicted by theory. Central fan with no filter or with a standard furnace filter increased deposition rates by amounts on the order of 0.1–0.5 h^{-1} . The fibrous filter increased deposition rates by up to 2 h^{-1} for UFP. The ESP increased deposition rates by 2–3 h^{-1} . However, the ESP lost efficiency after several weeks and needed regular cleaning to maintain its effectiveness. A reduction of particle levels by 50% or more could be achieved by use of the ESP when operating properly.

Hussein et al. (2002, 2004)	2002, 2004	Indoor-outdoor	Home	1	21	nano-DMA & DMPS	electric stove, steam iron, operating propane gas camping stove, electric air heater, electric radiators studied. Emission rates about 10^{11} min $^{-1}$ for many activities.
Hussein et al. (2005)	2005	Evaluate model	Office room, home	1 each	45 days (office); 21 (home)	DMPS	Loss rate ($a + k$) varied from about 1 h^{-1} for 10-nm particles to about 0.4 h^{-1} for 100-nm particles. UFP indoor-outdoor ratio with no indoor sources was about 0.36.
Matson (2005)	2005	Indoor sources	Homes, offices	5 offices, 3 homes	33	Model 3007, P-Trak	The home here is the same one as above. Emission rates were estimated for four activities in the home. Offices had I/O ratios < 1 , suggesting few indoor sources. Homes had strong indoor sources including cooking and candle burning
Wallace (2005)	2005	Gas clothes dryer as UFP source	Home	1	150 h over 18 months	SMPS	Vented gas clothes dryer produced UFP concentrations $> 100,000$, with estimated emission rate of 6×10^{12} particles per drying cycle.

Table 3 (continued)

Zhu et al. (2005)	2005	Penetration	Apt. building	4	6 days/apt. Then 2 apts sampled at night only	SMPS P-Trak	6–220 20– 1000	Indoor: 7000–12,000; outdoor: 14,000–20,000. I/O ratios appeared to increase below 20 nm for unknown reasons. Estimated penetration coefficient appeared to reach asymptote of 0.6, well below theoretical expectations. Air exchange measurements may be biased high in apartments
Hussein et al. (2006)	2006	Indoor sources	Apartment	1	14	SMPS	14–552	Cooking was the main source, producing values as high as 180,000 in the kitchen. Living room was typically about 1/3 of kitchen values. Smoking produced values of 36,000 from baseline of 6000.
Jeong et al. (2006)	2006	Particle number	Rochester and Toronto					
Murr et al. (2006)	2006	Composition	Residences	10	10	thermal precipitator	>10 nm	Thermal precipitator collects particles on TEM grids for elemental analysis. Gas particles contain primary 30-nm spheres and carbon nanotubes about 100 nm long by 10 in diameter.

See and Balasubramanian (2006)	2006	Emission rates of cooking	Home	1	1 h		SMPS	10–500	Five cooking methods tested on gas stove, with samples taken at nose height of cook. Concentrations increased from 54,000 (steaming) to 110,000 (frying) to 595,000 (deep-frying)
Wallace et al. (2006)	2006	Indoor sources, emission rates	Home	1	3 years		SMPS	10–950	18 activities analyzed, including cooking with gas stove, toasting, burning candles and incense, etc. Peak modes were near 10 nm for gas stovetop burners, around 30 nm for electric toaster and toaster oven, 60 nm for burning candles and incense, and near 70 nm for penetration of outdoor particles. The highest mean number concentrations were due to complex cooking, producing average number concentrations of $35,000\text{--}50,000\text{ cm}^{-3}$, compared to $12,000\text{ cm}^{-3}$ outdoors and 3500 cm^{-3} indoors when no sources were observed.

Table 3 (continued)

Diapouli et al. (2007)	2007	Indoor-outdoor	7 schools, 1 home	2–5 days per school	Model 3007	10–1000	Outdoor levels of 14,000–39,000 in Athens in winter, 5000–8000 in summer.
							Indoor mean in schools of 17,000–outdoor 27,000.
							Indoor mean in non-smoking homes 14,000.
Fromme et al. (2007)	2007	Levels	Schools	64	5 h/classroom	SMPS	10–487 Median (mean) 5660 (6509).
Mitsakou et al. (2007)	2007	Lung deposition during cooking	Apt. building	1	one 15-min cooking event, one overnight	SMPS	10–300 Lung deposition from a 15-min cooking episode >10 × total deposition over 8-h sleeping period.
Valente et al. (2007)	2007	Effect of banning smoking	Public places	40	20 min	P-Trak	20–1000 UFP reduced from 76,000 to 38,000 after smoking ban
Weichenthal et al. (2007)	2007	Effect of home heating systems	Homes	36	1 per home	P-Trak	20–1000 No increase due to home heating systems; strong increases from smoking, cooking with electric stove
Gehin et al. (2008)	2008	Size distribution emission rates					
Hoek et al. (2008)	2008	Indoor-outdoor	Homes in 4 cities	152	1 week/home	CPC	7–3000 Four cities:: Helsinki, Athens, Amsterdam, Birmingham. Regressed indoor on outdoor values to obtain average infiltration factor for central site (0.06,

					0.25, 0.43, and 0.15, respectively) and for just outside home (0.42, 0.42, 0.19, 0.22). Mean indoor-generated particles ranged from 3000–6000 from central-site regressions, 2000–7000 from outdoor regressions. Using sulfate, infiltration factor was 0.59, 0.61, 0.78, and 0.61, resp.
Stieb et al. (2008)	2008	Effect of air quality advice	Home, office, car	Variable	13 days P-Trak 20–1000
Wallace et al. (2008)	2008	Cooking emission rates	Test house	1 ~150 SMPS 2–64	First study to look at indoor sources in the 2–10 nm region. Both gas and electric stovetop burners/coils produced UFP peaks around 5 nm; 90% of total UFP <10 nm. Coagulation dominates deposition and air exchange rates in determining fate of UFP in first hour. Emission rates about 10^{13} min^{-1} .

(continued)

Table 3 (continued)

Weichenthal et al. (2008)	2008	Levels	Schools	2	60 (37 classrooms)	P-Trak	20– 1000	Outdoor levels of 14,000 exceeded indoor levels of 5000, indicating few sources of UFP in classrooms
Wensing et al. (2008)	2008	Laser printers	Chamber, office room	1	Multiple (12 in office room)	FMPS, SMPS, P-Trak	5.6– 560, 10– 1000, 20– 1000	Source may be fuser, not toner particles. 45-min average concentrations in office room (72 m^3) ranged from 4600–14,000 cm^{-3}
Wallace (2009)	2009	Indoor sources	Homes	2	~100	Model 3007	10– 1000	20 sources tested, including cooking, candles, steam iron, hair dryers, fireplace, laser printer, air popper.. Emission rates calculated for all sources
Rim et al. (2013)	2010	infiltration	test house	1	29 60-h weekends from August 2008– Sept 2009	SMPS	2– 64 nm, 3– 100 nm	Penetration P was near zero for particles < 10 nm, went from 0.2 at 10 nm to an asymptote of 0.6 for particles >30 nm. Finf ranged from 0–0.3 with windows closed and from 0 to 0.6 with one window open
Sultan et al. (2011)	2011	air cleaner UFP effectiveness	Test room	1		SMPS		12 portable air cleaners tested. HEPA and ESP were best performers.

Kearney et al. (2011)	2011	all except smoking	Homes	94	5 days	P-Trak	45 homes of adults one season; 49 homes with asthmatic children: 2 seasons
Wheeler et al. (2011)	2011	all except smoking	Homes	95	5 days	P-Trak	personal, indoor and outdoor concentrations measured using continuous monitors
Wallace and Ott (2010)	2010	stoves, driving, eating out	Homes, restaurants, autos		3 years	SMPS, Model 3007	Major sources included restaurants, cooking on gas or electric stoves, use of toaster ovens- emission rates $>10^{12}/\text{min}$
Rim et al. (2012)	2012	coagulation model	Test house			SMPS	10–400 nm 18–960 nm $>10 \text{ nm}$
Rim et al. (2012)	2012	Kitchen exhaust fans	Test house	2	2 fans tested at four flow rates	SMPS	2.5–100 nm Coagulation a significant contributor to particle loss/gain at concentrations $>20,000 \text{ cm}^{-3}$.

Chen et al. (2020)	2020	cooking with oil					

Concluding Note

In this chapter, we have presented an introduction to sampling and measurement instruments. This survey is not meant to be comprehensive and there are many similar tools available from other manufacturers. The mention of specific products was not meant to endorse them but to alert the reader to instruments that have been widely used and results published in the literature. The field is constantly advancing and thus, there may be alternative instruments that will be a better match to specific project goals and a wide search of what is available will be useful in allowing each investigator to find the best approach for their specific needs.

Abstract

Airflow measurement plays a crucially important role for studying the indoor environment. Two primary nonintrusive airflow approaches that use bubbles as seeds to visualize and track the airflow are particle tracking velocimetry (PTV)

H. Wang · X. Li (✉)

and particle streak velocimetry (PSV). The major advantage of PTV and PSV is the limited disturbance they impart to the tested airflow. However, the drawback is that they are not capable of room-scale measurements. Therefore, a new approach, i.e., color sequence enhanced particle streak velocimetry (CSPSV), is introduced. The core component of CSPSV is the color sequence illumination system (CSIS), which consists of three controlled lights of different colors and one of white light. The concept is to change the illumination color of the test zone in a given sequence during the exposure time. Then the color-coded time sequence information is inputted into an algorithm for both three-dimensional (3D) reconstruction and stereo pair matching. The theory and composition, image-processing and pair-matching algorithms, verification and applications of CSPSV are introduced in the chapter. The relative magnitude error of CSPSV is mostly below 5% within $0.12 \sim 2.45$ m/s, and the results from CSPSV are in consist with a hot-wire anemometer. CSPSV can be used in different indoor airflows such as vortex flow, airflows induced by the ceiling fan and adjustable fan networks, etc. CSPSV combines the advantages of PTV and PSV, reduces the requirement for high-speed cameras, and can be easily extended to measure the airflow in a large space.

Nonintrusive measurement · Particle streak velocimetry · Indoor airflow · Digital image process · Color sequence illumination

Introduction

The airflow pattern in a room is one of the key factors that affects indoor thermal comfort, energy efficiency, and air quality. Therefore, test and measurement technology for indoor airflows has been an important research area and is drawing increasing attention with latest technology developments. Because the range of indoor airflow velocities is large, normally from 0.5 to 10 m/s near an inlet or outlet to several centimeters per second near a corner or in an occupied zone, and indoor airflow is commonly highly turbulent and unsteady (Sandberg 2007), accurate measurement of indoor airflows in large spaces has been challenging for an extended period of time.

Historically, releasing smoke or colored gases to the target zone is one of the most easily conducted airflow visualization approaches. The drawback of this approach is that the phenomenon can only be visible for a short time period and provides almost little quantifiable airflow information. With the need for the development of flow measurement technologies, methods have been developed, such as ultrasonic anemometry (UA) (Knowles and Athelstan 1953), laser Doppler anemometry (LDA) (Cummins et al. 1964), and particle image velocimetry (PIV) (Adrian 1984; Pickering and Halliwell 1985). Both UA and LDA are point-wise solutions that provide precise three-component velocity information at one point or on a grid with a mobile

system. However, the test is time consuming, and it is difficult to guarantee that the indoor airflow field will be stable during the test. Thus, they are only suitable for stationary laboratory tests. PIV is currently the most widely used and commercially available nonintrusive airflow measurement system and has been used in indoor air tests. Given the potential danger of exposure to the laser slice and high cost for high-power laser generators, the measurement space of PIV is limited to dozens of square centimeters in a plane (Li et al. 2015) or even smaller zones.

Compared with PIV, particle tracking velocimetry (PTV) takes images at a higher speed and directly tracks each visible seeding particle instead of the image characteristics in PIV, by connecting the images taken at two or more given time intervals. Since the scale of indoor airflows is normally in meters, PTV selects bubbles as seeding particles for lower light intensity requirement. Its typical setup includes a bubble generator for air visualization, an illumination system to make the seeding bubbles more distinguishable from the background particles, and multiple cameras that can simultaneously record the test zone from different angles as shown in Fig. 1. The cameras and lights are operated at a typical sequence as shown in Fig. 2a, and a typical image (Fig. 2b) is obtained (Ohmi and Li 2000). Basically, similar to our eyes, a pair of cameras can perform stereo vision and calculate the three-dimensional (3D) position of each target based on the position, orientation, and settings of the cameras. By introducing more cameras, the 3D reconstructed results of PTV can be further checked and improved. Hence, PTV can provide 3D flow data with a relatively high spatial and temporal resolution (Maas et al. 1993). However, the tracking and 3D matching algorithm require the displacement of individual particles between each successive image to be no more than several pixels, which forces the image acquisition rate for each camera to be increased to 100 Hz (Biwole et al. 2009). The large amount of image data from

each camera exerts extreme pressure on the subsequent data-processing system and often requires a supercomputer to process the data (Li et al. 2008) while limiting individual sample times to be several seconds (Biwole et al. 2009; Fu et al. 2015). The development of parallel computation (Barker et al. 2012), new processing algorithms (Ohmi et al. 2010), and smart cameras (Kreizer and Liberzon 2010) can help to solve these problems to some extent. However, such new technologies may also make the measurement system much more complicated and difficult to design and operate for actual room-scale measurements. Another important drawback for the application of PTV is its illumination system. To obtain a clear image of each individual spot, the exposure time for each frame is usually within several microseconds. The illumination system has to be notably powerful, which delivers additional heat to the test zone and makes it difficult to extend the measurement domain. Since the frame rate and resolution are trade-off parameters for cameras, the low resolution of high-speed cameras also limits the extension of test zone for PTV. Limited by the image acquisition and analysis speed and the illumination system, the reported test zone of PTV is commonly approximately one cubic meter (Fu et al. 2015), which is still not sufficiently large for room ventilation tests.

In actual indoor environment, the airflow can be affected by many factors such as indoor partitions, heat sources, movement of objects and radiation, which make it difficult or even impossible to be totally simulated in a small-scale model. In addition, the velocity of indoor airflows covers a wide range. Hence, the normal intrusive measurement method cannot be sufficiently accurate for both normal and low-speed flows (Popielek et al. 2007). Therefore, a room-scale, high-dynamic-range, and nonintrusive airflow measurement system is crucial for the laboratory study of thermal comfort (Voelker et al. 2014), pollution transport (Kato et al. 2003; Mao and Gao 2015), and the field test of diffuser design (Elvsén and Sandberg 2009) and airflow pattern design (Rosenstiel and Grigat 2010).

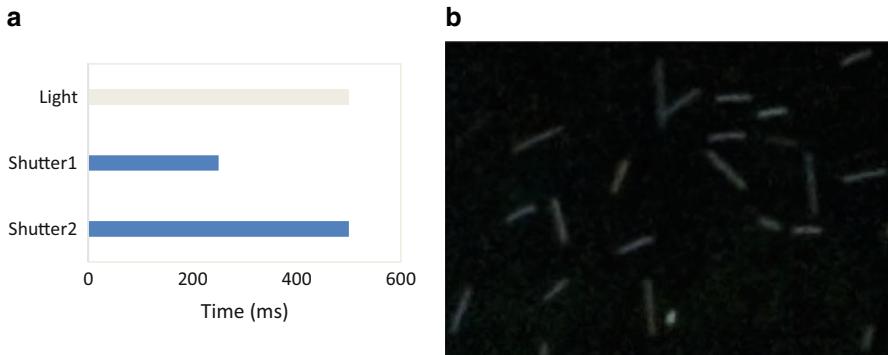

Fig. 3 Sequence of operation and typical image of PSV. (a) Typical sequence of operation of PSV. (b) Typical image of PSV. (Reprinted from Wang et al. (2017), with permission from Elsevier)

As another nonintrusive flow measurement method, particle streak velocimetry (PSV) operates with a longer exposure time and shares the typical setup of PTV in Fig. 1. However, PSV employs a much longer exposure time than PTV and records the bubble's trajectory as shown in Fig. 3. Because pair matching in PSV is conducted for streaks with two connected end points instead of individual points in PTV, PSV can function well with only two cameras. The three-component velocity is calculated based on the length of each streak and the exposure period (Fage and Townend 1932; Adamczyk and Rimal 1988). A longer exposure time enables both easier capture of the seeding particles and decreases the requirement of camera frame rate. Because two cameras capture the targets at the identical start time from different angles, the 3D position of these streaks could be reconstructed based on the calibration data of two cameras. Since the exposure time is preset, the velocity can be obtained by dividing the trajectory length by time.

Nevertheless, as shown in Fig. 3b, streaks on images cannot indicate the flow direction of seeding, which is the major drawback of PSV and attracted the attention of many researchers. One solution was to set the exposure time of one camera at half that of the other camera (Sun 2007) as shown in Fig. 3a. Because the indoor airflow is highly turbulent, the mathematical middle point of a long streak does not always denote the same end point of a short streak. Another widely used method is to compare the displacement in two consecutive images and assign the displacement by their similar geometrical characteristics (area and length) (Malavasi et al. 2011). The requirement of this method is that the time duration between two successive images is notably short and the density of particles is low. Another useful approach is using a multi-pulse laser or shutting down the illumination system for a short period during exposure to mark a blank space near the head or rear of the streak (Müller et al. 2001). These technologies enable the flow direction to be determined by adding temporal information to regular streaks and may be effective when the airflow is stable and the seeding density is relatively low. However, because the indoor airflow is three-dimensional and turbulent, the streaks could be highly twisted, which makes the recognition extremely difficult, especially for complex airflows.

As analyzed above, the study of indoor airflow patterns requires a room-sized, 3D airflow measurement system, and PTV and PSV both have their advantages and drawbacks. Photographic images captured by the camera can be affected by different aspects such as the light source, reflection properties of the object surface, and camera optics (Szelski 2011). Normally, PTV and PSV mainly focus on the image acquisition and process section. Using multiple light pulses to add more information onto one single frame was proposed (Adrian 1991; Ding et al. 2013) and proven to be efficient and effective (Voss et al. 2012; Westerweel et al. 2013). For small solid tracers, different color-dyed particles can help the search for homologous points in different frames much easier, and dramatically decreased the number of ambiguities (Tarlet et al. 2009; Bendicks1 et al. 2011). These studies provided hints to improve the performance of seeding particle tracking through specially designed optical imaging systems.

In room-scale airflow measurement, helium-filled soap bubbles (HFSB) are widely used seeding particles that provide a great potential for color-coded imaging methods. As the HFSBs are transparent and can reflect light notably well (Tropea 2011), changing the color of light source can change the bubbles' appearance on the imaging sensor that could provide more information than individual white spots. Investigators (McGregor et al. 2007; Pick and Lehmann 2009; Watamura et al. 2013) utilized this capability by marking the measurement space with different color layers of light to distinguish the distance in the depth direction. If a color sequence illumination system (CSIS) is involved to change the light color in the test zone in a given sequence, the path and flow direction of the bubbles can be simultaneously recorded in one frame. Therefore, particle path extrapolation (used in PTV) and streak direction trials (used in PSV) are no longer needed, which improves the measurement accuracy and decreases the calculation load. Since CSIS can be easily extended and the required frame rate of the camera is low allowing higher resolution cameras can be involved, the test space of such kind of velocimetry measurements can be extended to several cubic meters.

In this chapter, a new approach called color sequence particle streak velocimetry (CSPSV) is introduced by adding time sequence information into one single frame using CSIS (Wang et al. 2017). The basic principle and algorithm of CSPSV are introduced by utilizing digital image processing and multiple view geometry. The accuracy of CSPSV is verified by both the movement of white dots on a rotating target and in a wind tunnel comparison with hot-wire anemometer (HWA). Finally, three cases in actual indoor airflow studies are presented to demonstrate the capability and reliability of the CSPSV method including a vortex in a scale tunnel, and the airflow patterns induced by the ceiling fan and adjustable fan network.

Theory and Limitations of Traditional PSV

PSV partially fulfils the requirement of a room-scale ventilation measurement with its large test space and relatively low data acquisition rate but suffers from the streak direction ambiguities.

Theory of Traditional PSV

A brief introduction to the traditional PSV will provide a general view of how image-based multi-view velocimetry works. As previously mentioned, the setup of traditional PSV is similar to that of PTV as shown in Fig. 1 with a typical operation of sequence in Fig. 3a. For PSV, the most fundamental part is the matching and reconstruction of the 3D position of seeding bubbles based on the images captured from different angles. The basic model of binocular stereo vision for PSV is demonstrated in Fig. 4. The image coordinate frames of the left and right cameras are $o_1u_1v_1$ and $o_2u_2v_2$, where O_1 and O_2 are the optical centers, f_1 and f_2 are the focal lengths, and O_1n_1 and O_2n_2 are the optical axes of the cameras, which are perpendicular to the imaging sensors. Assuming that A is a seeding bubble in the test zone at (X, Y, Z) of the world coordinate, on two camera imaging planes, it is recorded as spots $a_1(U_1, V_1)$ and $a_2(U_2, V_2)$ in each image coordinate. In the camera calibration process, matrix C can be determined, which contains the positions of O_1 and O_2 and the orientation of camera optical axes O_1n_1 and O_2n_2 . Then, the camera model can be built as in Eq. 1 (Heikkila and Silven 1997), where i refers to different camera numbers, and matrix C contains the camera calibration information. Basically, by back-projecting lines O_1a_1 and O_2a_2 and calculating whether they have a conjugate point, we can determine whether a_1 and a_2 correspond to point A in 3D space. In detail, the matching criterion indicator δ can be written as in Eq. 2 (Sun 2007), where the point information indicators S_{11} , S_{21} , S_{31} , S_{12} , S_{22} , and S_{32} are defined in Eq. 3,

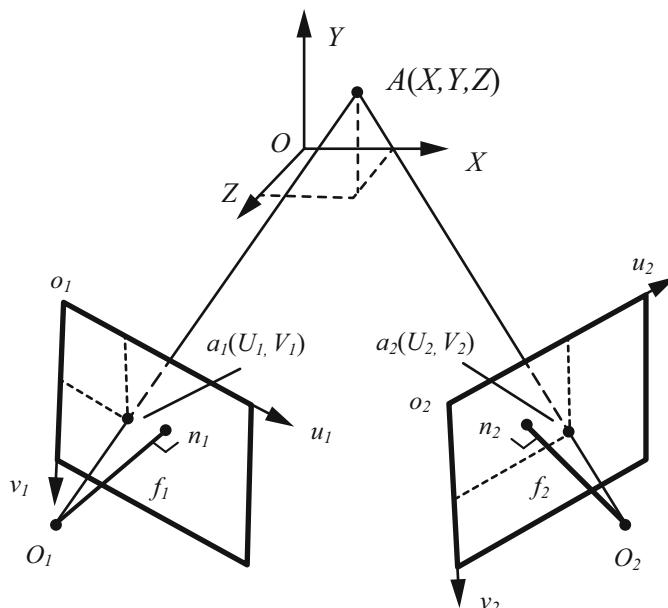

Fig. 4 Model of a binocular stereo vision. (Reprinted from Wang et al. (2017), with permission from Elsevier)

and c_{jkn} are the elements of matrix C with j as the row index, k as the column index and n as the camera number index. If δ for a pair of points from separate images is below a threshold, this pair of points corresponds to one bubble, and its position in the world coordinate system can be calculated using Eq. 4.

$$\begin{Bmatrix} U_i W_i \\ V_i W_i \\ W_i \\ 1 \end{Bmatrix} = \begin{bmatrix} c_{11i} & c_{12i} & c_{13i} & c_{14i} \\ c_{21i} & c_{22i} & c_{23i} & c_{24i} \\ c_{31i} & c_{32i} & c_{33i} & c_{34i} \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{Bmatrix} X \\ Y \\ Z \\ 1 \end{Bmatrix} = C \begin{Bmatrix} X \\ Y \\ Z \\ 1 \end{Bmatrix} \quad (1)$$

$$\begin{aligned} \delta \equiv & (S_{21}S_{32} - S_{31}S_{22})(c_{142} - c_{141}) + (S_{31}S_{12} - S_{11}S_{32})(c_{242} - c_{241}) \\ & + (S_{11}S_{22} - S_{21}S_{12})(c_{342} - c_{341}) \end{aligned} \quad (2)$$

$$\left. \begin{array}{l} S_{11} = c_{111}U_1 + c_{121}V_1 + c_{131} \\ S_{21} = c_{211}U_1 + c_{221}V_1 + c_{231} \\ S_{32} = c_{311}U_1 + c_{321}V_1 + c_{331} \\ S_{12} = c_{112}U_2 + c_{122}V_2 + c_{132} \\ S_{22} = c_{212}U_2 + c_{222}V_2 + c_{232} \\ S_{32} = c_{312}U_2 + c_{322}V_2 + c_{332} \end{array} \right\} \quad (3)$$

$$\begin{pmatrix} x \\ y \\ z \end{pmatrix} = \frac{S_{11}(c_{242} - c_{241}) - S_{21}(c_{142} - c_{141})}{S_{12}S_{21} - S_{11}S_{22}} \begin{pmatrix} S_{12} \\ S_{22} \\ S_{32} \end{pmatrix} + \begin{pmatrix} c_{142} \\ c_{242} \\ c_{342} \end{pmatrix} \quad (4)$$

Limitations of Traditional PSV

In PSV, the two end points of a streak extracted by morphology analyses are used as key points. However, the streak direction is unknown from individual images. A common solution (Sun 2007) is to set the exposure time of one camera (image 2) to be only half of that of the other camera (image 1) to obtain a long streak AB and a short streak CD as shown in Fig. 5. Then, the streak with a longer exposure time AB is cut into two halves at the mathematical middle point marked M. With different initial assumptions of the streak direction, four pairs of streaks AM-CD, MB-CD and AM-DC, MB-DC are formed and calculated for their match criterion. If the pair-matching criterion of the two ends $|\delta_{start}| + |\delta_{end}|$ is less than a threshold implies that both end points match and the corresponding initial assumed direction is correct. Then this pair of streaks captured by different cameras belongs to one bubble and the 3D displacement of the bubbles in a given time duration can be calculated. Because the time interval is known, the velocity components can be reconstructed in 3D space (Sun et al. 2004). However, the mathematical middle point M is not the actual middle path point of the streak M', and the displacement between them produces serious errors when the bubble's path is curved. Because indoor airflow is commonly highly

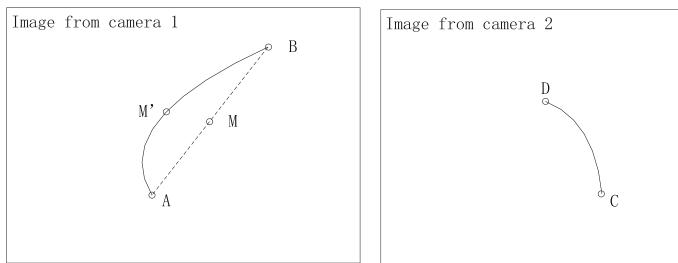

Fig. 5 3D reconstruction for PSV. (Reprinted from Wang et al. (2017), with permission from Elsevier)

turbulent, this drawback introduces ambiguities to pair matching and affects the accuracy of PSV.

Theory and Implementation of CSPSV

Based on the fundamental principles of CSPSV, the system setup and operation procedure for 3D velocity reconstruction are introduced in the following sections, including the components and function of CSIS, extracting streak and spot information from images, reconstructing the bubbles' trajectory, and determining the 3D velocity in the test zone.

Color Sequence Illumination System

The task of the illumination system in regular PSV and PTV is only to illuminate the seeding particles, whereas in CSPSV, CSIS is introduced primarily as a time sequence marker, which codes the test zone with different color of light and helps to capture more time sequence information with the color cameras.

In detail, CSIS has three color lights (red, green, and blue) and a white light, typically functioning in the pattern presented in Fig. 6a. When the shutters open, the light color of the test zone is first changed to red and a red spot is marked on the camera sensor. After that, the white light is immediately switched on to help to record the streaks of the bubbles after the red spots. The white streaks are designed to link together the color spots of one bubble and differentiate them from the other spots. When half of the exposure time has been reached, the green light is switched on to mark a green spot on the sensor. During the exposure time, the white light is switched off when colored light pulses to improve the contrast. Then, the white light is turned on until the blue pulse is initiated. Such a design for CSIS can increase the signal-to-noise ratio of color spots, especially for the low-speed spots.

With CSIS and operating at a longer exposure time, the color cameras can capture the sequence of color spots on the bubble's white path, as shown in Fig. 6b. The white light is used to link the color spots produced by one single bubble. Since the

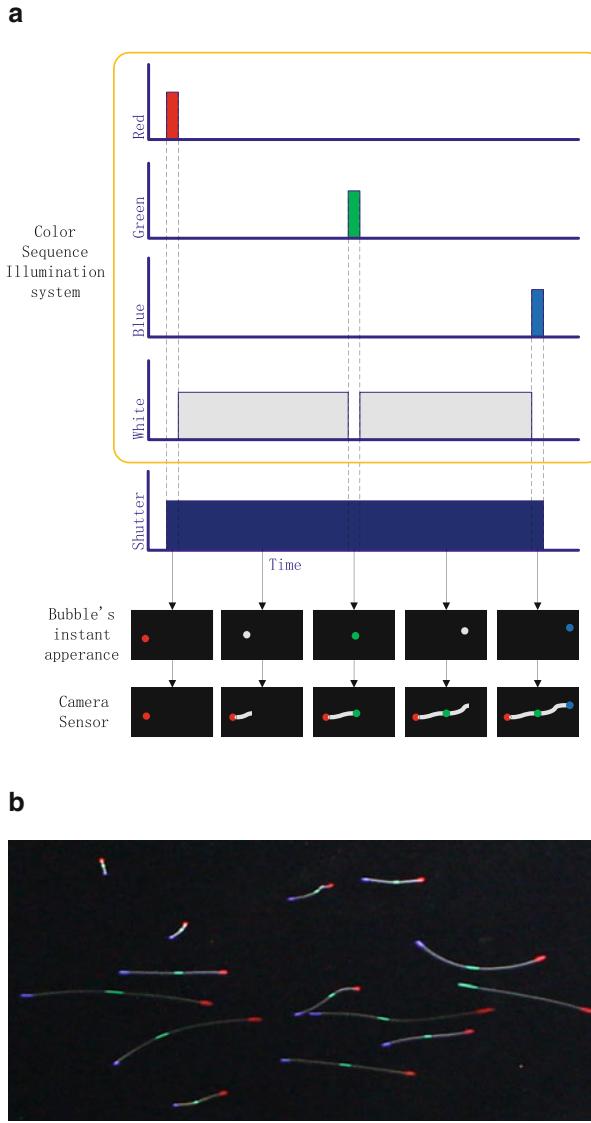

Fig. 6 Sequence of operation and a typical image of CSPSV. (a) Illumination sequence of CSPSV. (b) Typical image of CSPSV. (Reprinted with permission from Wang et al. (2018), © The Optical Society)

three different colors are introduced within one camera frame, both the path and direction of each bubble are simultaneously recorded. With the white streak linking the start, middle, and end points of a bubble, it becomes much easier and reliable to track the seeding bubbles. With this information, stereo pair matching can be more

accurately processed, and hence, the 3D information of the flow field can be obtained more reliably.

The CSIS also plays a crucial role in extending the measuring space. The CSPSV method records the bubbles' path with direction instead of individual spots (in PTV) and addresses the ambiguous direction problem of PSV. Thus, the frame rate requirement of CSPSV is reduced from 100 Hz (typical PTV) to 10 Hz (typical PSV). Further, there are at least two time intervals recorded by the camera in a single frame. The lower frame rate requirement enables higher-resolution cameras to be feasible for CSPSV, covering a wider space and extending the test zone to a larger space, potentially including whole-room ventilation tests.

In CSPSV, because the start and end points of a streak have been clearly marked with CSIS, the direction matching trials are no longer required. Thus, the pair-matching calculation for each streak can be four times faster than that in normal PSV (Sun 2007). Moreover, CSPSV uses the same sequence of operation for each camera, i.e., each key point is simultaneously taken. This character helps to reduce pair-matching ambiguities and results in a significantly improved pair-matching success rate than PSV. Compared with PTV, CSPSV utilizes the white streaks to link the color key spots, which makes bubble tracking notably easy with no need for extrapolation and reduces the camera frame rate from 100 Hz to several Hz.

Operational Procedure of CSPSV

The operational procedure of a CSPSV system is shown in Fig. 7. First, the bubbles are released into the test zone as tracers, to check the view of each camera. Then, the CSIS should be synchronized with the cameras to ensure the time sequence of each frame. After the cameras are set, the camera calibration should be performed to obtain the information of stereo cameras for 3D reconstruction. During the recording images, the cameras and CSIS should be simultaneously operated. Subsequently, the digital image processing and 3D reconstruction algorithm can rebuild the 3D vector for captured bubbles. Finally, data post-processing and visualization tools are utilized to achieve a better illustration of the airflow field.

Quad-View CSPSV

The primary drawback of CSPSV with two cameras or a stereo CSPSV is the blind zone as illustrated in Fig. 8. To illuminate the whole test space with little effect, a light source is placed both on the top of the ceiling and under the transparent glass floor, projecting toward each other. This type of setup causes a blind zone for each camera orientation, and the blind zone varies with the direction of the camera's orientations. As in Fig. 8, the blind zone of upper cameras is marked blue and that of the lower cameras orange. The zone that can be captured by both cameras is in green. The view angles are presented with a dashed line to mark the limitations of overexposure caused by placement of the CSIS modules.

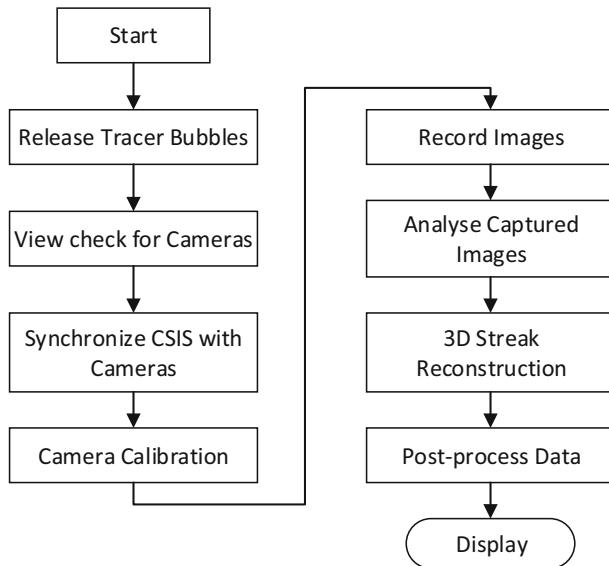

Fig. 7 Operation process for CSPSV

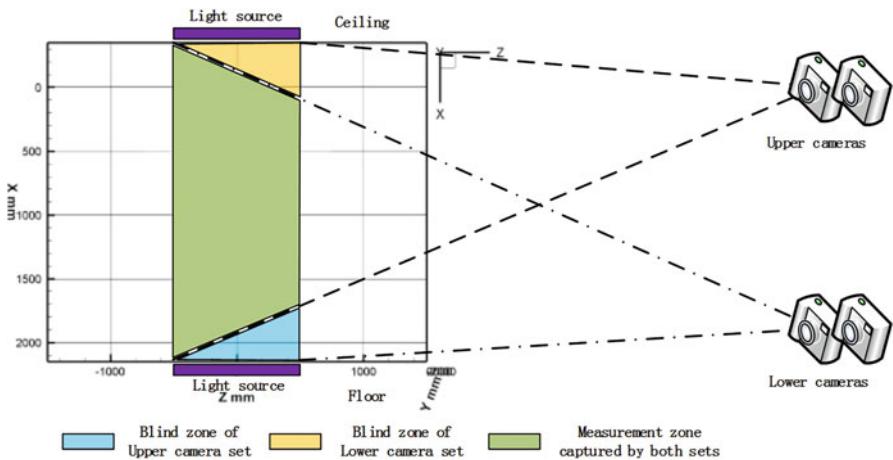

Fig. 8 Comparison for blind zone captured by two pair of cameras. (Reprinted from Wang et al. (2019), with permission from Elsevier)

As mentioned above, the measurement zone of a stereo CSPSV is always affected by overexposed regions. When the flow measurements could be crucial near light sources, one method to increase the measurement space is to add more cameras to capture the movement from different angles and merge the measurement data together. In this section, a new quad-view CSPSV is introduced with four cameras that are deployed in two groups and operated synchronously. The upper cameras are

primarily used to capture the air movements near the ceiling while the lower cameras primarily target the air movements near the floor, as shown in Fig. 8.

With these settings, both camera sets can capture the airflow in the middle of the room as marked in green. If the results are simply added together, some vectors will be duplicated. To solve this problem, a data merge algorithm was designed as described in Fig. 9. The 3D streak reconstructions for each pair of cameras are conducted separately. Subsequently, the distance between each pair of 3D vectors in 3D spaces is calculated, which consists of two vectors from the same frame but in different pair-sets, as in Eq. 5.

$$D = \sqrt{(X_{1s} - X_{2s})^2 + (Y_{1s} - Y_{2s})^2 + (Z_{1s} - Z_{2s})^2 + (X_{1e} - X_{2e})^2 + (Y_{1e} - Y_{2e})^2 + (Z_{1e} - Z_{2e})^2} \quad (5)$$

where X , Y , and Z are the components of the vector in the 3D space. The subscripts s and e represent the start and end points of the vector. Subscripts 1 and 2 are for the vectors from the upper cameras and the lower cameras, respectively.

When the distance between two streaks are extremely close, the streak with a larger epipolar error is rejected. The distance threshold is set at 20 mm in most cases. With this algorithm, the vectors captured by two camera sets can be merged together for a wider measurement space.

The quad-view CSPSV combined the measurement results of two normal stereo CSPSV systems. Therefore, the measurement region is expanded, the blind zone is minimized, and the high accuracy of each stereo CSPSV is preserved. Since there are a lot of buildings with even larger spaces that cannot be covered by a pair of cameras, this system is designed to accommodate more cameras to create the multiple-view

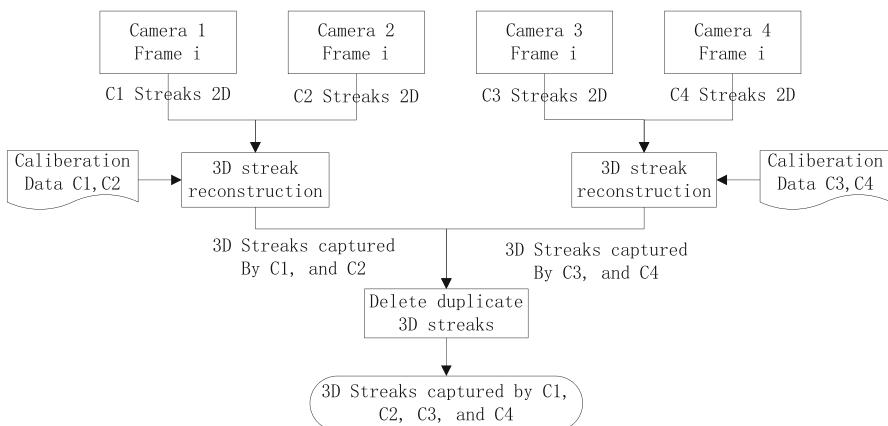

Fig. 9 Algorithm for quad-view CSPSV. (Reprinted from Wang et al. (2019), with permission from Elsevier)

CSPSV and will further support three-dimensional three-component (3D3C) airflow pattern measurements in large spaces like stadiums.

Image Processing and Stereo Correspondence Algorithm

With CSIS, the information on individual image is significantly richer. Specific digital image-processing algorithm and pair-matching algorithm are designed to extract the information and make full use of these advantages.

Digital Image Processing

After the acquisition of these informative images, the segmentation algorithm and information-handling process must be carefully designed. Unlike in PSV, where only the measured end points are employed, CSPSV images have multiple types of information that is collected: spot color, spot location, streak location, and number of pixels that each streak covers as shown in Fig. 6b. The spot and streak locations are of fundamental importance. Although humans can easily distinguish spots and streaks from the background, the computer has difficulty doing so. By changing the color image into grayscale and expressing its level on the z axis, the light intensity of pixel can be better displayed as shown in Fig. 10. The streaks and spots appear like ridges of different heights and mountain peaks, respectively. For spots, the light that is scattered and transmitted from seeding bubbles obeys a Gaussian distribution (Nobach and Honkanen 2005), and the streak can be considered as a series of spots along the given path. Therefore, the segmentation and enhancement can be based on a Gaussian distribution.

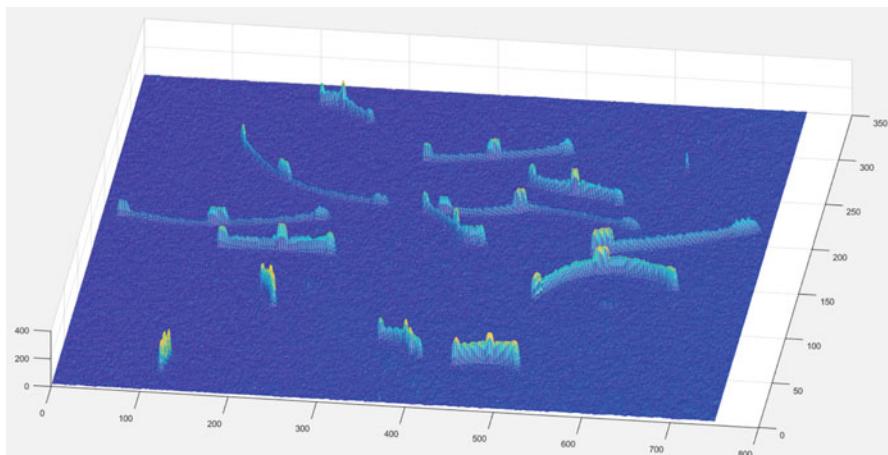

Fig. 10 Grayscale mesh of Fig. 6b

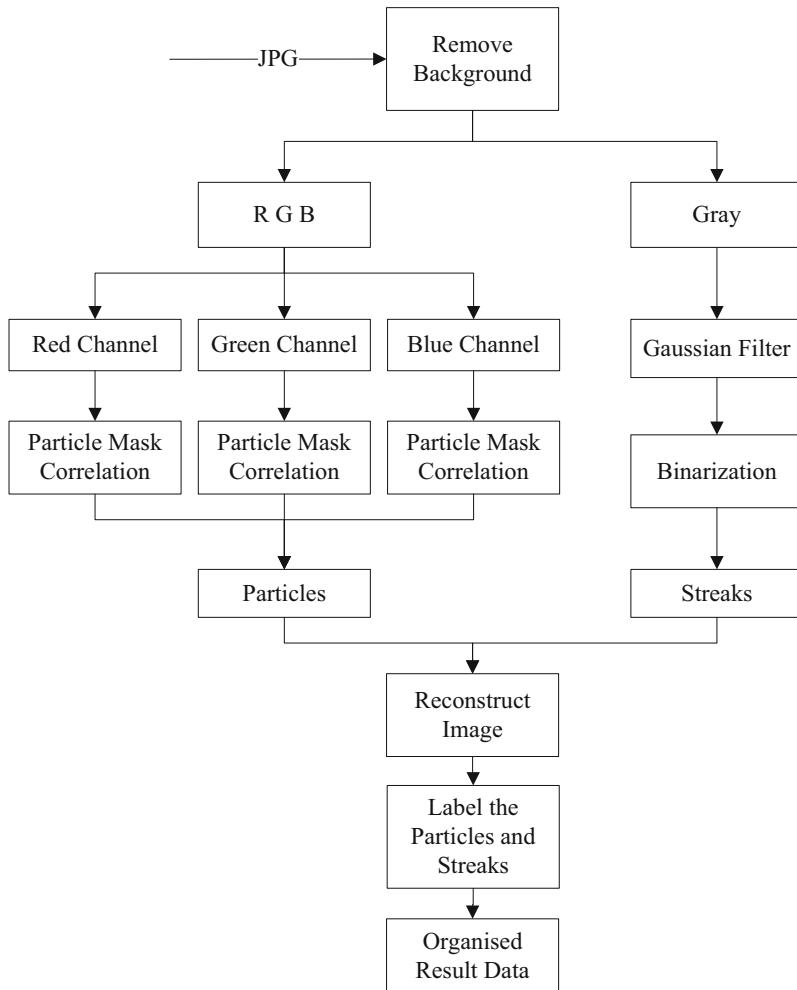

Fig. 11 Flowchart for image processing. (Reprinted from Wang et al. (2017), with permission from Elsevier)

The flowchart for image processing is shown in Fig. 11. Because the background remains bright, removing the background is essential to enhance the distinction between streaks and background. Since spots and streaks have different characteristics, they are handled with two separate procedures. For spot detection of the three different colors, i.e., red, green, and blue, dividing the original image into the respective RGB channels can reduce the effect of the white streak. Next, the particle mask correlation (PMC) method (Takehara and Etoh 1999) based on a Gaussian distribution is used to identify the spots in different color channels. For streak recognition, the total signal recorded in all channels is summed and converted into a grayscale image. Because the streaks can be considered as gathered spots, a

Gaussian filter can also help to suppress the background noise and enhance the signal from the bubbles. Then, the OTSU algorithm (Otsu 1979) is applied to enhance the binarization of images.

In CSPSV, the colored spots provide the key points for the start, middle, and end time of bubbles. Therefore, image information extraction is conducted to link the spots of the same seeding bubbles. If images are taken using the sequence in Fig. 6a, three vectors can be extracted from the image: from the red spot to the green spot, from the green spot to the blue spot with one time duration, and from the red spot to the blue spot with two time durations. Using this digital image-processing scheme, the bubble trajectory information of these images is collected and automatically arranged for 3D streak pair matching with high precision.

Rectification-Based Sparse Stereo Correspondence

After image processing, the 3D stereo reconstruction algorithm is designed to evaluate the 2D vectors from two cameras to produce the 3D vector results. Unlike traditional stereo correspondence, the information gathered from the raw CSPSV image is a series of sparse vectors, invalidating the smoothness assumptions for regular stereo correspondence (Szeliski 2011). As a sparse stereo correspondence problem, the traditional matching algorithm for neighboring pixels (Shi et al. 2015) also becomes ineffective. Pair matching based on the end points (Sun 2007) is also not enough for complex flow phenomenon. However, the start, middle, and end points of a streak together can be used for pair-matching judgment, which can improve the system accuracy.

Since the epipolar constraint alone is not adequate for pair-matching judgment (Maas 1992), rectified images from two cameras are adopted as important criteria. With the calibration data of the cameras, the streaks on the rectified images of the same bubble can be adjusted along the same horizontal line (Fusiello et al. 2000) as shown in Fig. 12. The pixel difference, Delta, of the corresponding color spots from two cameras in Y-axis after rectification can be calculated in Eq. 6:

$$\Delta = Y_1^{\text{rectified}} - Y_2^{\text{rectified}} \quad (6)$$

By adding the absolute number of pixels between the corresponding spots of each streak from different cameras in the rectified Y-axis, a new criterion, $C_{\text{Rectified } Y}$, between each streak from different cameras is defined in Eq. 7.

$$C_{\text{Rectified } Y} = |\Delta_{\text{start}}| + |\Delta_{\text{middle}}| + |\Delta_{\text{end}}| \quad (7)$$

If two streaks captured by different cameras are from the same bubble, $C_{\text{Rectified } Y}$ should be very close to zero and can be used as a prefilter to expedite the search for candidate matching streak pairs and, at the same time, improve the accuracy of pair matching.

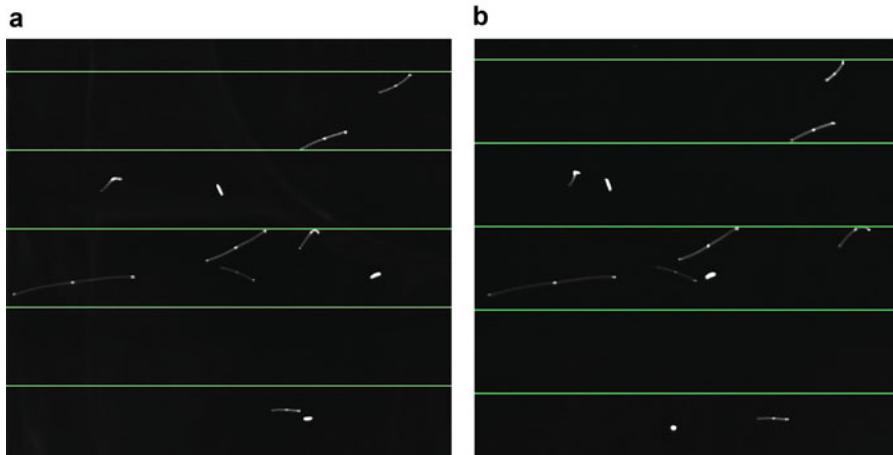

Fig. 12 Rectified image from cameras. (a) Left camera. (b) Right camera. (Reprinted with permission from Wang et al. (2018), © The Optical Society)

After finding the candidate matching streak pairs, the epipolar constraint residual is calculated for three spots:

$$\mathbf{R}_{\text{spot}} = \mathbf{P}_1^T \mathbf{F}_{12} \mathbf{P}_2 \quad (8)$$

where \mathbf{P}_1 and \mathbf{P}_2 are the normalized pixel coordinates in cameras 1 and 2, respectively, and \mathbf{F}_{12} is the fundamental matrix based on the calibration data (Fu et al. 2015),

$$\mathbf{F}_{12} = [\mathbf{T}_1 - \mathbf{R}_1 \cdot \mathbf{R}_2^T \cdot \mathbf{T}_2] \times \mathbf{R}_1 \cdot \mathbf{R}_2^T \quad (9)$$

Matrixes \mathbf{R}_1 , \mathbf{T}_1 , \mathbf{R}_2 , and \mathbf{T}_2 are extrinsic parameters from calibration. By adding the residuals together for the whole streak pair, C_{Epipolar} is calculated in Eq. 10.

$$C_{\text{Epipolar}} = \mathbf{R}_{\text{start}} + \mathbf{R}_{\text{middle}} + \mathbf{R}_{\text{end}} \quad (10)$$

C_{Epipolar} can be used to evaluate the entire streak matching performance. Finally, the geometry bounds are evaluated for gross errors.

With these specific designed digital image-processing algorithm and pair-matching algorithm, the color-coded sequence information can be accurately extracted and made full use of, which lay the solid foundation for the accuracy of CSPSV system.

Accuracy Verification

The accuracy of the CSPSV measurement system was verified before further application. Two different targets were employed: a rotating board test for detailed three-component velocity verification and a wind tunnel test for the comparison with regular instruments HWA.

Experimental Setup of Rotating Board Test

Because the airflow speed is notably difficult to be precisely measured and used as a known speed, image-based velocimeters commonly use rotating white dots of a known track and speed instead. The dots are usually indicated on a rotating black board or a needle to simulate the particle motion (Sun 2007; Barker 2012; Zappa et al. 2013). The rotating board here is made of black PVC reinforced with an aluminum support. Along its longitudinal axis, dots are placed at 10, 15, 20, 30, 35, and 40 cm from the center of rotation. The board is driven by a closed-loop step motor with a 1:50 harmonic wave reducer that increased the torque and smoothed the rotation. By sending different pulse frequencies to the motor, the rotation speed can be adjusted from 0 to 1.6 rev/s. In this experiment, the rotation speed was selected as 0.2 rev/s and 0.6 rev/s, which corresponds to the speed magnitude of these dots of 0.12–2.45 m/s, respectively. To verify the velocity of each dot in three directions, the position of the rotating board was also monitored and shown on a LED lattice board. Therefore, from a single image, the velocity of the dots and the position of the board can be determined.

Because CSPSV reduces the requirement for a high-speed camera, regular single-lens reflex cameras can handle the task. In this test, two common single-lens reflex cameras (model: Cannon 70D) with 24 mm focal length lens are utilized. During the test, the exposure time for the two cameras is 200 ms, and they are synchronized with CSIS. As in Fig. 6b, the color sequence of CSIS is from red to green and blue with a pulse width of 3 ms and a flashing frequency of 10 Hz. The raw image is shown in Fig. 13, from which we can clearly determine the color spots and white streaks. With images taken by two cameras from different angles, the tracks of each dot can be reconstructed in 3D space using the aforementioned algorithm. Given the location and rotation speed of the board, the speed of these dots in three directions can be calculated and treated as the known speed.

Accuracy Verification on Rotating Board

For a stereotypical 3D imaging system, the measurement error varies with different directions. Comparisons of each component velocity between the measured and known speeds are shown in Figs. 14 and 15. The U, V, and W directions represent the velocity vector directions in the X, Y, and Z axes, respectively. The red and green bars represent the real and measured speed of the dots, respectively.

In the low-speed test, the rotating speed was set to 0.2 rev/s, which made the velocity of the dots so low it is difficult to be precisely measured. In Fig. 14a and b, the displacement between the actual speed and the measurement in the U and V directions is small (generally below 5%). Although the relative error is larger at some points, it is mainly because the actual speed is so small. Figure 14c shows that the relative error of CSPSV in the W direction is higher than those in the U and V directions because there were only two cameras in the tested system. Thus, the information gathered in the Z direction was insufficient. Despite this systematic

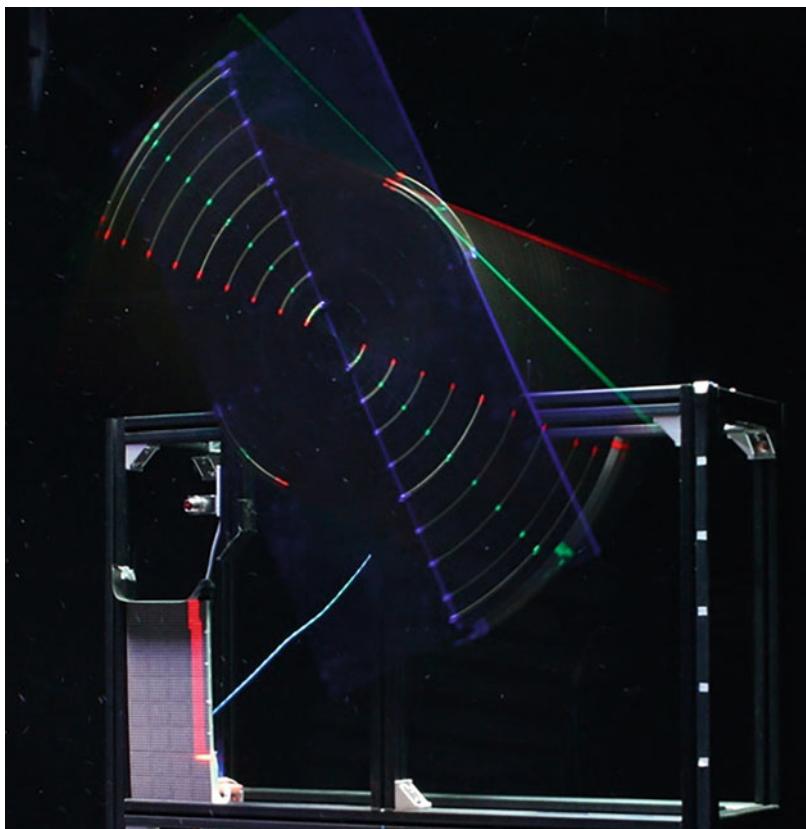

Fig. 13 Image of a rotating board for verification. (Reprinted from Wang et al. (2017), with permission from Elsevier)

drawback, the result for the W direction remained acceptable, particularly for the low-speed airflow measurement. The magnitude accuracy is notably satisfactory as shown in Fig. 14d.

In the high-speed test, the rotational speed increases to 0.6 rev/s, and the tangential speed of the outer dots increases to 2.5 m/s. In Fig. 15a, b, c, and d, the relative error in all directions decreases when the real speed increases. In most cases, the relative error is less than 5%, which is satisfactory for room ventilation measurement.

The verification range of $0.12 \sim 2.45$ m/s covers the primary testing speed in normal room airflow speed measurement. The CSPSV system showed an excellent precision in this range. In addition, all the streaks were successfully matched with a much lower magnitude of relative error than that in a previous study, where only half of the pair matching was successful and the relative error was 20% (Sun 2007). The rotating-board experiment confirms that CSPSV can perform highly accurate speed measurements.

Experimental Setup in the Wind Tunnel

The CSPSV system is further verified in a wind tunnel to test the parallel flow for verification with regular airflow measurement instrument HWA. As shown in Fig. 16, the wind tunnel is 4.5 m long. The main fan with an inverter blows airflow into the plenum chamber at one side of the main tunnel to provide a steady airflow into the tunnel. The section of the tunnel is 20 cm high and 54 cm wide. A bypass tunnel and a recirculation fan are set beside the main tunnel.

During parallel flow verification, only the main fan is operating to offer a steady and smooth airflow of different speeds within the main tunnel.

The test zone is located near the middle of the tunnel marked with an orange dashed line. During the experiments, two cameras (sp-20000c, JAI) with a 35-mm lens (F1.4, Zeiss) are set above the test zone. The CSIS is set beside the test zone, projecting color-coded light into the test zone. Buoyancy-neutral helium-filled soap bubbles are released at the outlet of the fans marked with yellow dots.

Verification with HWA

The verification experiment was between the high-accuracy HWA and CSPSV to evaluate the accuracy of CSPSV in real airflow measurement. The HWA was the

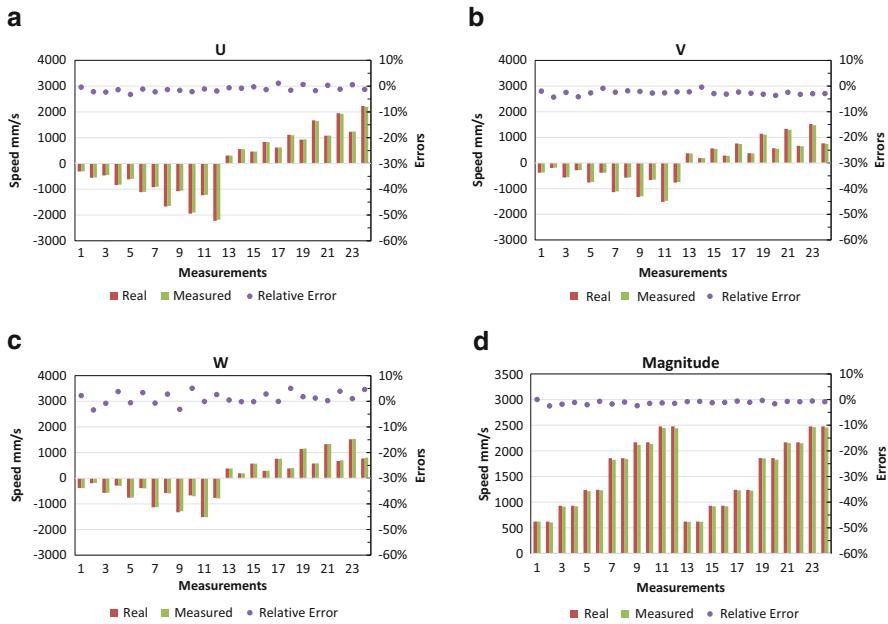

Fig. 15 Verification results for a high rotation speed. (a) U direction and relative error. (b) V direction and relative error. (c) W direction and relative error. (d) Magnitude and relative error. (Reprinted from Wang et al. (2017), with permission from Elsevier)

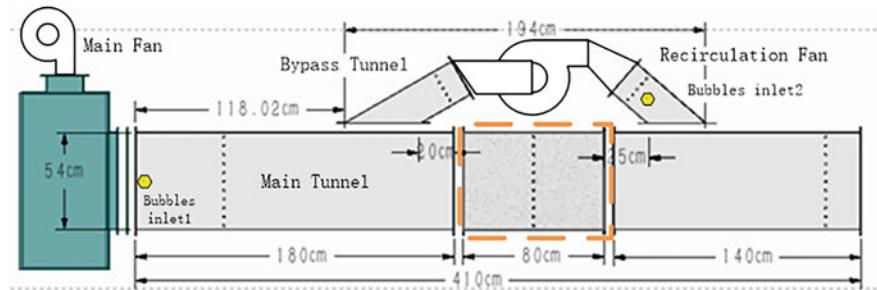

Fig. 16 Experimental setup of wind tunnel. (Reprinted with permission from Wang et al. (2018), © The Optical Society)

principal research tool for most turbulent flow studies and always used for verification. The HWA tests the heat release rate from the hot wire to calculate the airflow speed. It is more sensitive to flows perpendicular to its hot wire (Bruun 1995). Therefore, parallel flow, which is easy to produce and can be measured precisely by both the normal HWA and CSPSV, is selected as the flow pattern for verification. By changing the inverter frequency of the main fan, three cases are tested for different airflow speeds. In this test, the flash time period of the CSIS is set to 30 ms, while the exposure time for the two cameras is set to 60 ms. The HWA is from KANOMAX

(model 0963-00), which can provide an accuracy of ± 0.1 m/s within the range of 0.1–4.9 m/s.

The test results are presented in Fig. 17a when the main fan is running at 10 Hz. It can be seen that most vectors are parallel and the velocity is somewhat equal. A detailed comparison of the measurement from the HWA and CSPSV is presented in Fig. 17b, c, and d. Three different airflow speeds were tested: 0.67, 1.0, and 1.36 m/s. The average speeds measured by the HWA at different locations on the X-axis are marked by orange triangles with error bars. The magnitudes of the vectors measured by CSPSV under different wind speeds are marked with blue dots. When the wind speed of the tunnel is high, it was not easy for the bubbles to spread along its path within a short distance. Therefore, the resulting vectors are more highly clustered at the higher speed as shown in Fig. 17c and d.

From Fig. 17b, c, and d, the average speeds of both instruments were very similar, and the scatter of the CSPSV results was near the average level. Overall, the speed provided by CSPSV was slightly higher than that of the HWA. One possible reason could be that the sensor wire of the HWA is more sensitive to the perpendicular flow than the parallel flow. Although most of the airflow in the wind

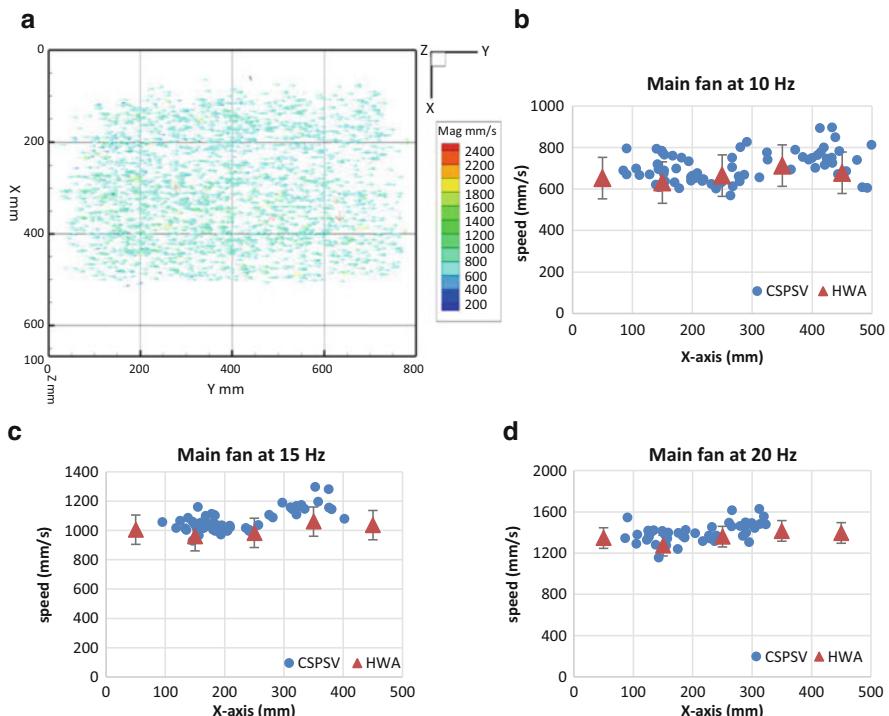

Fig. 17 CSPSV results and comparison with HWA. (a) Vectors results at 10 Hz. (b) Magnitude at 10 Hz. (c) Magnitude at 15 Hz. (d) Magnitude at 20 Hz. (Reprinted with permission from Wang et al. (2018), © The Optical Society)

tunnel is perpendicular to the sensor wire, there is still some turbulent flow that cannot be measured precisely by the HWA, whereas it can be captured by CSPSV. This verification with the normal instrument has proven the accuracy of CSPSV for airflow measurements in a moderately large zone.

Applications and Results

In this part, three cases have been measured to demonstrate the capability and reliability of the CSPSV method in actual tests including the vortex in a scale tunnel, and the airflow patterns induced by a ceiling fan and an adjustable fan network (AFN).

Vortex Flow Test

Theoretically, a vortex is very sensitive to the disturbance from invasive sensors and difficult to measure with regular instruments (such as a HWA). Hence, CSPSV is utilized for the vortex flow test for its nonintrusive advantage. The test is conducted in the scale tunnel with the recirculation fan set on the bypass tunnel opened as shown in Fig. 16. This setting can produce a large vortex in the main tunnel. During the experiment, the main tunnel fan supplies $260 \text{ m}^3/\text{h}$ of air into the tunnel, while the circulation fan circulates $523 \text{ m}^3/\text{h}$ of air within the tunnel. Hence, there will be a large vortex within the test zone, which is a much more complicated airflow phenomenon and difficult to measure with normal instruments, especially at this large scale. Since the target air speed is faster in this experiment, the exposure time was set shorter. The flash rate of the CSIS is set to 25 ms, and the camera exposure time is 50 ms. The 3D vectors are presented in Fig. 18a and b.

Since the vectors are the 3D3Cs distributed in the space, they are interpolated into grid for further calculation and analysis. In this test, uniform 50 mm grids were used to investigate the turbulence intensity (TI). The turbulent velocity fluctuation is calculated using Eq. 11.

$$v' = \sqrt{\bar{v}^2} \quad (11)$$

where v' is the root-mean-square of the turbulent velocity fluctuations. Subsequently, the TI can be calculated using Eq. 12.

$$TI = \frac{v'}{\bar{V}} \quad (12)$$

where \bar{V} is the mean velocity. The averaged results and TI results are presented in Fig. 18c and d. From vector field as in Fig. 18b, the gradient of the flow is very large and the flow is chaotic. The region of the vortex core can be captured and illustrated very well for this large space and shows a good consistency with the flow dynamics

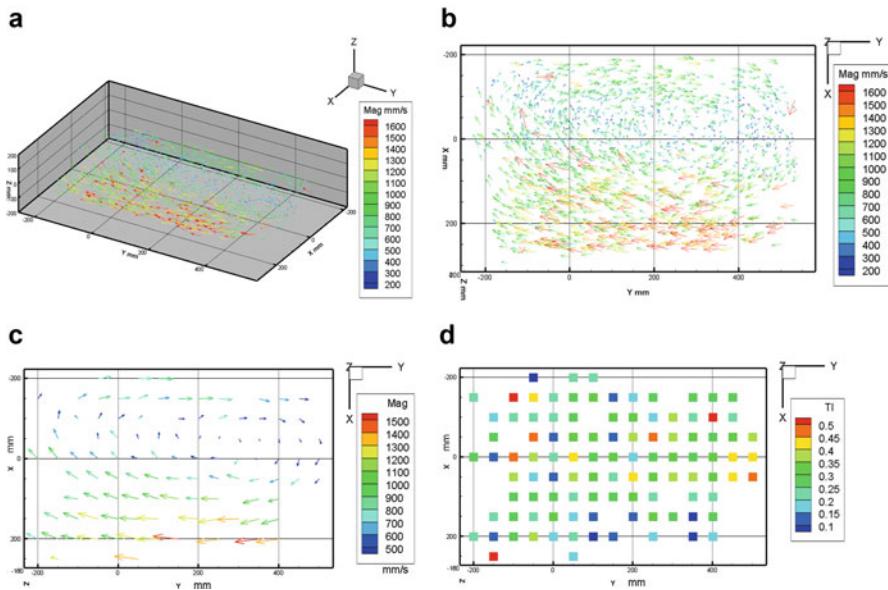

Fig. 18 Test results of CSPSV. (a) 3D view. (b) Vortex top view. (c) Averaged vectors. (d) TI. (Reprinted with permission from Wang et al. (2018), © The Optical Society)

analysis. This test proves the capability of CSPSV to capture and measure the complex airflow with a moderately large measuring space.

Airflow Pattern Induced by Ceiling Fan

This test is designed to measure the airflow pattern induced by ceiling fan, which is of high gradient and fast velocity.

Chamber Setup

The experiment is conducted in the airflow visualization and measurement platform located at Tsinghua University. The platform consists of a sealed chamber, four cameras, and illumination systems. The chamber is $4\text{ m} \times 2.5\text{ m} \times 3\text{ m}$ in width, height, and depth. Three surfaces (e.g., the ceiling, roof, and front-side wall) of the chamber are made of high-transparency glass. To avoid the airflow field in the chamber from being blocked, the cameras and illumination systems are placed outside the chamber. In total, 40 CSIS modules are located above the ceiling and under the floor. They are placed on the length direction of the chamber from left to right, creating an illumination zone that is also the airflow measurement zone sizes: $4\text{ m} \times 2.5\text{ m} \times 0.8\text{ m}$ in the middle of the chamber. As the CSIS modules are isolated from the chamber, the heat produced from them affects little on the airflow field.

A normal ceiling fan with three plastic blades of diameter 60 cm is utilized. It rotates at a constant speed of 330 rounds per min (rpm). The power supply is 220 V AC, with a constant power consumption of 6.34 W. The fan is fixed at 2.15 m above the floor, 0.35 m away from the ceiling, and in the middle of the test chamber.

The seeding particles used are HFSBs produced by a commercially available bubble generator SAI Model 5. The diameter of the HFSB ranges from 1 to 3 mm and filled with helium, thus rendering the Stokes' number less than 0.1. These bubbles are released from the top center of the ceiling over the fan, and a complement diffuser is utilized to decelerate the bubble speed to 0.15 m/s, such that its effect on disturbing the primary airflow field can be ignored.

The typical image with 50 ms exposure time during experiment is shown in Fig. 19. Some regions are partially enlarged in the image for a better illustration. From Fig. 19, the streaks with different length and direction can demonstrate the dramatic changes of airflow pattern between these regions as well as the effectiveness of CSIS.

Imaging Settings

To capture the airflow characteristic near the ceiling and floor, four high-resolution cameras (sp-20000c, JAI) with 35-mm lens (F1.4, Zeiss) are utilized for different view angles, as shown in Fig. 8. The four cameras are located on the transparent side and out of the chamber. As mentioned in a previous study (Liu et al. 2018), a fan-induced airflow demonstrates a large gradient between the jet core and surrounding entrainment flow. In this test, two types of cases are set for different exposure times, as shown in Table 1. A long-exposure-time case aims at the low-speed entrainment airflow, while a short-exposure-time case aims at the high-speed jet

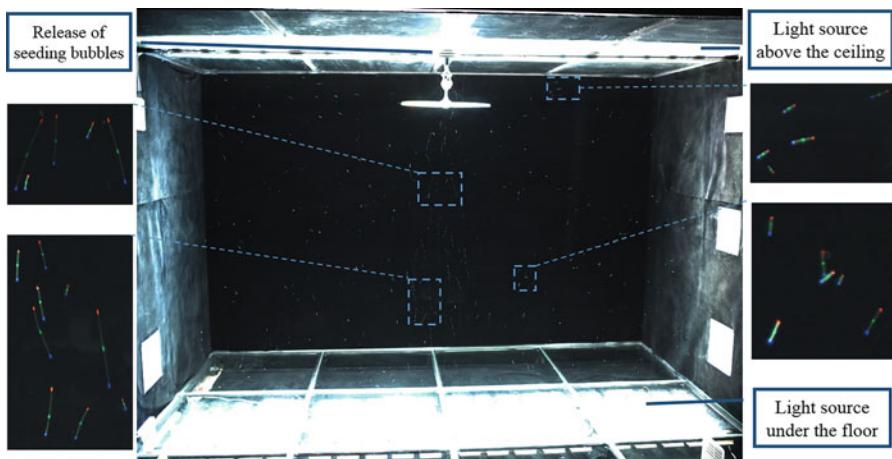

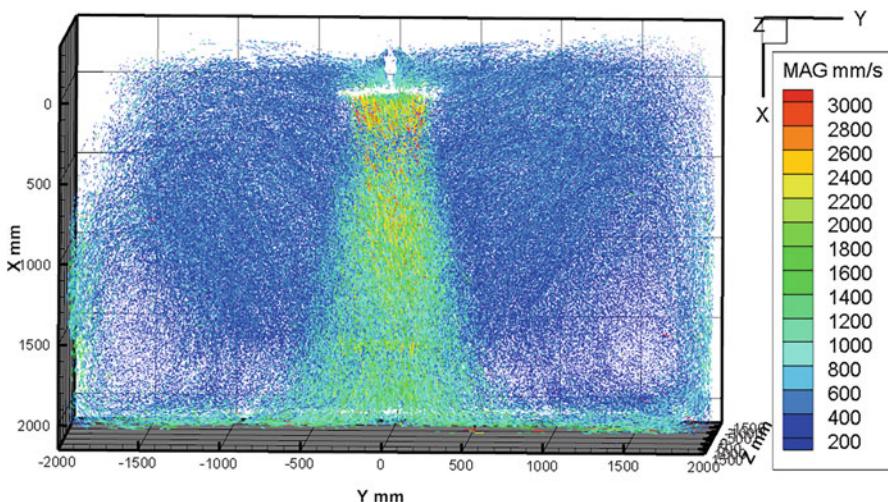

Fig. 19 Experimental setup and typical image of fan test. (Reprinted from Wang et al. (2019), with permission from Elsevier)

Table 1 Case setting

Case name	Exposure time	Target zone	Sample frequency	Sample frames	Time interval between two color flashes
Short exposure	50 ms	Jet Core	10 Hz	2700	25 ms
Long exposure	200 ms	Entrainment	4 Hz	3300	50 ms

**Fig. 20** Vectors induced by ceiling fan. (Reprinted from Wang et al. (2019), with permission from Elsevier)

core region. In total, each camera captures 6000 frames of the bubble's time sequence image. During experiments, the CSIS is synchronized with camera.

Results

After the images are captured, the time sequence information on the images is processed with the algorithms mentioned above. Quad-view CSPSV can provide detailed 3D velocity vectors field within the test space and can be illustrated as air velocity vectors similar to the CFD simulation results. In this test, 417,671 vectors are reconstructed and are presented in Fig. 20. For the convenience of calibration and image processing, the height of chamber is presented as X axis, the width of chamber is presented as Y axis, and the depth of chamber is presented as Z axis.

In addition to the vector field, the raw images can also provide considerable information about the flow pattern. Figure 21 demonstrates the accumulated color streaks of 200 images in the measurement zone with short exposure time. It is obtained by subtracting the raw image with the background to get the streaks in each image and then adding them together. Figure 21 shows the continuous trajectory of seeding bubbles during 20 s, and from the movements, two big vortices can

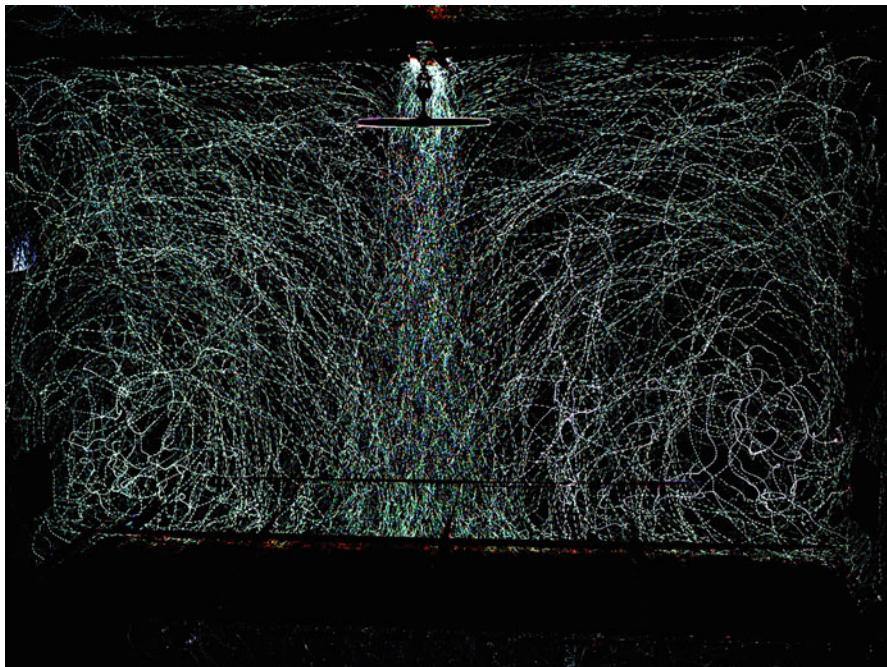

Fig. 21 Accumulated traces of 200 images in the measurement zone. (Reprinted from Wang et al. (2019), with permission from Elsevier)

be observed located in the lower part of the room, and the main part of the room is influenced by the fan jet.

To streamline the vector data interpretation, the results are interpolated with 20 mm grids with inverse-distance interpolation method (Tecplot 2018) to investigate the detailed airflow characteristics in different regions. Figure 22 shows the middle section from the front view of the chamber. As shown, the airflow induced by the ceiling fan can be divided into six zones based on the airflow patterns.

The jet core zone is located immediately under three fan blades, and the fast jet flow is the primary momentum of chamber circulation. The jet has the highest speed at its boundary and expand slowly along its path. **The spreading zone** is near the floor where the jet core impinges the floor; this layer is relatively thin while the speed is higher than 1 m/s. When the spreading airflow reaches the wall, the flow direction changes to vertical upward and decelerates gradually. Between the spreading zone and wall zone, **the recirculation zones** are marked with triangular frames on both sides. The recirculation flow zones are surrounded by the entrainment flow, recirculation flow, and wall flow, while the vortex flow follows the change in direction of these flows. **The entrainment zone** is primarily induced by the jet core. The entrainment zone occupies the largest space in the chamber with an evenly low air speed, and the boundary between the jet core and entrainment flow is sharp and clear. **The suction zone** is located above the fan blades. As the fan is located

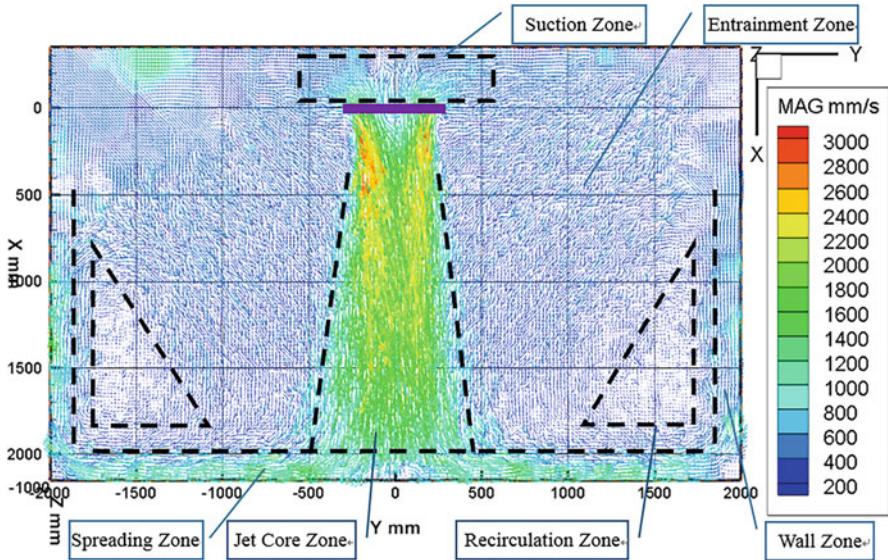

Fig. 22 Velocity distribution on the middle section of fan-induced airflow (Reprinted from Wang et al. (2019), with permission from Elsevier)

sufficiently far from the ceiling and the speed of the convergent flow decays rapidly, the suction zone is not large and appears symmetrical. These characters convey the complexity of the flow pattern induced by the ceiling fan and can facilitate in the better understanding and utilization of ceiling fans in an indoor environment.

The raw data can be further mapped into a grid of size 100 mm × 100 mm × 100 mm to calculate the TI level. As shown in Fig. 23, the zone under the fan blade tip has a much higher TI values, while the center of the fan has relatively lower TI values. The edge of the jet core zone has TI levels of 50–75%, but the TI level in the center part of the core zone are between 15% and 35%. From the view of the entire space, the TI levels are higher in the bottom part but lower the in upper part especially when close to the ceiling and walls. The overall averaged TI is approximately 40% and is much larger than that in regular rooms.

As the result vector field is of high density and 3D3C, the vorticity can be calculated for the better understanding of the swirling character of airflows, which can hardly be achieved with regular measurement instruments especially in this scale. The vorticity on different directions is calculated respectively for a better understanding of this flow pattern. The equation is as follows:

$$\omega_z = \frac{\partial v}{\partial x} - \frac{\partial u}{\partial y} \quad (13)$$

$$\omega_x = \frac{\partial w}{\partial y} - \frac{\partial v}{\partial z} \quad (14)$$

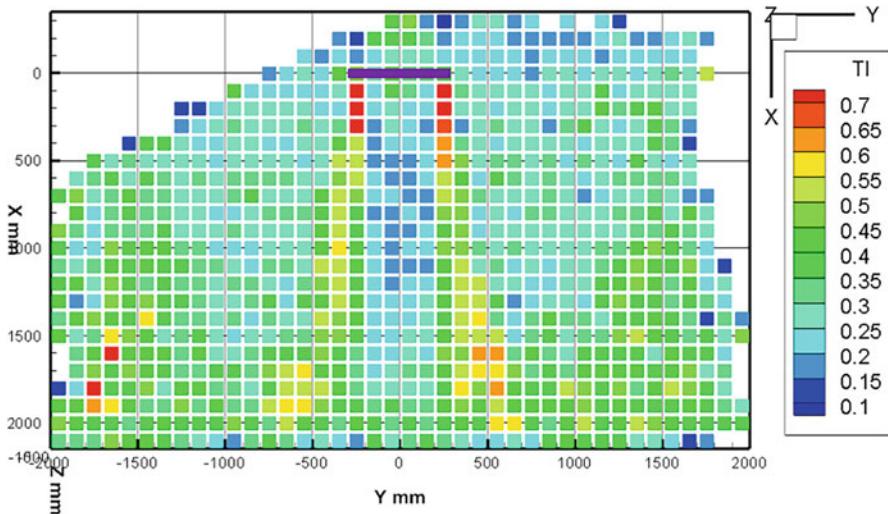

Fig. 23 TI distribution in the middle section. (Reprinted from Wang et al. (2019), with permission from Elsevier)

where u is the velocity component in the X direction, v is the velocity component in the Y direction, and w is the velocity component in the Z direction. ω_z can illustrate the swirling direction of flow in the XY plane, and ω_x can illustrate the swirling direction of flow in the horizontal plane. Figure 24a presents the vorticity ω_z calculated with Eq. 11 in the middle section of the chamber and illustrates the swirling direction of flow on the XY plane. The color legend on the right side represents the swirling direction of the airflow on the XY plane. Red means the airflow swirls in the counterclockwise direction, while blue means the airflow swirls in the clockwise direction. It can be seen that the airflow under the fan blades swirls in different directions. The two edges of the jet core zone exhibit higher but opposite directions of ω_z vorticity, thus demonstrating the highest speed airflow caused by the fan blade on each side swirl to opposite directions. Meanwhile, in the center region of the fan, counter direction swirling flows exist that may be caused by the difference in rotation speed along the radii of the fan blades.

Figure 24b demonstrates the vorticity ω_x calculated with Eq. 12 illustrate the swirling direction of the airflow in the horizontal plane. The almost continuous blue region means the airflow swirl with the same direction of the fan blade. This phenomenon becomes gradually inconspicuous beyond a three diameter length from the fan blade. However, in other regions, the swirling phenomenon is not evident.

Unlike the normal jet promoted by pressure difference, a fan jet is propelled by the rotation of fan blades, which produces its own characteristics. The detailed velocity field is further illustrated and studied below. As shown in Fig. 25, the peak air speed occurred at one-third of the fan blade radius below the fan. The highest speed regions only constitute a small portion of the jet core, and the gradient

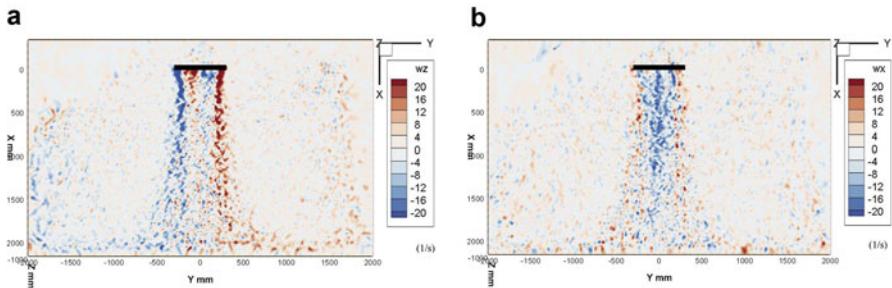

Fig. 24 Vorticity in the middle section of the fan-induced airflow. (a) Vorticity ω_z , (b) Vorticity ω_x . (Reprinted from Wang et al. (2019), with permission from Elsevier)

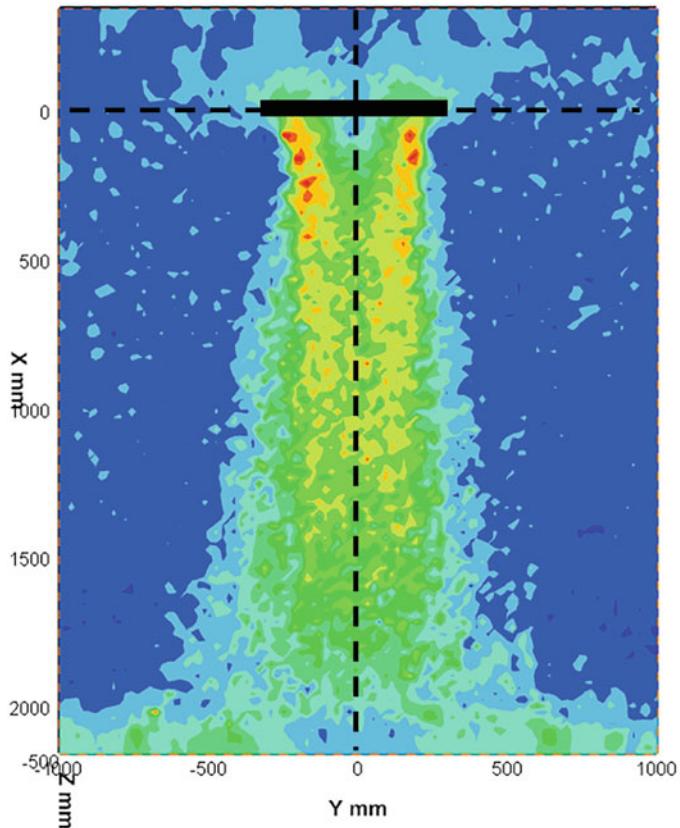

Fig. 25 Velocity contour through fan's center (Reprinted from Wang et al. (2019), with permission from Elsevier)

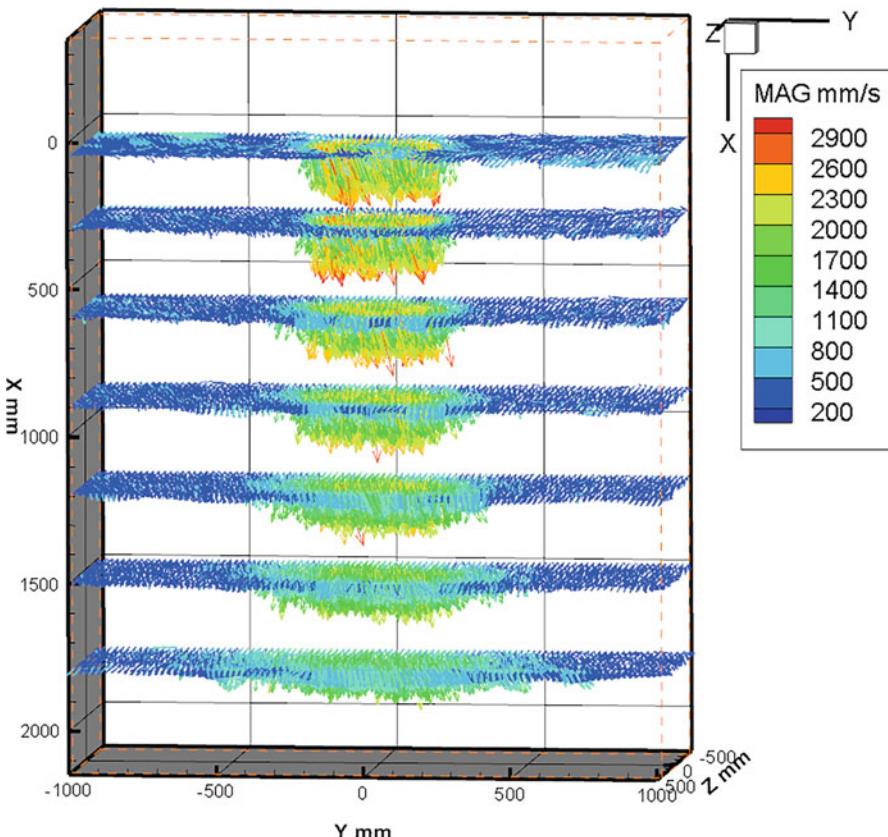

Fig. 26 Vectors on different horizontal planes (Reprinted from Wang et al. (2019), with permission from Elsevier)

of the speed difference is large and becomes diluted along its path. The diameter of the jet flow narrows slightly at first and subsequently expands gradually. The jet flow also swirls in the same rotation direction with the fan blades as shown in Fig. 26. The vertical planes are at 5 cm, 30 cm, 60 cm, 90 cm, 120 cm, 150 cm, and 180 cm from the fan's blades. From the vectors' direction, it can be found that the rotation speed along the jet path decreases while the jet expands in a larger space.

To better illustrate the changes of the airflow induced by the jet, slices of a velocity vector field are plotted at different heights as shown in Fig. 27 and discussed below. Figure 27a demonstrates the airflow 10 cm above the fan. It can be found that within the suction zone, when the air gathers from the surrounding to the fan blade while at the center of the fan, the air speed is low. Figure 27b more clearly illustrates the high-speed swirling ring produced by the fan blades. A clear high-speed vector ring can be seen that has a narrower diameter than the fan blades and rotates in the same direction. Around the jet core, the surrounding air is drawn towards the center. Unlike a normal circular jet with the highest speed jet core located in the center of the

flow, a fan jet exhibits the highest speed region near the outer boundary of the jet. As shown in Fig. 27b, c, d, and e, within a 30 cm distance (semidiameter of the fan blade) from the fan blades, the flow characteristic does not change significantly thereby proving the stability of this unique jet flow pattern. When comparing Fig. 27e and f, the high-speed region becomes diluted and the core region expands as the distance goes further downward. At an even longer distance from the fan blades, the highest speed decreases. The diameter of the jet core extends to the same diameter of the fan blade below 60 cm as shown in Fig. 27h.

The high-speed ring was further diluted at longer distances as shown in Fig. 27i, j, k, and l. When the fan jet reaches two times its diameter as shown in Fig. 27m, the high-speed ring almost disappeared. The jet center also has the highest speed

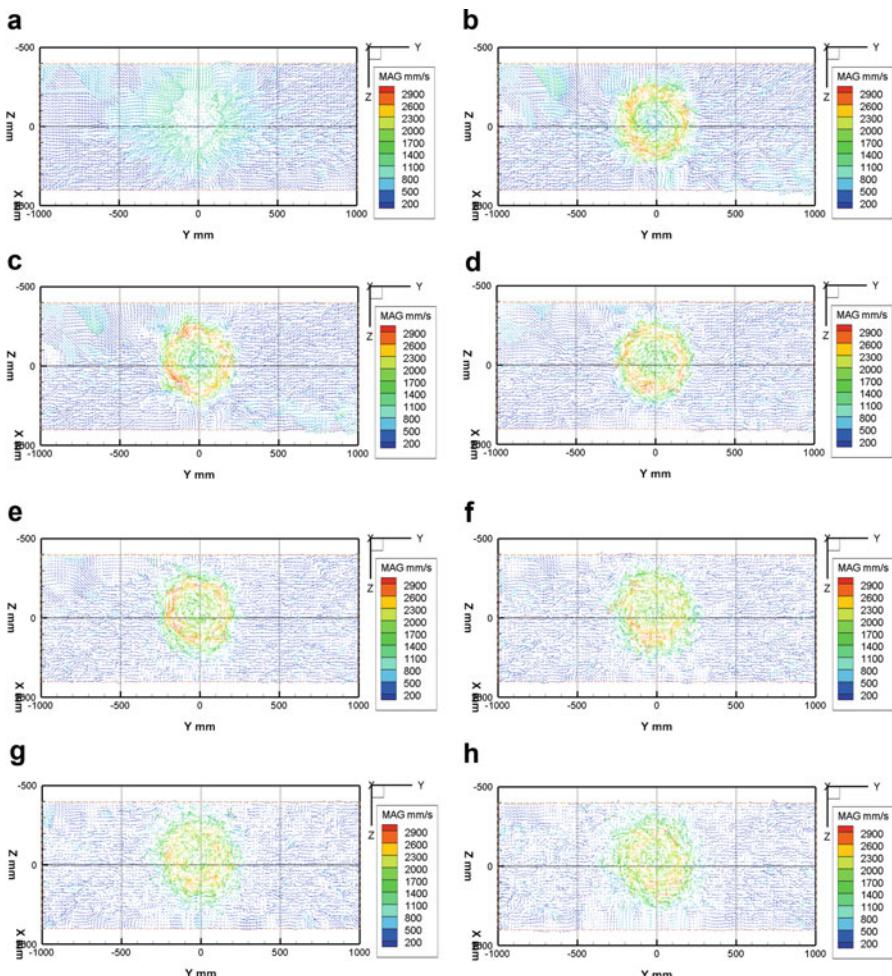

Fig. 27 (continued)

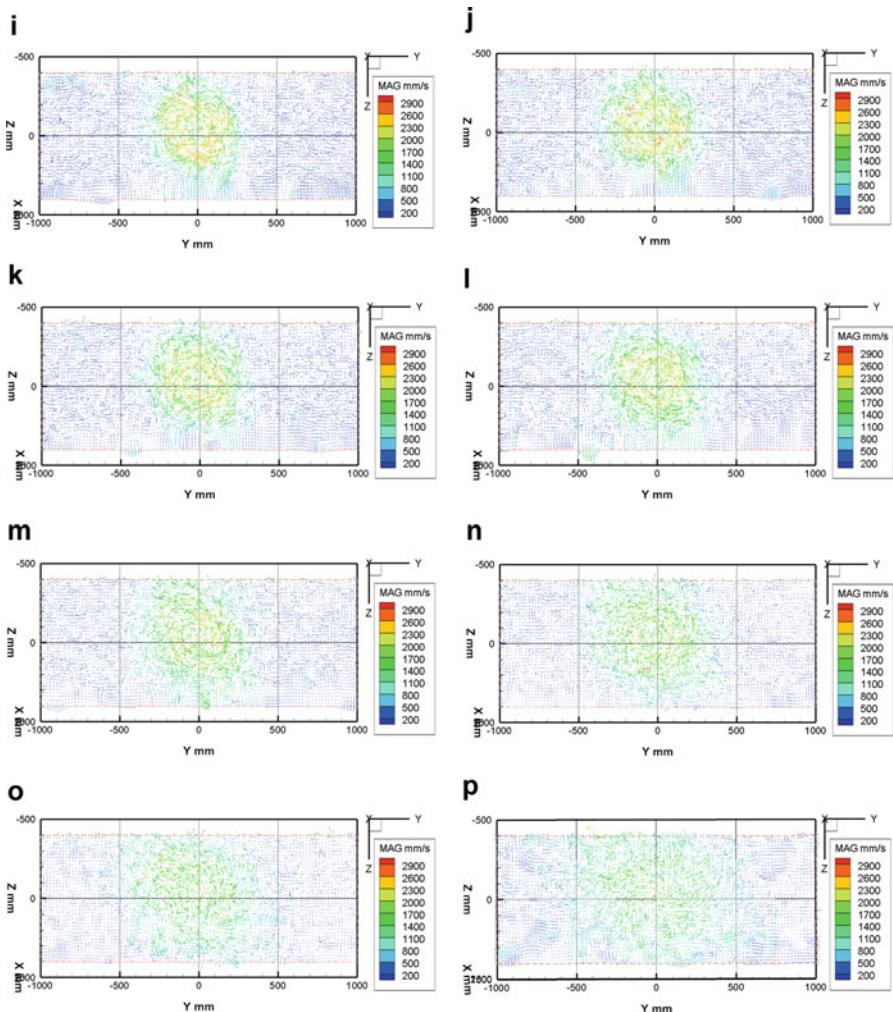

Fig. 27 Vector field at different heights. (a) 10 cm above the fan blades. (b) 5 cm below the fan blades. (c) 10 cm below the fan blades. (d) 20 cm below the fan blades. (e) 30 cm below the fan blades. (f) 40 cm below the fan blades. (g) 50 cm below the fan blades. (h) 60 cm below the fan blades. (i) 70 cm below the fan blades. (j) 80 cm below the fan blades. (k) 90 cm below the fan blades. (l) 100 cm below the fan blades. (m) 120 cm below the fan blades. (n) 140 cm below the fan blades. (o) 160 cm below the fan blades. (p) 180 cm below the fan blades. (Reprinted from Wang et al. (2019), with permission from Elsevier)

and the entire jet region is swirling as shown in Fig. 27n. When the jet travels even further as shown in Fig. 27o, the jet velocity becomes almost uniform. However, swirling phenomenon still exists even when it is three-times-diameter away from the fan blades and the speed is lower than 1.5 m/s as shown in Fig. 27p.

Based on the results above, CSPSV can be a more promising method for complicated indoor airflow measurements.

Airflow Pattern Induced by Mixing Ventilation and AFN

Traditional heating, ventilation, and air conditioning systems are predesigned and operated using a fixed airflow pattern like mixing ventilation (MV). However, the indoor occupancy and heat sources always vary, making the fixed airflow pattern may not always be efficient. Therefore an adjustable fan network (AFN) (Wang et al. 2020) was proposed for improving airflow pattern flexibility and tested with CSPSV.

Flow Pattern of MV

The airflow patterns of MV with different air exchange rate per hour (ACH) are measured as a comparison baseline. With the seeding bubbles released and mixed in the supply air, the trace of the supplied air can be recorded and compared with the baseline MV cases to illustrate the airflow pattern and evaluate the effects of the AFN.

(a) CASE-A (ACH = 1)

The continuous trace of seeding bubbles within the 20 s is shown in Fig. 28a. The supplied air-jet spread diagonally across the room and produces a large vortex located at the lower-left part of the room. The vector fields were calculated as shown in Fig. 28b. Based on the vector field, the penetration length of the supplied air is also short, and the entire indoor air movement is overly slow. Therefore, the main function of AFN for this case is set to extend the penetration length.

(b) CASE-B (ACH = 3)

The accumulated traces of seeding bubbles within 20 s for CASE-B is shown in Fig. 29a. The vector fields are shown in Fig. 29b. The supplied air flows across the upper part of the room and hits the opposite wall at high speed, as opposed to flowing into the occupied zone. The main target of AFN would, therefore, be diffusing the air more directly into the occupied zone.

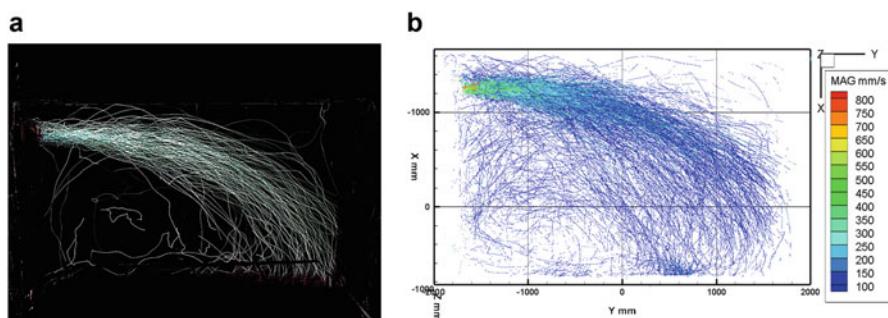

Fig. 28 Accumulated traces and vector field result of MV (ACH = 1) (Wang et al. 2020). (a) Accumulated traces. (b) Vector field

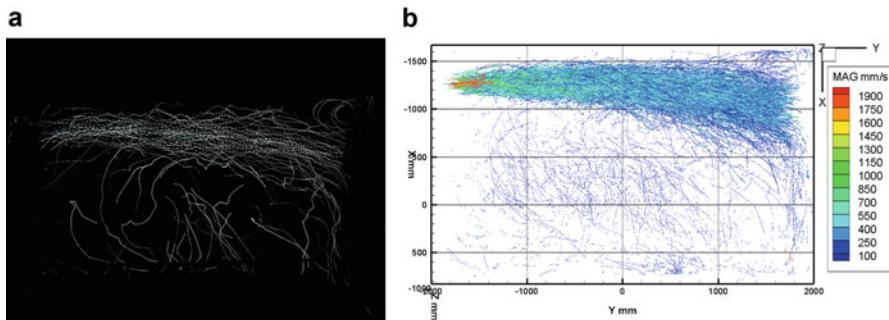

Fig. 29 Accumulated traces and vector field result of MV ($ACH = 3$) (Wang et al. 2020). (a) Accumulated traces. (b) Vector field

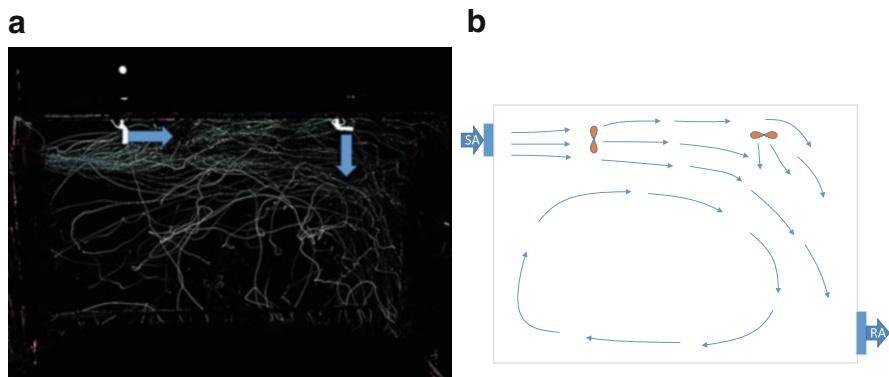

Fig. 30 Accumulated traces and schematic diagram of CASE-A1 (Wang et al. 2020). (a) Accumulated traces. (b) Schematic diagram

Flow Pattern of Cases with AFN

The measurement results presented above indicate that the ventilation effects of MV vary significantly with the air exchange rate, which is difficult to manipulate for the different indoor scenarios. The main limitations of CASE-A are the low ventilation rate and short penetration length. Therefore, two cases are tested to extend the spread region of the supplied air with AFN.

For CASE-A1, the operation of vector air-driven modules (VADM) (Wang et al. 2020) and the accumulated traces are shown in Fig. 30a. The VADM on the left propels the supplied air up to the right corner like a relay. Next, the VADM on the right pushes the supplied air downward into the occupied zone. A schematic diagram of this airflow pattern is shown Fig. 30b. With AFN, the indoor airflow pattern can efficiently transport the supplied air for a longer range.

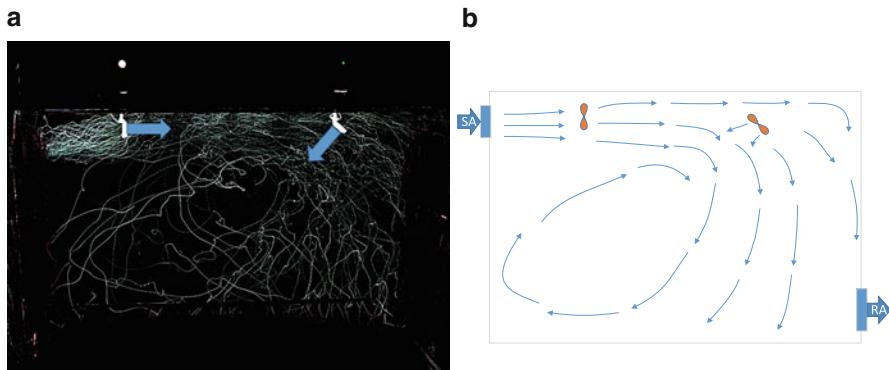

Fig. 31 Accumulated traces and schematic diagram of CASE-A2 (Wang et al. 2020). (a) Accumulated traces. (b) Schematic diagram

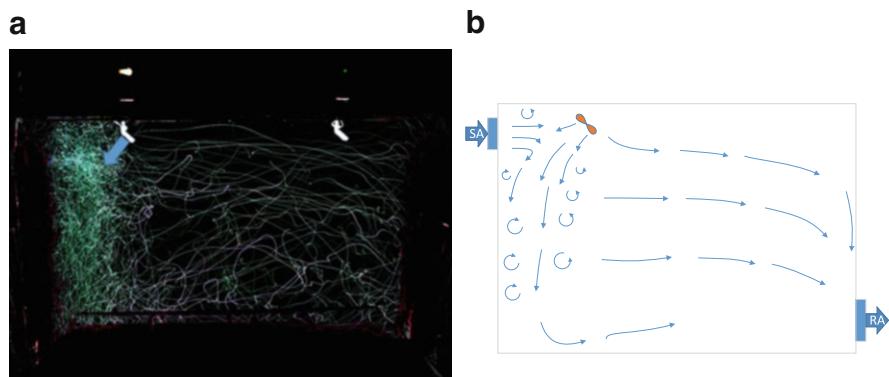

Fig. 32 Accumulated traces and schematic diagram of CASE-B1 (Wang et al. 2020). (a) Accumulated traces. (b) Schematic diagram

For better diffusion of the supplied air into the right-side occupied zone in CASE-A2, the right side VADM reverted to backward blowing. As shown in Fig. 31a, the supplied air is more evenly distributed into the right-side occupied zone. A schematic diagram of this airflow pattern is shown Fig. 31b.

For CASE-B, the increased ventilation rate results in a large increase in the penetration length, and the supplied air-jet mainly remains in the upper zone of the room as opposed to being in the occupied zone. Therefore, the main target of CASE-B1 is to enhance the ventilation in the left section of the room. Elsewhere, the left VADM is turned backward and blew downward against the inlet airflow. As shown in Fig. 32a, the left VADM pushes the inlet airflow into the left occupied zone. A schematic diagram of this airflow pattern is shown Fig. 32b. This leads to improved ventilation in the left part of the room according to the accumulated traces.

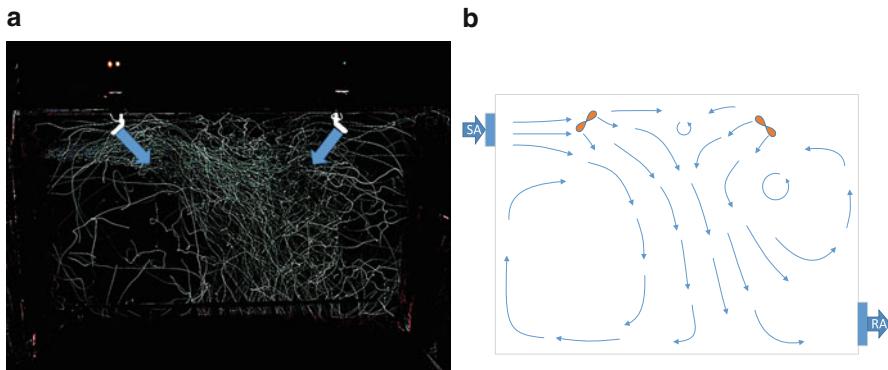

Fig. 33 Accumulated traces and schematic diagram of CASE-B2 (Wang et al. 2020). (a) Accumulated traces. (b) Schematic diagram

When multiple people are evenly distributed in the occupied zone, a well-mixing flow pattern offers the best solution. In CASE-B2, the two VADMs are set to blow towards the middle section of the room. As shown in Fig. 33a and b, this resulted in improved mixing ventilation in the entire room.

As demonstrated in the six cases, VADMs can operate as a network that enhances its maneuverability compared to the traditional air distribution systems. With an AFN, the indoor airflow pattern can be easily adjusted based on the real-time position of occupants and other sources.

Conclusions

In this chapter, CSPSV is introduced as a method to combine the advantages of the PTV and PSV with a new bubble-information-gathering scheme. Some conclusions can be drawn as follows:

1. By coding the test zone using the CSIS, more information was added to one single streak (including the time interval and time sequence). CSPSV made the tracking and 3D trajectory reconstruction of bubbles' tracks much easier and more reliable.
2. Through verification with different targets, it was observed that in the verification range of $0.12 \sim 2.45$ m/s, the relative error of the CSPSV results were mostly below 5%, and the results from CSPSV were consistent with the traditional instrument, HWA.
3. Applications in multiple cases showed that CSPSV was capable of effectively measuring complex airflows.

Abstract

Chemical analysis of the composition of indoor air characterizes exposures, but sometimes this analysis may be insufficient to describe the effects of these exposures on building occupants, especially to characterize sensory effects caused by exposures to pollutants in buildings. The present chapter presents the methods used to characterize these effects. The methods using olfactometers and gas chromatography-olfactometry-mass spectroscopy (GC-O-MS) are described together with the methods using sensory panels and subjective evaluations. The latter provides direct information on how indoor air quality is perceived by building occupants, and includes assessments of acceptability of air quality and the perceived odor intensity; the assessments of acceptability can be used to determine the percentage of people dissatisfied with air quality. The limitations of methods are described together with the factors influencing the measurements using human subjects, including physical factors such as temperature and relative humidity, psychological factors such as adaptation, and procedural factors such as the number of inhalations before the assessment is completed. Possible applications of the results of measurements are shown, including characterization of emissions from building products and determination of ventilation requirements to reach a specific level of air quality characterized by the percentage of dissatisfied occupants. It is concluded that the methods presented should be considered supplementary to the chemical measurements as none of both methods can provide complete characterization of indoor air quality. When used together, they provide a more comprehensive characterization of indoor air and its quality. It is subsequently recommended that sensory evaluations of air quality and olfactometry methods (also using GC-O-MS) become part of protocols used for characterizing indoor air quality because they can capture the effects and potential consequences that other methods for measuring indoor air quality are not fully capable of measuring.

Indoor air quality · Perceived air quality · Sensory assessments · Olfactometry

Introduction

Humans are constantly exposed indoors to varying concentrations of chemical compounds. The compounds originate from outdoor sources, e.g., urban traffic, and indoor sources such as people, tobacco smoking, and the building (building materials and furnishing, electronic equipment, and the heating, ventilation, and air-conditioning systems) (Wargocki 2004). A typical mixture of chemical compounds indoors may contain several hundred or more compounds. These compounds can affect indoor air quality thereby the well-being and health of occupants.

Despite significant progress in analytical chemistry, a complex compound-by-compound approach employing detailed chemical analysis may not always provide an adequate basis for modeling the effects of indoor air quality on humans. This limitation is, among others, due to complicated indoor air chemistry, interactions between compounds, and mainly insufficient sensory and toxicological information regarding single compounds and particularly their mixtures. Considering additionally that various physiological and psychological variables play an essential role when humans evaluate air quality, it seems reasonable to use the human response to measure indoor air quality supplementing chemical analysis.

Different methods have been used to measure the effects of indoor air quality on humans (e.g., ECA 1991, 1999; Rohr 2001; Wyon and Wargocki 2005). These measurements can be used to set the limiting criteria regarding indoor air quality. The present chapter focuses on the methods used for evaluating the sensory effects on humans caused by exposure to air indoors.

Sensory effects are caused by stimulation of the olfactory sense situated in a small area of the nasal cavity and sensitive to around half a million odors, the general chemical sense situated all over the mucous membrane of the nose and sensitive to more than one hundred thousand irritants, and the thermal sense located in the nasal cavity and sensitive to varying levels of air temperature and relative humidity, providing that the air temperature is different from the mucosal temperature which is about 30–32 °C (Fig. 1). Some harmful pollutants such as radon or carbon monoxide cannot be sensed and quantified using sensory evaluations. Still, in majority of cases, the sensory effects may provide the first indication of possible adverse effects of exposures since the human senses have an important warning function against danger in the environment (Sowa 2020).

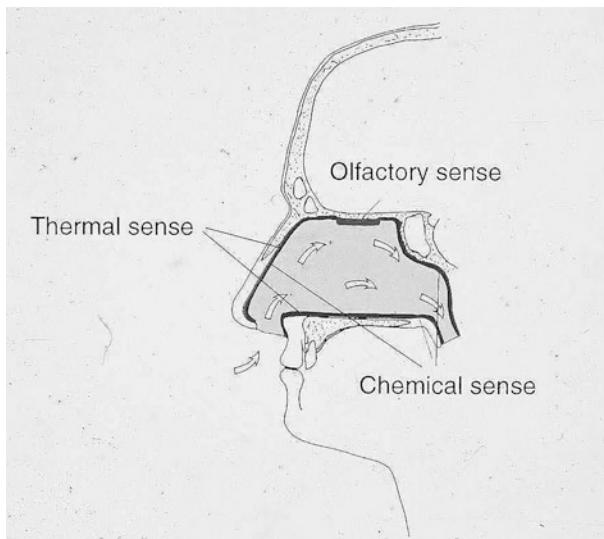

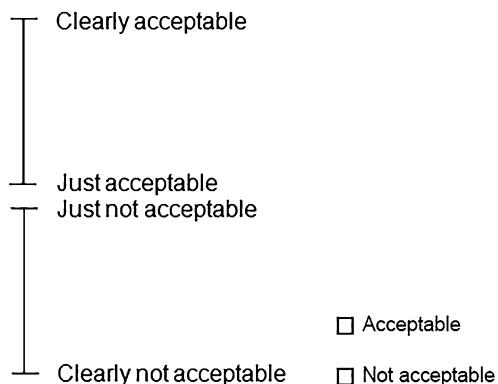

Fig. 1 Human nose

Sensory measurements of air quality using humans to assess air quality have been routinely used in air quality investigations since the 1990s. They have been used in laboratory experiments (Knudsen et al. 1998) and during field evaluations in existing buildings (Wargocki et al. 2004). Among many applications, sensory assessments have been used to characterize the emissions from building materials (ISO 16000-28 2012) and consequently have become a part of some labeling schemes defining requirements for emissions from building products (ECA 2005; Daumling et al. 2008). They have also been used when prescribing ventilation requirements indoors by specifying the maximum proportion of dissatisfied people with indoor air quality (ASHRAE Standard 62.1 2019; EN16798-1 2019). Recently, the developments have been in progress to use these methods to rate the air cleaners' performance as well (Olesen et al. 2021). Additionally, they are essential parameters when discussing the morphology of the models describing indoor air quality and indoor environmental quality (Licina and Langer 2021; Wargocki et al. 2021; Wei et al. 2020; Altomonte et al. 2020; Piasecki and Kostyrko 2019), and when the interactions between the parameters describing indoor air quality are described for the purpose of deriving the weighting coefficients depicting their importance when the overall indoor air quality and indoor environmental quality are determined (Frontczak and Wargocki 2011; Piasecki and Kostyrko 2020).

Measurements of Perceived Air Quality (PAQ)

Assessments of acceptability of air quality have been used to determine air quality as is perceived by building occupants and expressed by the percentage of satisfied or dissatisfied building occupants. Initially, in the case of assessments of acceptability of air quality, the dichotomous yes/no scale was used (Fanger and Berg-Munch 1983), Fig. 2. Later, it became more common to use a continuous acceptability scale (Gunnarsen and Fanger 1992) or its slightly modified version (Clausen 2000), Fig. 2. In addition to the methods described above in which people performing evaluations are not specially trained and only taught how to use the scales (and called

Fig. 2 The dichotomous (left) and continuous (right) scale used to assess the acceptability of air quality

subsequently untrained observers, subjects and panelists while their group untrained panel), it was common for a period to use specially trained people to perform sensory evaluations (a so-called trained observers, subjects and panelists and their group trained panel) using a well-defined reference exposure created from different levels of acetone (2-propanone) in the air (Bluyssen et al. 1989), Fig. 4.

Untrained Panels and Acceptability Scale

To assess the acceptability of air quality, a continuous visual analog scale is typically used by untrained human observers (Fig. 2). Observers are instructed to indicate whether the quality of air to which they are exposed is acceptable or not, and the degree of acceptability. To create the proper context for evaluations, the scale is usually preceded by the following sentence: "Imagine that you are exposed to this air during your daily work. How do you assess the air quality?". If the quality is assessed as acceptable, the observers mark the degree of acceptability on the upper part of the scale. If it is not acceptable, they mark the lower part of the scale. No additional instructions or training are given to the observers regarding the use of the scale; this is why they are called untrained observers (subjects) or untrained panelists. Observers usually receive written instructions concerning measurements and there should be at least one practice session before the actual measurements so that the observers become familiar with the measuring procedure. Assessments of acceptability of air quality are made immediately upon exposure to pollutants as the number of inhalations may cause olfactory fatigue (adaptation) and thus affect the sensory evaluations. Prior to the subsequent evaluation, observers take several inhalations of unpolluted air. Also, the temperature and relative humidity of the exposure can influence acceptability ratings. These parameters and other procedural aspects that can disturb sensory evaluations are discussed later.

The exposure can be partial (e.g., only nose or face being exposed to the air under evaluation) or full (when whole body is exposed to the air being assessed). The former is usually used in laboratory evaluations in which the assessments are typically made after just one inhalation of the air being evaluated, while the latter in the field measurements where observers render acceptability votes after entering a space and usually inhale more than once the air being evaluated. The described types of exposure may also affect the sensory evaluations and is discussed later.

All votes are rendered independently of other observers and without influence from a person conducting the measurements to avoid bias. The assessments are balanced for order of presentation and randomized to avoid systematic errors.

Using sensory assessments of the same exposure in a given environment made by a group of observers (a panel), mean votes of acceptability of air quality are usually calculated after the ratings made on the paper questionnaire are digitized at least twice in order to avoid gross errors; sometimes medians are used as well. Before doing so, the continuous acceptability scale is coded as follows: Clearly acceptable = 1; Just acceptable/Just not acceptable = 0; Clearly not

acceptable = -1 (Fig. 2). In the case dichotomous acceptability scale is used, it is coded as follows: Acceptable = 1; Not acceptable = 0 (Fig. 2).

Single ratings made by each observer in a group are used for calculating the group mean vote of acceptability characterizing indoor air quality in a given environment as shown in Eq. (1):

$$\text{ACC} = \frac{\sum_{i=1}^{i=N} (\text{ACC})_i}{N} \quad (1)$$

where

ACC = average vote of acceptability of air quality

ACC_i = acceptability vote by the observer

N = number of observers

The accuracy of evaluations is expressed by an experimental standard deviation (or standard error, SE) of the average of the N votes of acceptability (Eq. 2):

$$\text{SE} = \frac{\text{SD}_{\text{average}}}{\sqrt{N}} \quad (2)$$

where

SE = experimental standard deviation of the average of the N votes of acceptability scores

$\text{SD}_{\text{average}}$ = experimental standard deviation of individual observations

N = number of observers

Using mean acceptability ratings, the percentage dissatisfied with the air quality can be calculated (Gunnarsen and Fanger 1992) as follows:

$$\text{PD} = \frac{\exp(-0.18 - 5.28 \cdot \text{ACC})}{1 + \exp(-0.18 - 5.28 \cdot \text{ACC})} \cdot 100 \quad (3)$$

where

PD = percentage dissatisfied with the indoor air quality, %

ACC = average vote of acceptability

The relationship presented in Eq. (3) is typically used to determine the percentage of people dissatisfied with air quality; Figure 3 presents also other attempts, where the relationships between the ratings of acceptability of air quality and the percentage of dissatisfied were created. They deviate slightly especially at the levels below 50-60% dissatisfied.

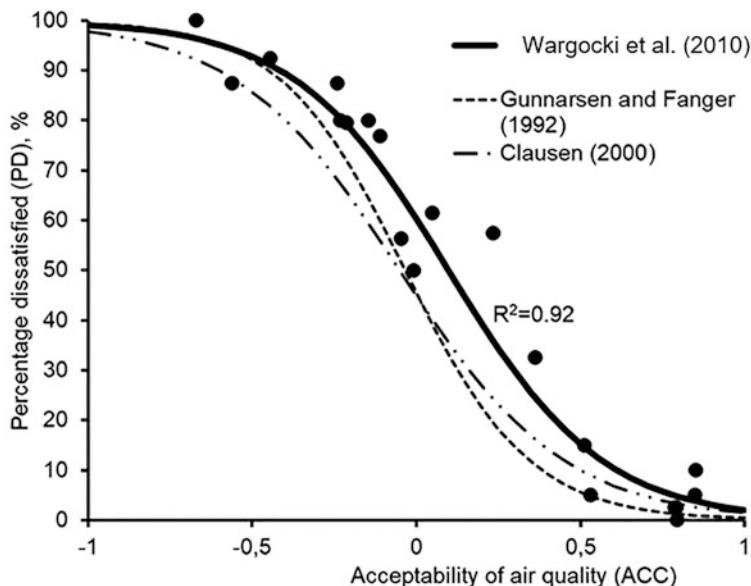

Fig. 3 Percentage of dissatisfied with air quality as a function of acceptability of air quality. To determine PD, the assessments of acceptability on a dichotomous scale (Fig. 2) were collected, while to determine acceptability levels the continuous acceptability scale was used to ensure that the votes on both axes are independent. Dashed line shows the relationship of Gunnarsen and Fanger (1992) (equation (3)), dashed-dotted line of Clausen (2000) and the thick continuous line show the relationship developed by Wargocki et al. (2009, 2010)

Trained Panels and Decipol Scale

To reduce the number of observers and, at the same time, the cost of the measurements without reducing accuracy of sensory evaluations, the measurements of perceived air quality with trained observers (panelists) have been proposed and adopted. Usually, 10–15 trained observers (panelists) are selected to perform these measurements. Unlike untrained observers rendering the assessments on an acceptability scale, as described above, trained observers assess the air quality directly in decipol. Decipol is a unit describing the perceived air quality as defined by Fanger et al. (1988): One decipol is the pollution caused by one standard person (one olf), ventilated by 10 l/s of unpolluted air. The relationship between decipol and the percentage of dissatisfied is expressed by the following equation:

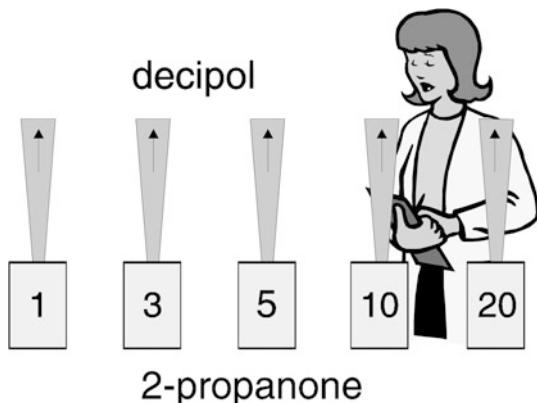

$$\text{PAQ} = 112 \cdot [\ln(\text{PD}) - 5.98]^{-4} \quad (4)$$

where

PAQ = perceived air quality, decipol

PD = percentage dissatisfied with the air quality, %

Fig. 4 The principle of measurement of perceived air quality using trained observers (panelists)

Trained panels performing sensory evaluations in decipol use the reference exposures of 2-propanone (acetone). The different levels of 2-propanone are used to reproduce perceived air quality levels in decipol (Fig. 4) according to the relationship of Bluysen et al. (1989), as shown in the following equation (5). Usually, five reference levels are used corresponding to 1, 3, 5, 10 and 20 decipols (see Fig. 4):

$$\text{PAQ} = 0.84 + 0.22 \cdot C \quad (5)$$

where

PAQ = perceived air quality, decipol

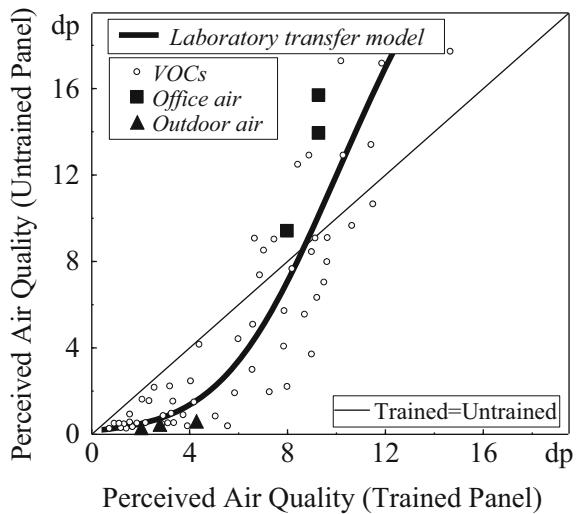

C = concentration of 2-propanone (acetone) over background level, ppm

The method using trained observers (panelists) to assess air quality is similar to the odor equal-intensity matching described later.

Comparison of Assessments Made by Trained and Untrained Panels

In theory, the ratings using the acceptability scale and decipol should not be different because they use the same underlying theory (Fanger 1988). However, deviations between the two measuring methods have been observed (Spiess and Fitzner 1999; Wargocki and Fanger 1999). To accommodate these differences, the relationship was developed between the sensory ratings performed by the trained subjects in decipol using the reference scale made of 2-propanone (acetone) and untrained observers (panelists) using the acceptability scale after they were converted to decipol. Figure 5 shows this relationship indicating that at low decipol levels corresponding to low concentrations of air pollutants, when untrained observers (panelists) assess the air quality to be good, their trained counterparts rate the quality of the same air to be worse; the reverse is observed at high concentrations of air pollutants.

Fig. 5 Panelists' reliability characteristics in the sensory analysis showing the ratings of perceived air quality made by trained and untrained subjects (Wargocki and Fanger 1999)

To adjust for this systematic difference, the transfer function (equation 6) was developed by Wargocki and Fanger (1999); the function is valid at levels below 16 decipols:

$$ACC = 2.7 - 2.3 \cdot \log(PAQ_{TR} + 7.4) \quad (6)$$

where

ACC = mean vote of acceptability of air quality by untrained observers

PAQ_{TR} = perceived air quality in decipol assessed by trained observers, using 2-propanone (acetone) as a reference gas

Applications – Estimation of Sensory Pollution Load

Measurements of perceived air quality can be used to estimate a sensory pollution load defined as the equivalent number of standard persons (called olfs) required to cause the same percentage of dissatisfied observers with the air quality as is the percentage dissatisfied caused by the actual pollution source (Fanger 1988):

$$G = 0.1 \cdot (PAQ_i - PAQ_o) \cdot Q \cdot \varepsilon_V \quad (7)$$

where

G = sensory pollution load (expressed as pollution caused by the equivalent number of standard persons), olf

Q = outdoor air supply rate (ventilation rate), L/s

PAQ_i = perceived indoor air quality, decipol

PAQ_o = perceived outdoor air quality, decipol

ε_v = ventilation effectiveness

Measurements of Odor Intensity

The Weber-Fechner law states that the change in a stimulus (perceived intensity of an odor) that will be just noticeable is a constant ratio of the original stimulus (perceived intensity of an threshold odor). Therefore intensity as a measure of the strength of the odor stimulus can be related to odor concentration.

Odor intensity can be measured using different scales. Figure 6 shows two examples of such scales: the category odor intensity scale used by Yaglou et al. (1936) and the category ratio scale CR10 developed by Borg and Borg (2001). The two scales use very similar descriptors of odor intensity. The difference is that the CR10 scale follows the psychophysical function that describes the relationship between the strength of the stimulus and the response.

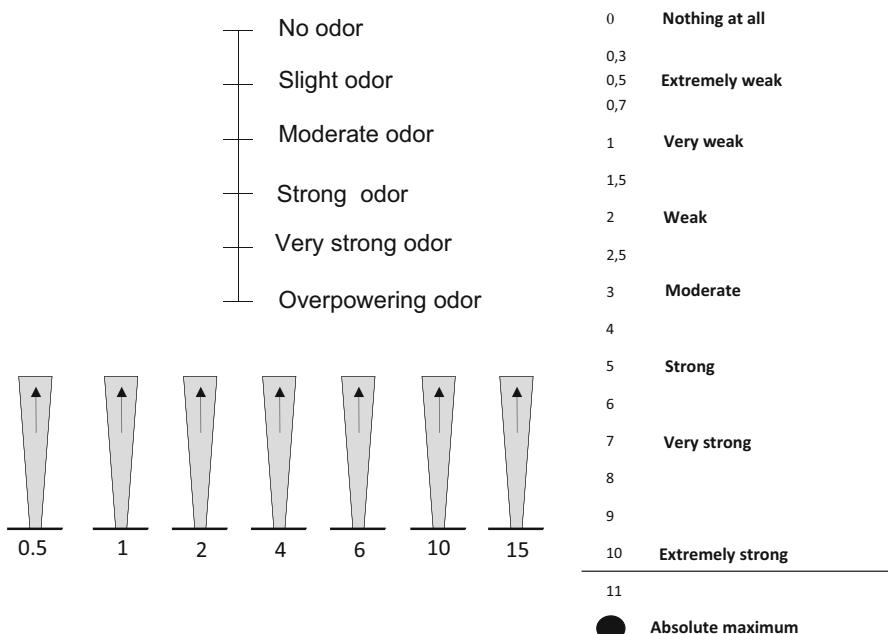

Fig. 6 Three different scales used to assess odor intensity. Top left – category odor intensity scale (Yaglou et al. 1936); the ratings on the scale are coded as follows: No odor = 0; Slight odor = 1; Moderate odor = 2; Strong odor = 3; Very strong odor = 4; Overpowering odor = 5. Right: Category–ratio scale, CR10 scale (Borg and Borg 2001). Bottom left – equal-intensity matching scale with acetone as a reference (Müller et al. 2005) where 0 corresponds to an odor intensity produced by acetone at a concentration of 20 mg/m^3 (odor detection threshold of acetone), 1 corresponds to an odor intensity produced by acetone at 40 mg/m^3 , 2 corresponds to an odor intensity produced by acetone at 60 mg/m^3 , and so on

Another method for assessing odor intensity being an extension of trained panel assessments is the method of equal-intensity matching with acetone as a reference proposed by Müller et al. (2005) (Fig. 6). The method uses the same approach as in the case of measurements with trained panels but uses the unit PI, perceived intensity, (Π) to express the sensory impact. According to the PI definition, the lower limit of the equal-intensity matching acetone scale, i.e., its zero value, is determined by the odor detection threshold of acetone (2-propanone). The tests performed with the dynamic and static olfactometer have shown that the average value of the acetone detection threshold in the air is approximately 20 mg/m^3 (it is in the range of $15\text{--}35 \text{ mg/m}^3$ in the so-called standardized olfactory thresholds, e.g., Devos et al. (1990)). The equal-intensity matching with acetone and PI unit are included in the ISO Standard 16000-28 (2012) and are the part of building material emission testing in Germany (AgBB 2005).

Figure 7 shows the relationship between different odor intensity scales indicating strong correlations between different odor intensity scales suggesting that they can be used interchangeably.

The relationship between the sensory ratings made using the acceptability scale and different odor intensity scales is shown in Fig. 8 (Wargocki et al. 2009, 2010). The figure shows that acceptability ratings of air quality are strongly linearly correlated with the ratings of odor intensity regardless of the type of scale and independently of the type of exposure (the dots represent air polluted by different building materials at different exposure/concentration levels).

As a result of the relationship presented in Fig. 8, Fig. 9 was developed (Wargocki et al. 2009, 2010). It shows the relationship between perceived air quality expressed as the percentage of dissatisfied and odor intensity (on the category scale). It can be observed that moderate odor intensity ($OI = 2$) corresponds to about 50% dissatisfied; moderate odor intensity level was used by Yaglou et al. (1936) to determine ventilation requirements in spaces occupied by people. It should be noted that the relationship

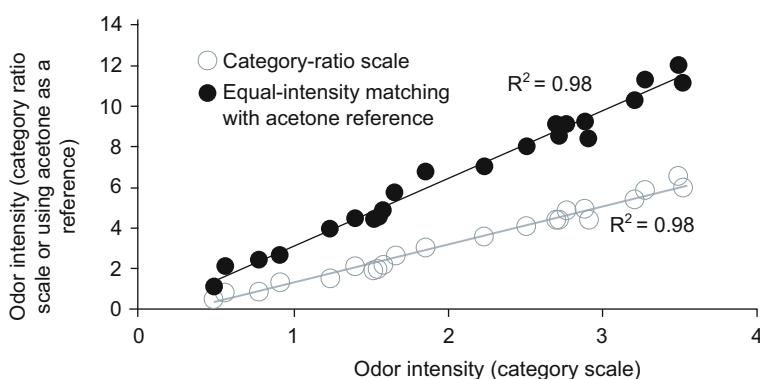

Fig. 7 Odor intensity assessed using a category-ratio scale and equal-intensity matching with a reference gas of acetone as a function of odor intensity assessed using a category scale (Wargocki et al. 2009, 2010). The coding of the scales is presented in Fig. 6

presented in Fig. 9 was developed by exposing people to emissions from building materials, whereas Yaglou et al. (1936) exposed people to emissions from humans (bioeffluents).

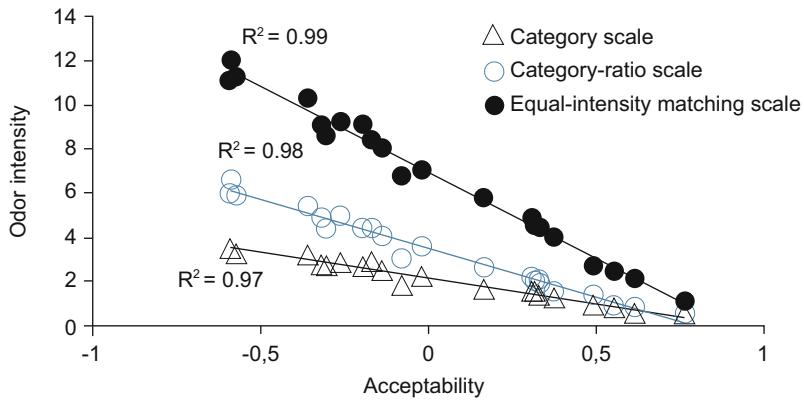

Fig. 8 Odor intensity assessed using a category scale, category-ratio scale, and equal-intensity matching scale with a reference gas of acetone as a function of the assessments of the acceptability of air quality (Wargocki et al. 2009, 2010). The coding of the scales is shown in Fig. 6

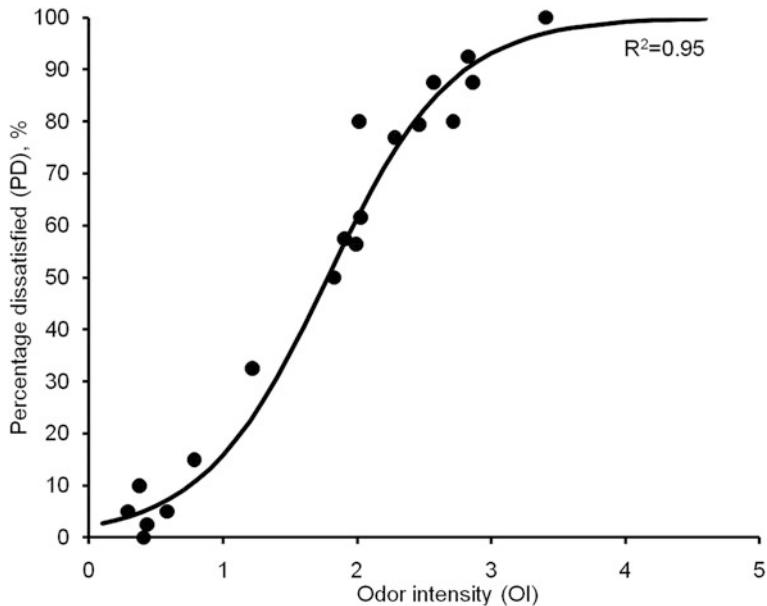

Fig. 9 Percentage of dissatisfied with air quality (estimated using assessments of acceptability on a dichotomous scale) as a function of odor intensity (Wargocki et al. 2009, 2010). The coding of the scale is shown in Fig. 6

Applications – Odor Persistency

Odor persistency was proposed to define how easy it is to remove the odor by reducing its concentration when, e.g., ventilation is applied. It is assumed that the less persistent the smell, the easier it is to remove it from the room. Dravnieks and Jarke (1980) developed the method of determining odor persistency using n-butanol as the standard; the method is recommended by the ASTM E544-99(2004) standard.

Odor persistency (m) describes how odor intensity decreases as the odorous pollutants are diluted (Fig. 10). Odor intensity is related to the odor concentration (dilution ratio) by the power law (Steven's law):

$$I = kC^n \quad (8)$$

where

I is the odor intensity

C is the dilution ratio

k and n are constants for each odor sample

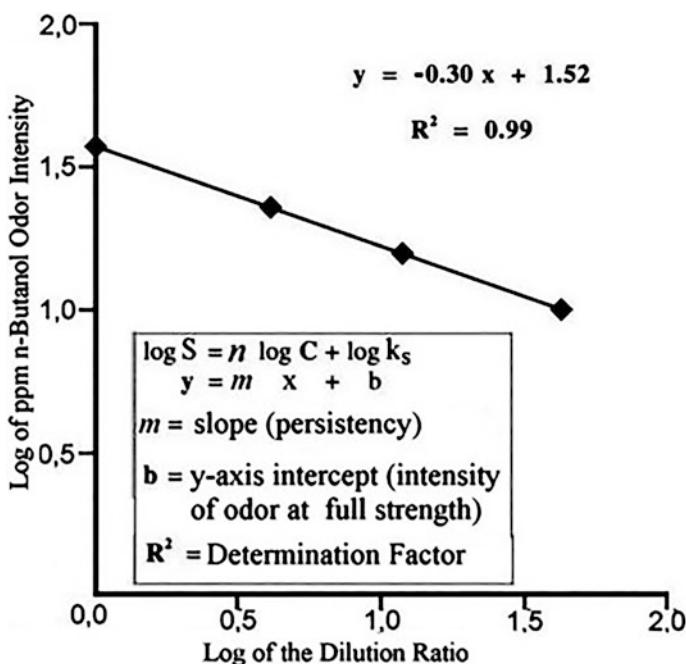

Fig. 10 An example showing how odor persistency in a room can be calculated. With an initial dilution factor of an odorant in the air equal to 0 (characterized by the logarithm of the odor intensity S and expressed in the mixing ratio of n-butanol in air in ppm equal to 1.52), the odorant had to be diluted 1.7 times (by ventilation), yielding the mixing ratio of n-butanol in air at 1.01 ppm as a result. The odor persistency was determined from the slope (m) of the curve. The example is taken from (McGinley and McGinley 2000)

The logarithmic transformation can transform the power law into a straight line as is indicated in Fig. 10:

$$\log I = n \log C + \log k \quad (9)$$

Procedural Aspects of Sensory Measurements of Perceived Air Quality

Many procedural details need to be considered during sensory measurements because many factors can influence sensory ratings. Some of these factors include temperature and relative humidity of inhaled (sniffed) air (Fang et al. 1998a), adaptation (Gunnarsen and Fanger 1992; Clausen 2000; Knudsen et al. 2004), the air speed in the facial region (Melikov and Kaczmarczyk 2008), and whether only face (facial exposure) or the entire body (the whole-body exposure) are exposed to the air that is being assessed (Knudsen et al. 1993; Fang et al. 1998b; Clausen 2000). Procedural details involve, among others, how many inhalations (sniffs) of the assessed air should be taken before the assessment is rendered and whether observers (panelists) are aware of the exposure being assessed, i.e. whether information about the exposure is given. The latter was investigated by Wilkins et al. (2007); they informed the subjects about exposures by placing a written label where the assessments were performed. It was also examined by Moschandreas and Relwani's (1992) where, the subjects could or could not see the cigarettes' smoking during sensory assessments. Besides, no studies have been conducted to examine whether sensory ratings are affected when subjects can see sources creating the exposure so no firm conclusions on this aspect can be drawn. Finally, an important methodological aspect is how many persons are selected and using which selection (inclusion) criteria when the persons are selected for the sensory panels to perform the ratings of perceived air quality.

Selection of Human Observers (Panelists) for Sensory Measurements

The selection of human observers performing sensory evaluations of air quality can bias the results of measurements of perceived air quality and therefore must follow the specific rules. At best, the observers from the relevant population for which the measurements are addressed should be selected. This approach may however be difficult to achieve in practice. A rational compromise is to select observers of a similar age, as age has been shown to have a considerable impact on olfaction. Selection criteria should additionally ensure the inclusion of nonsmokers, subjects with no asthma, allergy, or other hypersensitivities, no sensory handicaps (e.g., hearing impairment), and generally people in a good health condition (taking no regular medication or not suffering from the upper airway or respiratory infections); people with asthma and allergy could be included but their number should reflect the

proportion in the population, it must though be ensured that the sensory evaluations do not elicit allergic symptoms. The information necessary during the selection process can be collected by interviewing the potential subjects or through self-reports on the specially prepared questionnaires. In a short interview prior to selection, the attitude of people who are being selected toward the measurements, their motivation, and personal hygiene should be evaluated. Those whose personal hygiene could influence the measurements and whose motivation is poor should be excluded.

The olfactory sensitivity of observers should be documented. This, for example, can be done by exposing the observers to reference stimuli. In such case, the observers can take olfactory tests comprising a ranking test with n-butanol at four concentrations: 10, 80, 320, and 1280 ppm (vol./vol.) and a matching test with n-butanol, 2-butoxyethanol, and 2-butanone, each compound being at a concentration of 640 ppm (vol./vol.) and a “blank” exposure with no chemical compound according to ISO 8587 (1988) and ISO 8586-1 (1993). The former evaluates the ability of people to classify different odor intensities of the same substance, and the latter the capacity of people to identify several odorous stimuli. A questionnaire with a chemical sensitivity scale (CSS) can additionally be used to characterize further the sensory panel; it examines the experience with and exposure to odors and sensory irritants, and compares with the data for general population (Nordin et al. 2003, 2004). Other methods can be found later in the present chapter (EN 13725 2003; Kosmider, 2008).

The number of observers evaluating the air quality considerably affects the accuracy of measurements. This is because of considerable variation in ratings of acceptability of air quality among individuals due to variation in chemosensory sensitivity and an influence of other variables such as personality, preference, mood, and prior experience with different odors and exposures to pollutants. The standard deviation of the acceptability ratings is usually between 0.3 and 0.6 (Gunnarsen and Bluyssen 1994; Knudsen et al. 1998). Increasing the number of observers above 30–50 people has consequently a small effect on accuracy (Fig. 11). At the same time, increasing the number of observers causes logistic problems and increases the cost of the measurements, especially when they are conducted in the field. Considering the above reasoning, 30–40 observers are usually selected (Wargocki, 2004).

Adaptation

Human senses exhibit a reduction in sensitivity with the duration of exposure when the air is polluted by odors (adaptation), while the increase in the intensity of response with the duration of exposure when the air is polluted by irritants. Gunnarsen and Fanger (1992) observed considerable adaptation when human bioeffluents were the pollution source, probably due to bioeffluents comprising mainly odors, moderate adaptation when tobacco smoke was the source, and almost no adaptation when the air was polluted by building materials, as the last two sources probably also included many irritants. They observed that adaptation occurred within the first 6 minutes of exposure, while in the work of Jørgensen and

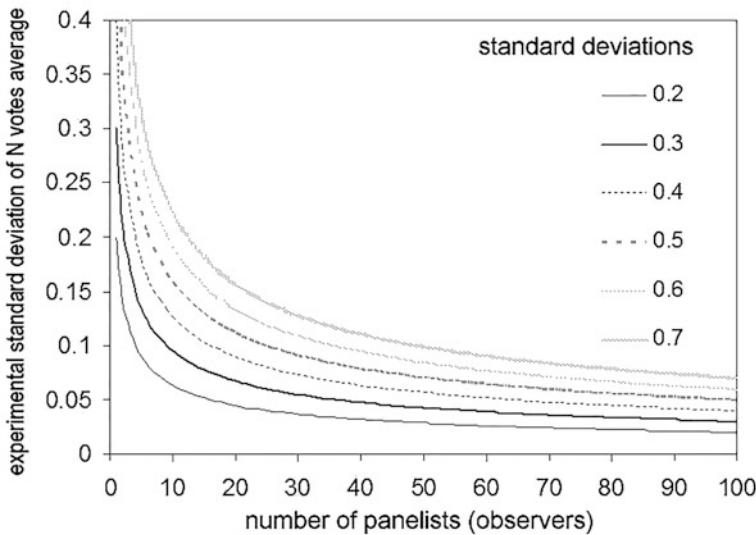

Fig. 11 The relationship between the size of the panel assessing air quality using the continuous acceptability scale and the experimental standard deviation of the average vote made by the observers (panelists); the dependence was calculated for different values of the standard deviation of individual assessments of the observers. As indicated in the text, increasing the number of observers above 40 has very little effect on the experimental standard deviation independently of standard deviation. The relationship is from (Berglund et al. 2010)

Vestergaard (1998) cited by Clausen (2000), the strong adaptation to indoor air polluted by typical building materials occurred already in the course of the first seven inspirations, corresponding to an exposure of about 24 seconds (Fig. 12).

Since it is often challenging to conduct measurements in which observers take only one breath when rendering the air quality assessment, especially in field measurements, some sensory adaptation would always be present when the measurements of perceived air quality are made. Consequently, to make it possible to compare the results of different indoor air quality measurements, the exposure time during assessment should be standardized. It can be done in the laboratory measurements by allowing subjects always to take the same number of inhalations of polluted air (preferably one) when assessing the air quality. In the case of field measurements, the exposure time can be standardized by having the subjects walk a similar distance prior to assessing air quality after preferably one inhalation. To further reduce systematic errors, the assessments can be repeated.

Impact of Temperature and Relative Humidity

Assessments of perceived air quality using an acceptability scale are strongly affected by the air's temperature and relative humidity, while their impact on the assessments of

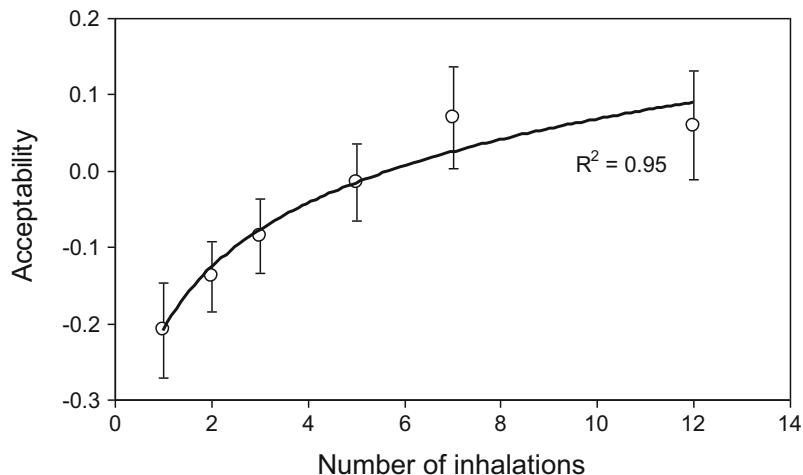

Fig. 12 Assessment of indoor air quality as a function of the number of inhalations; error bars indicate the standard deviation of individual assessments of the observer (Clausen 2000). The coding of the scale is shown in Fig. 2

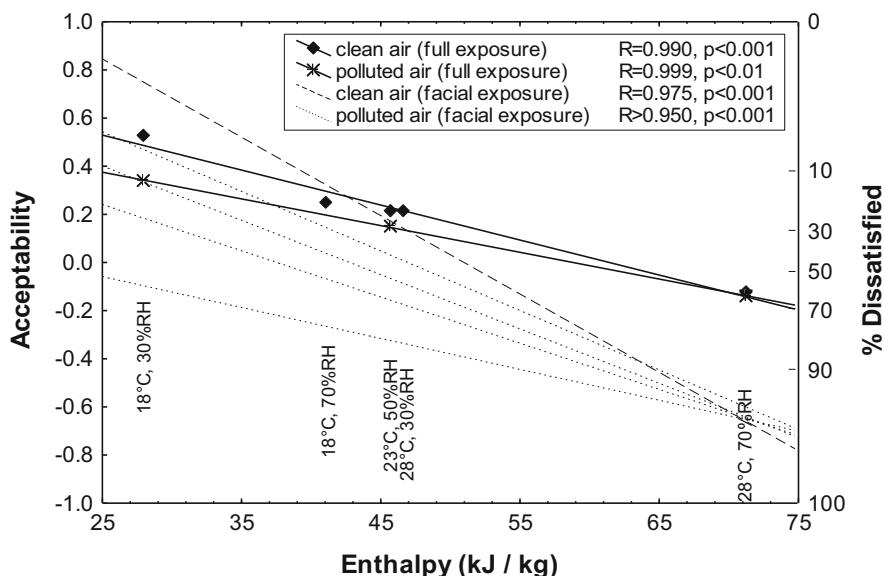

Fig. 13 The impact of temperature and relative humidity on perceived air quality evaluated using acceptability scale; the figure is from Fang et al. (1998a, b)

odor intensity is less pronounced (Berglund and Cain 1989; Fang et al. 1998a; Toftum et al. 1998). Figure 13 illustrates the effects of temperature and relative humidity on acceptability ratings (Fang et al., 1998a, b) where temperature and relative humidity

are expressed as enthalpy of air Fig. 13 shows that the effect depends on the type of exposure - facial (when the only face is exposed) and whole body (when the assessments are made by entering the space); the effect is stronger for the former.

It should be noted that the relationships presented in Fig. 13 intersect at the same enthalpy for either the facial or whole-body exposure. This result may suggest the underlying mechanism which is surmised to be the cooling of the nasal mucosa (see Fig. 1) decreasing with increasing enthalpy of air.

Fang et al. (1998a, b) developed models allowing conversion of the acceptability assessments at different temperatures and relative humidities of air (expressed as enthalpy) performed using facial (Eq. 10) and whole-body (Eq. 11) exposures to the reference conditions of 23 °C and 50% RH (enthalpy of 45.39 kJ/kg):

$$\text{ACC} = \text{ACC}_0 - 0.0247 \cdot (E - E_0) - 0.0416 \cdot \text{ACC}_0 \cdot (E - E_0) \quad (10)$$

$$\text{ACC} = \text{ACC}_0 - 0.00416 \cdot (E - E_0) - 0.0416 \cdot \text{ACC}_0 \cdot (E - E_0) \quad (11)$$

where

ACC = acceptability of air quality at any enthalpy in the range between 18°C/30% RH to 28°C/70%RH

ACC_0 = acceptability of air quality at the reference condition (enthalpy E_0)

E = enthalpy (kJ/kg) of the air at which the assessments of acceptability (ACC) were made

E_0 = enthalpy of air at the reference conditions set to 23 °C and 50%RH and thus the resulting enthalpy of 45.39 kJ/kg

Equation (10) can only be applied for the assessments of acceptability higher than -0.6 , and Eq. (11) for the ratings higher than -0.1 . Other reference conditions than 23°C and 45%RH can be selected; in such the case, the coefficients in Eqs. (10) and (11) need to be recalculated (Bluyssen et al. 1996; Spiess and Fitzner 1999).

Piasecki et al. (2020) studied the impact on sensory discomfort (expressed as percentage of dissatisfied with air quality, PD) at air humidity from 60% to 90%RH and temperature from 26°C to 28°C (Fig. 14). They observed that the impact of humidity on the dissatisfaction in a warm and humid indoor environment is higher than that indicated in the thermal comfort model (Fanger 1970). They proposed an experimental relationship to be used in environments with a high enthalpy of humid air in which Fanger's comfort model begins to show lower dissatisfaction than the experimental results, thus suggesting that a separate element should be included in the model to describe dissatisfaction.

Roelofsen (2016) analyzed the impact of the air temperature and relative humidity on perceived air quality and proposed the relationship between the freshness of the air polluted by human bioeffluents and its temperature and humidity. Similarly to the study of Piasecki et al. (2020) and Fang et al. (1998a, b), he strongly emphasized the need to account for dissatisfaction caused by reduced perceived air quality due to

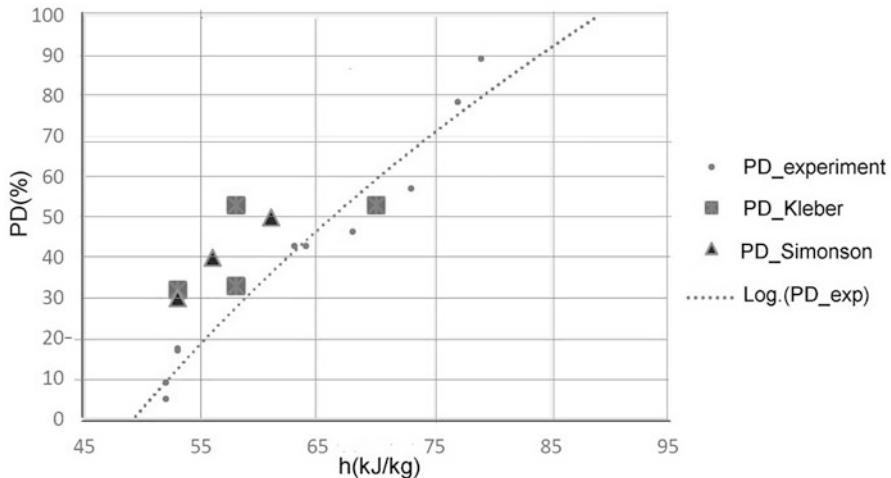

Fig. 14 Comparison of the experimental results of Piasecki et al. (2020) with the former similar research by Kleber and Wagner (2018) and Simonson (2000) showing the percentage of dissatisfied (PD) in hot and humid environments; PD is percentage dissatisfied and h is enthalpy of hot and humid air.

increased temperature and relative humidity of air when designing buildings and indoor space, rather than using the requirements only to avoid thermal discomfort.

To account for moisture balance of the nasal mucosa in sensory ratings, Roelofsen (2018), based on the published results, proposed the following model where freshness of air is expressed on a seven-point scale from 0 to 6 (Fanger et al., 1988; Berglund and Cain, 1989); the model accounts for the heat transfer in the nose:

$$F = a + b \cdot (\text{ta}_{\text{nasal mucosa}} - \text{ta}) + c \cdot (\text{pa}_{\text{nasal mucosa}} - 0.01 \cdot \text{pa}) + d \cdot 10 \cdot G / (V \cdot \varepsilon_v) \quad (12)$$

where

F = freshness of the air, according to a seven-point continuous linear scale

ta = air temperature ($^{\circ}\text{C}$)

$\text{ta}_{\text{nasal mucosa}}$ = mean temperature of the nasal mucosa surface ($^{\circ}\text{C}$)

$\text{pa}_{\text{nasal mucosa}}$ = mean vapor pressure at the nasal mucosa surface (Pa)

pa = vapor pressure of the air (Pa)

G = sensory pollution load (olf) at different metabolism expressed as

$$G = 0.985 \cdot M^{1.299} \quad (13)$$

M = metabolic rate (met)

V = outdoor air supply rate (L/s)

ε_v = ventilation-effectiveness, according to CR 1752 (1998)

$a - d$: regression coefficients(–)

Quantification of Odor Pollution Sources in Buildings

Nonsensory Analysis of Odorant Concentration in the Air

Nonsensory analysis methods are described in EPA Method TO-17 (1999), and a scientific monograph by Kostyrko and Wargocki (2014), as well as other chapters in the present Handbook. In these methods, a known volume of air (a sample for subsequent analysis) is taken from the room by aspiration through one (or several) sorption tubes containing, e.g., Tenax® TA sorbent, placed in the air of the volume where IAQ is tested. Volatile organic compounds (VOCs) are retained on the sorbent filling of the sorption tube connected to the suction pump. After sampling, the tubes are transported to the laboratory for analysis where they are analyzed. If possible, the analysis is made within 4 weeks; more extended storage is possible if properly conditioned (EN ISO 16000-5 2007). Further description of the measurements of VOCs can be found in the present Handbook in ► Chap. 3, “[Volatile Organic Compounds \(VOCs\)](#),” by Huang (2022). The GC-MS analysis method is also described in detail in ISO 16000-6 (2004). The sampling and analysis strategy described in EN ISO 16017-1 (2002) and EN ISO 16017-2 (2003) cover a wide range of VOC including aromatic hydrocarbons, chlorinated hydrocarbons, esters and ethers, glycols, ketones, and alcohols, among which there are many aromatic compounds (Massold et al. 2005).

Measured concentrations of organic pollutants can be compared against their odor thresholds (if available) by dividing the concentration by the odor threshold. Such derived ratios are summed up to determine whether their sum is below one; if higher it is likely that the mixture can produce perceptible odor (Salis et al. 2017). However, the VOCs (e.g., mVOCs derived from metabolic transformations of biological impurities (Kostyrko and Kozicki 2018; Liu et al. 2018) having exceptionally low odor thresholds can be overlooked in this method. Generally, past experience shows that it is a good approximation that VOCs having extremely low odor thresholds will dominate the odor perception, thus even when the sum of derived ratios is lower than one the mixture can be perceptible.

With regard to odor detection thresholds, the newest published measurements should be used, e.g., Nagata and Takeuchi (2003), since older work such as those by Devos et al. (1990) and therein may not provide an accurate estimation of the detection threshold - they can provide odor detection thresholds a few orders of magnitudes higher. The work of Abraham et al. (2002) and Cain and Cometto-Muniz (1995) can also be considered when determining odor thresholds of individual compounds and their mixtures (Cometto-Muñiz et al. 1997, 2004). Methods of analysis of air pollution with odorants should be further developed considering more precise analyses and a broader range of odorants.

Gas Chromatography-Olfactometry-Mass Spectrometry (GC-O-MS)

Gas chromatography-olfactometry-mass spectrometry (GC-O-MS) is a combination of gas chromatography-olfactometry (GC-O) and gas chromatography-mass spectrometry (GC-MS). Gas chromatography-olfactometry (GC-O) is a method combining the information supplied by chemical characterization and by odor perception. A panelist (an observer) sniffs the gas, and every time he/she sniffs an odorous substance, a sensorial response in terms of presence and type of odor is marked on the chromatogram.

In the environmental analysis, particularly in the analysis of air content odorants, the most important advantages of the GC-O-MS include much better-resolving power and higher sensitivity than the classical chromatography.

The primary device in the method is a modified gas chromatograph so that the “Y” divider is located at the end of the chromatography column to which the detector is connected (e.g., FID) on the one end of the “Y” divider and the olfactometer with the odor port on the other one (Fig. 15). A sample of the odorous gas is split into two streams, one of which is directed to the olfactometer. Before presenting it to a panelist, it is first mixed with moist air (to avoid discomfort during assessments) and then passes through a heated pipe. During analysis, a panelist indicates when the odor is perceived. At the same time the compound can be detected with the detector included in the GC. As a result of the analysis, an aromagram is obtained presenting olfactory peaks (Fig. 15).

In the measurement system where mixtures are analyzed with a GC chromatograph, substances, including odorants, leave the GC column separately. As the entire mixture is not analyzed at any given moment as a whole, individual chemical compounds can be detected, which allows the detection of odorants individually (Cai et al. 2007; Kozicki 2022) but not the entire mixture as a whole.

GC-O-MS was used in applications regarding pollution sources in buildings, e.g., to detect pollutants emitted from linoleum (Jensen et al. 1995).

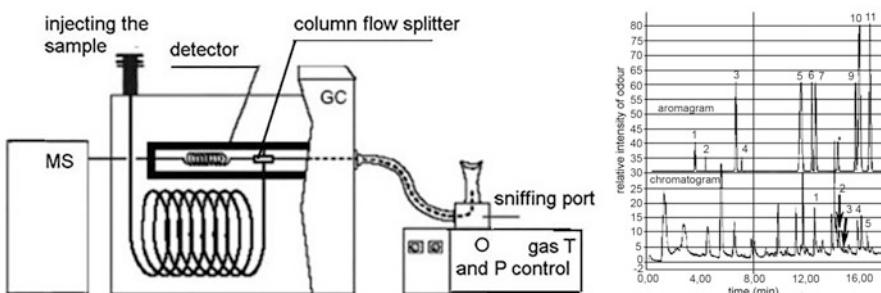

Fig. 15 GC-O-MS: apparatus (left) and the method of presenting the results on a mass spectrometer-chromatogram-aromagram (from Zhang et al. 2010) (right)

Olfactometry

Olfactometry is the principal tool for measuring odor characteristics. An olfactometer is designed to dilute the odorous gas samples and present these dilutions to the sensory panel. After obtaining their responses, a statistical treatment of the data permits the olfactometric result to be calculated.

The olfactometry method was born in the 1960s in the USA but developed and introduced into the regulations as dynamic olfactometry only in 1979 when described in the ASTM E 679-79 (1979) standard replaced by the ASTM E 544-2004 (2004). In Europe, due to the economic importance of odor nuisance, the international research program on Interlaboratory Comparison of Olfactometry (ICO) was carried out in 2002–2003 to compare the results obtained in various research laboratories, and run continuously ever since (Maxeiner 2005). As a result of this undertaking, the EN13725 (2003) standard was created concerning the determination of the odor concentration by the dynamic olfactometry method. The standard was established to provide a common basis for assessing odorant emissions in the European Union Member States and is used to evaluate odorant emissions released from point and surface sources.

The physical quantity measured by olfactometry is the odor concentration c_{od} , which defines the “distance” of c , the odorant concentration in air, from the odorant threshold concentration c_{th} . It is a dimensionless number determining the physical intensity of the odor. The odor concentration c_{od} expresses the ratio of $c[\mu\text{g}_{\text{odorant}}/\text{m}^3_{\text{air}}]$, the actual odorant concentration in the air, to $c_{\text{th}}[\mu\text{g}_{\text{odorant}}/\text{m}^3_{\text{air}}]$, the concentration at the level of the odor threshold, and denotes the degree to which the odorant had to be diluted (in fragrant gas) to reach the threshold when it can be perceived:

$$c_{\text{od}} = c/c_{\text{th}} \quad (14)$$

For convenience, both concerning single odorants and their mixtures, the concept of the odor unit (ou) was introduced with the following definition:

The odor concentration is the number of units of odors in 1 m^3 of gas under standard conditions.

One ou/m^3 equals 40 ppbv n-butanol. Odor concentration, c_{od} in ou_E/m^3 , expressed as the number of European odor units in 1 m^3 of gas under standard conditions, is determined by the **EROM** reference standard (European Reference Odor Mass). The dilution factor at the panel threshold $\bar{Z}_{\text{ITE,pan}}$ denotes the dilution factor (degree) at the 50% detection threshold and is multiplied by the unit $1 \text{ ou}_E/\text{m}^3$

$$c_{\text{od}} = \bar{Z}_{\text{ITE,pan}} \times 1 \text{ ou}_E/\text{m}^3 \quad (15)$$

where $\bar{Z}_{\text{ITE,pan}}$ is the geometric mean of dilution ratio values Z_{ITE} of all valid panel members in one measurement after the retrospective screening. It is also the

numerical result of odor concentration measurement with the dynamic olfactometer according to EN 13725-03 (2003).

The dilution factor at the panel threshold $\bar{Z}_{ITE,pan}$ is the dilution factor applied to the sample to arrive at the physiological response of the panel that is equivalent to that for 1 ou_E/m³. This dilution factor is the nominal value of the odor concentration of the examined sample c_{od} in ou_E/m³.

Olfactometric analyses are tested in the laboratory (EN 13725-03 2003 and ASTM E544-04 2004) or in the field, during which the odor samples are gathered and then exposed to the target population in the study area. The main advantage of olfactometry is the direct correlation between the odor and the detector's sensitivity where the detector is human nose.

Olfactometry Analysis for Determining the Odorant Detection Threshold (Test D)

The “triangle” differential test described in the standard ISO 13301 (2002) is the widely used classical method to determine the odor detection threshold. Standard ISO 13301 (2002) describes the “triangle test” method in the forced-choice version, which is called the “three-alternative forced-choice (3-AFC) procedure.” In the terminology of psychophysical tests (Lötsch et al. 2008), the method is called a sensory discrimination test (Test D – Discrimination).

The triangle bag method is often used (Ueno et al. 2008), involving a specific order of presenting the samples with odors:

- Creating a selected assessment team (panel) of at least six people (panelists)
- Presenting to each panel three bags, including two with a different gas (e.g., clean air) and one with a diluted sample of the tested odorant with a known odorant concentration; each of the panelists judges in which bag the smell differs from the other two bags; the presentation of samples of the tested odor is continued, increasingly diluted with a dilution step of three, until the panelists give erroneous answers
- Calculating the individual odor detection threshold for each panelist as the geometric mean of the two values – the sample dilution value that was correctly recognized last and the dilution value of the sample that was misidentified first
- Calculating the detection threshold of the tested odorant as the geometric mean value of the individual detection thresholds of all panelists

Dynamic Olfactometry – Analysis of Odor Concentration

A dynamic olfactometer is an apparatus in which a sample of an odoriferous gas (fragrant air) is gradually diluted with an odorless gas in a specific Z ratio and presented to a team of odor panelists for assessment through the outlet delivering successively streams of odorous and odorless gas, i.e., clean air (Fig. 16). Dynamic

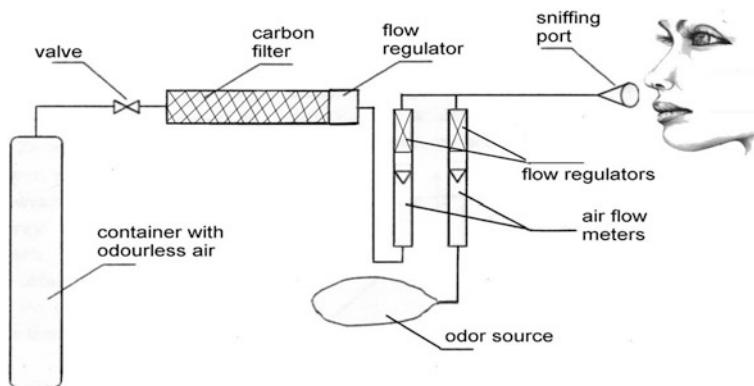

Fig. 16 Principle of diluting a sample of an odoriferous gas with odorless air for the determination of the odor concentration in a dynamic olfactometer

olfactometry includes the analysis of the olfactory stimulus using panelists' ratings against the setting of the Z dilution rate on a dynamic olfactometer.

In the method, samples are diluted with clean air and then connected to an olfactometer. A panel (composed of trained people, see selection procedure below) sniffs the diluted odor through the olfactometer. The level of dilution is gradually reduced until a panelist first perceives the odor and presses a button providing the signal for the odor concentration. The panelists are selected by examining their individual detection thresholds (at least in three sessions) according to the requirements specified in EN 13725 (2003).

In the standardized dynamic olfactometry method (EN 13725 2003), two methods of collecting responses from panelists are used:

- A forced selection method – panelists are presented with gases from two, three, or more ports, one for odorous gas and the other two for inert gases. The order of changes in odorant concentration and the location of the odorant gas nozzle is random, with the evaluation time <15 s.
- A simplified “yes/no” method – the procedure of estimating the test result does not consider the level of certainty of the answers; there is no question whether the answer is certain, guessed, or just a guess.

The average degree of dilution is expressed by the geometric mean of the individual Z values (dilution ratios) indicated by the panelists (Z_{ITE}). The result of an olfactometer measurement is numerically equal to the odor concentration c_{od} value expressed in European odor units [ou_E/m^3]. According to Van Harreveld et al. (2008) and Maxeiner (2005), the inaccuracy of the result of the odor concentration measurement is 10–20%.

The dynamic olfactometry method is used to measure the odor concentration of odorants when evaluating odor nuisance (with restrictions for toxic gases) both in open spaces and in ventilated indoor spaces (EN 13725: 2003). The uncertainty

analysis given in the standard does not consider the findings of the BIPM-ISO, “guide on the expression of uncertainty in measurements” (JCGM100 2008).

Calibration of an Olfactometer

The olfactometer should perform a dilution at the specified step ranging from 2 to at least 2^{14} . With the introduction of the European odor unit $1 \text{ ou}_E/\text{m}^3$, the typical dynamic olfactometer measuring range should be $1^1 \text{ ou}_E/\text{m}^3 - 10^7 \text{ ou}_E/\text{m}^3$ (including predilution).

Calibration is performed using a tracer gas – the recommended gases are CO₂ and CO. During calibration, an analytical gas dilution control method is used, most often using an NDIR, a nondispersive infrared (NDIR) analyzer. Following the standard’s requirements (Ueno et al. 2008), two metrological parameters of the dynamic olfactometer are checked by precise measurement of the mass streams of mixed gases after setting each successive dilution value of the tested gas stream on the olfactometer.

Performance quality requirements are:

- Accuracy of setting the dilution ratio for each dilution step <0.20 (20%)
- Instability of the set dilution ratio over time for each dilution step <0.05 (5%)

This olfactometer calibration technique has metrological traceability if the mass flow meters are calibrated using the primary calibration standard. As a result of the performance testing, the measured dilution ratios are calculated for each dilution step. These ratios, not theoretical values, are used in the final measurement calculation.

The European Standard EN 13725 (2003) describes the calibration procedure. Five test results shall be collected for every dilution setting. Between measurements of each test result, the controls of the dilution instrument are set to another setting, if applicable. Accuracy and operative speed at high dilutions have been examined by Cozzutto et al. (2018). Based on the studies by Jiang (2002) and standard AS/NZS 4323.3 (2001), determination of the accuracy of the dynamic olfactometer requires taking readings every 10 seconds. This repetition is relevant for the determination of instability. At least ten panelists’ observations shall be recorded. Thus, metrological testing of the olfactometer should be done before the sensory performance and should not be replaced by sensory performance. Figure 17 shows an example of calibration results.

A dynamic olfactometer should be calibrated at least once a year.

Selection of Panelists for Performing Measurements Using Dynamic Olfactometry

The selection of panelists is based on at least ten assessments of individual variability and sensitivity of smell to the smell of n-butanol (Kośmider 2008). A measure of odor sensitivity is the *individual threshold estimate (ITE)* value of n-butanol in

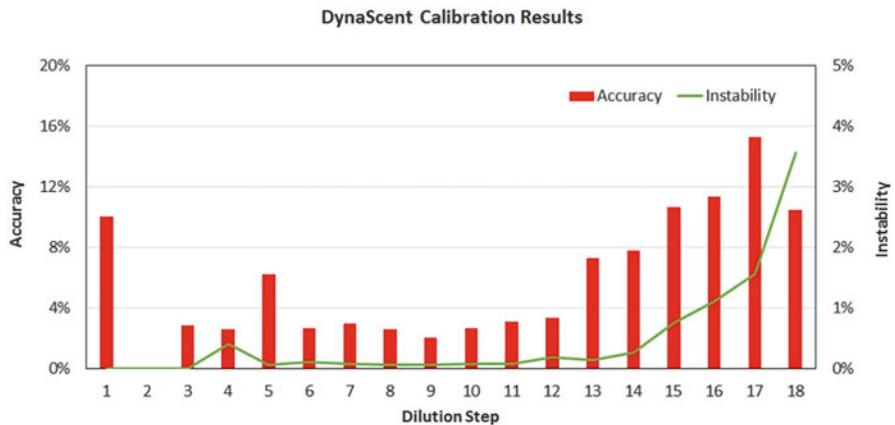

Fig. 17 An example of the stationary olfactometer calibration results. The bars represent the accuracy (left) and the curve shows instability (right) (source: <https://environodor.com.au/products/dynascent-digital-olfactometer/instrument-calibration>)

nitrogen ITE_{butanol}. ITEs should be collected over a minimum of three dilution series presentation sessions on separate days with an interval of 1 day between sessions. The individual standard deviation (SD_{ITE}) is calculated for each panelist from the logarithms of these individually obtained threshold values.

The requirements for panelists are defined by odor sensitivity within a specific tolerance limit when evaluating odor concentration c_{od}

$$c_{\text{od}} = \bar{Z}_{\text{ITE,pan}} \times 1 \quad [\text{ou}_E/\text{m}^3] \quad (16)$$

where $\bar{Z}_{\text{ITE,pan}}$ is the average value of the dilution numbers using the votes of panel members.

The panelist is selected when the geometric mean of the n-butanol sensing threshold ITE_{butanol} is between 0.5 and 2 times the concentration of the EROM standard, i.e., in the range from 62 to 246 $\mu\text{g}/\text{m}^3$. Additionally, the panelist is selected when the standard deviation SD_{ITE} antilog is less than 2.3. To check the latter, the standard deviation of the individual threshold sensing SD_{ITE} is calculated for each panelist and compared with the entire panel's antilog value.

As a result, these panelists are excluded whose individual ITE_{butanol} sensing threshold scores differ by more than five times the geometric mean for the entire panel calculated from the individual Z_{ITE} scores of all panelists. A panelist is also excluded if during a test in which a series of dynamic dilutions of gas streams from several odor samples are presented, including blank samples, more than 20% TRUE responses to the blank samples are given.

The sense of smell of each panelist should be systematically tested at least once every 12 measurements in which the panel has participated. Not meeting the above criteria results in temporary exclusion (EN 13725 2003).

Indirect Olfactometry

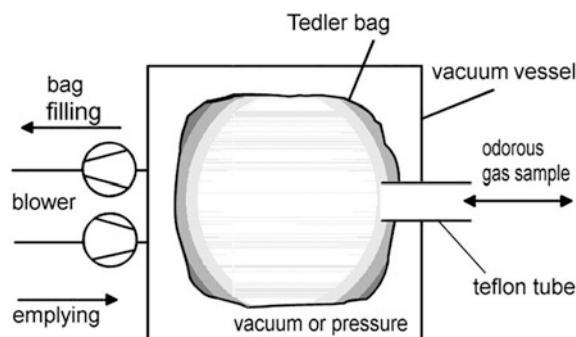

In the case of the indirect olfactometry (delayed measurement), the odorous gas samples are collected into foil bags and transported to a fixed or mobile olfactometric laboratory for analysis with a dynamic olfactometer. When the extracted odorous gas is hot or humid, it should be initially diluted with a dry, odorless, and chemically inert gas to prevent condensation.

If the concentration of odorants in the room is considered constant, it is recommended to determine the average odor concentration based on three samples taken at random during 1 day. With fluctuating odor emissions, instantaneous samples should be taken several times. The general rules for determining the number of samples follow the metrological rule of achieving maximum precision in odor measurement. Theoretical models making measurement precision dependent on the sampling point densities related to the area of the tested room in m^2 are somewhat unreliable (Mui et al. 2008).

The sampling technique differs substantially according to the type of odor emission source. From point sources, such as the ventilation outlets, samples are collected either directly into bags or a sampling line consisting of a sampling probe, a guide tube, and a particulate filter (see also ISO 10396 2007). Contact surfaces of the sample with construction materials should be limited, as far as possible, and in practice conditioning (rinsing) of containers (Fig. 18). The storage time of the sample prior to analysis should not exceed 30 hours. The sampling method for assessing the quality of air contaminated by building materials using bags is described by Müller et al. (2003, 2005).

The bags for odorous gas samples are made of a foil of nalophan, Tedlar, hard polyethylene, and polycarbonate, or fluorinated ethylene propylene (FEP). The feed tube is made of quartz glass or Teflon; the pipes are made of Teflon, stainless steel, or other odorless and practically nonabsorbent materials. Due to the low price and advertised chemical resistance, the most popular in the USA and European laboratories are DuPont™ bags called Tedlar Bags or Tedlar® made of PVF (polyvinyl fluoride) foil. Three US laboratories (Lötsch et al. 2008) carried out tests to check how the parameters of the samples change when stored in the bags: The chemical

Fig. 18 Principle of the design of vacuum vessels for taking gas samples into sealed bags

composition of the standard changed linearly due to the adsorption and chemical reactions of the ingredients, and the odor concentration dropped sharply after the third day. Various ways of conditioning Tedlar® bags (e.g., for 24 h in an oven at 100 °C) have been examined as well.

Materials for containers (bags) for odorous air samples are described in the EN 13725 standard (2003). According to Kouichi Tatsu et al. (2008), the most suitable sample material for the odorous gas containing volatile VOC odorants is FEP, a copolymer of tetrafluoroethylene and hexafluoropropylene.

In some measuring conditions, samples of odorous gas for olfactometer testing are taken using syringes, e.g., Hamilton syringes, canisters, or other equipment.

Direct Olfactometry

In the case of direct olfactometry, the measurements are performed online without delay. In this mode, the fragrant gas stream directly enters the dilution apparatus and is diluted therein with the odorless, inert gas stream before being fed to the port, where it is assessed as one stream using the sense of smell. The device used for direct olfactometry is illustrated in Fig. 19.

The field olfactometer carries out a series of dilutions by mixing a stream of fragrant air $V_{\text{fragrant air}}$, with a clean air V_{cleanair} filtered through a carbon filter and thus free of any odorants (McGinley and McGinley 2003). In the case of field olfactometry, the measurement result is the degree of odor gas dilution set by the panelist when the odor in the gas is at the perceptible threshold. This result is recorded as the value of the ratio of the mixed gas streams D/T (*dilution-to-threshold*):

$$D/T = \frac{V_{\text{clean air}}}{V_{\text{fragrant air}}} \quad (17)$$

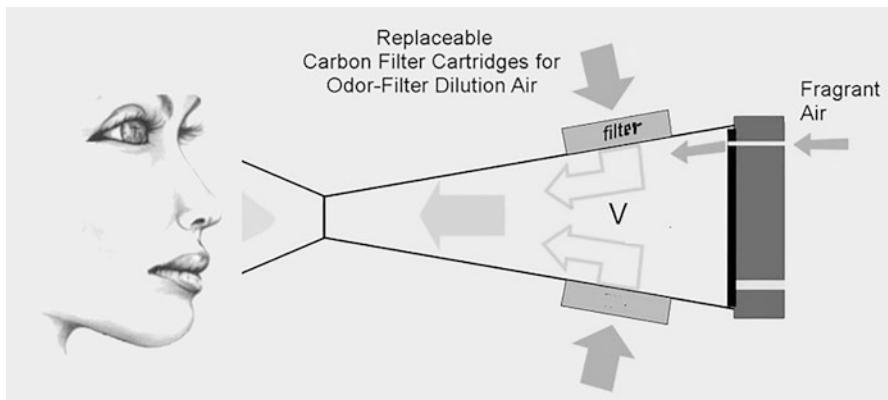

Fig. 19 The field olfactometer (Nasal Ranger® Field Olfactometer)

During the measurement, as in dynamic laboratory olfactometers, the panelists themselves increase by changing the set D/T value and the proportion of the odorous (unfiltered) air stream until an individual odor perception threshold is reached. Based on the D/T value, the preliminary individually estimated odor concentration Z is calculated as:

$$Z = \frac{V_{\text{clean air}} + V_{\text{fragrant air}}}{V_{\text{clean air}}} = \frac{V_{\text{clean air}}}{V_{\text{fragrant air}}} + 1 = \frac{D}{T} + 1 \quad (18)$$

However, considering the large jump in the D/T settings value, it is safer to calculate the Z_{ITE} value from the YES setting (Z_{n+1}) and the previous setting (smell not yet felt), i.e., Z_n (Sheffield et al. 2004). Then the estimation of the individual Z_{ITE} detection threshold is expressed as the geometric mean of the values of Z_{n+1} and Z_n

$$D/T_{\text{average}} = 10^{\frac{\log D/T_n + \log D/T_{n+1}}{2}} \quad (19)$$

If the panelists take the measurements, a series of field olfactometer measurements with the team members can be performed. The odor panel value can be calculated from the set of individual Z_{ITE} detection threshold results obtained by panelists (assuming a certain constancy of odor conditions in the environment in a given place and a given period). The geometric mean formula is used for the calculations:

$$c_{\text{od}} \ [\text{ou}/\text{m}^3] = \sqrt[n]{\prod^n Z_{ITE}} \quad (20)$$

where c_{od} is the odor concentration and n is the number of Z_{ITE} scores obtained by the members of the assessment team (panelists).

The field direct olfactometer equipment includes a set of 15 scented pencils saturated with n-butanol at various concentrations (*n-butanol Odor Pen Test Kit*) (Lay et al. 2004) intended for use in the selection and screening of members of the sensory panel (evaluation team).

Conclusions

Sensory evaluations of indoor air quality provide information on the effects of air pollutants in buildings on indoor air quality as it is perceived by building occupants. They can be performed in situ (in actual buildings) and the laboratory. They are supplementary to chemical measurements, which may not capture all pollutants that cause sensory discomfort. Therefore, they should always be considered for inclusion in protocols for characterizing indoor air quality in buildings.

Sensory evaluations of indoor air quality can be used for estimating the percentage of occupants dissatisfied with indoor air quality and, subsequently, ventilation

requirements to improve air quality as occupants perceive it. This approach has been used to define ventilation requirements included as prescriptive requirements in ASHRAE Standard 62-1 (2019) and CEN Standard EN-16798-1 (2019).

Sensory evaluations can also be used to characterize the emissions from building materials and products. This method is used in the Danish labeling scheme (Witterseh 2002; Daumling et al. 2008) and Germany (AgBB 2005). The method for using sensory panels to characterize emissions from building products is described in ISO 16000-28 (2012).

Sensory evaluations of indoor air quality can also be used to characterize other effects on building occupants. For example, Wargocki et al. (1999, 2000) showed the relationship between perceived air quality and the performance of office work, while Wang et al. (2013) and Kim et al. (2019) related the perception of indoor air quality with the sick building syndrome (SBS) symptoms.

Abstract

Quantitative knowledge of indoor source and sink characteristics is fundamental to understanding mass-transfer behavior of indoor organic chemicals, e.g., very volatile organic compounds (VVOCs) and volatile organic compounds (VOCs), and reducing human exposures to those contaminants. The key to acquiring source and sink characteristics of VVOCs and VOCs is to establish accurate physically based models with rational parameters to describe the mass-transfer process and to reliably obtain the key parameters involved in models. In this chapter, we therefore introduce representative research on the topic of “source/sink characteristics,” spanning mass-transfer analysis at the micro-, meso-, and macroscales. This research covers: (i) modeling the emissions from indoor sources, (ii) measuring the characteristic parameters used in source/sink models, and (iii) dimensionless analysis and influencing factors of the characteristic parameters. A general introduction of modeling and key parameters is presented for researchers to comprehensively understand the emission mechanism and mass-transfer principles, as well as to develop engineering applications. Additional details can be obtained from the original papers. The research summary presented in this chapter provides a foundation for future investigation in the broader area of “indoor air quality control.”

Introduction

Many new man-made materials (including composite wood, vinyl flooring, and plastic products) have been developed and widely used in indoor environments in the past few decades. These materials may emit a range of potentially hazardous airborne pollutants including very volatile organic compounds (VVOCs, specified as compounds with a boiling point of less than 50 °C, such as formaldehyde, acetaldehyde) and volatile organic compounds (VOCs, specified as compounds with a boiling point in a range of 50–240 °C, such as benzene, toluene, xylene) (Weschler 2009; Weschler and Nazaroff 2008). Exposure to these chemicals, sometimes referred to as “modern exposure,” is associated with certain health concerns (such as headaches, asthma, lung cancer) (Wolkoff and Nielsen 2001; Boeglin et al. 2006; Jie et al. 2011; Zhang et al. 2013), and has the potential to significantly degrade indoor air quality, work efficiency, and individual health. To effectively assess and reduce such health risks, it is necessary to comprehensively understand the mechanistic pathway of airborne pollutants from source to exposure.

In the past three decades, research on mass-transfer phenomena and exposure control of airborne organic compounds in indoor environments has greatly increased. Chronologically, the focus of research is linked to the requirements of the time. In the early stage, more attention was paid to whether the properties of the target building material would meet consumer requirements. Thus, European and American labeling procedures focused on the resulting concentration or emission rate from a single building material in a test chamber, and specified a threshold concentration for the target compound within a specific time period as the quality standard for the building material. The limitation is that some knowledge about the test material was obtained, but the test results could not be used to predict or explain indoor transport and exposure. For example, when several such test materials are placed in a room simultaneously, the resulting pollutant concentration cannot be easily assessed. As a result, there was a need to understand the mechanistic mass-transfer behavior (i.e., source/sink characteristics) of VVOCs and VOCs. To meet this need, research was directed at the development of mass-transfer models and the determination of model parameters. Further, with the development of green and healthy buildings, the traditional indoor air-quality assessment performed after building completion was costly and seldom met consumer expectation. With the growing demand for resource conservation and pollution reduction, there was a need to evaluate the possible impact on indoor concentrations before building construction. In general, it was this continuous improvement in engineering requirements that deepened the understanding of mass-transfer mechanisms and the resulting ability to control indoor air quality.

To effectively control hazardous organic compounds in indoor air and reduce their potentially adverse effects on human health, it is necessary to quantitatively understand the transport of the pollutants from sources to the occupants. As shown in Fig. 1, this primarily includes understanding of (1) the source, that is, target pollutants being emitted from indoor sources or entering from outdoors to indoors (steps 1.1 and 1.2 in Fig. 1); (2) transport, that is, pollutants from indoor or outdoor sources will transfer and distribute between various indoor media, and affect indoor chemical concentrations (step 2); (3) exposure, that is, occupants can be exposed to indoor pollutants via multiple pathways with associated health risks (steps 3 and 4); and (4) feedback, that is, control strategies that can be applied to the preceding steps (step 5).

Thus, the objectives of this chapter are to: (1) review representative research on source/sink characteristics; (2) identify problems or tasks worthy of further study; and (3) attract more researchers to address the so-called “modern exposure” issues.

It should be noted that although VVOCs and VOCs are handled differently when sampling due to their different physical properties, the mechanisms affecting emissions and transport within the indoor environment are similar. Thus, the research reviewed in this chapter is applicable to mass transfer of both VVOCs and VOCs.

Model Development for Describing Source/Sink Processes

To characterize VVOC/VOC mass transfer from building materials to occupants for risk assessment purposes and source emission control, emission chamber tests are often performed. Although valuable results for specific test conditions can be

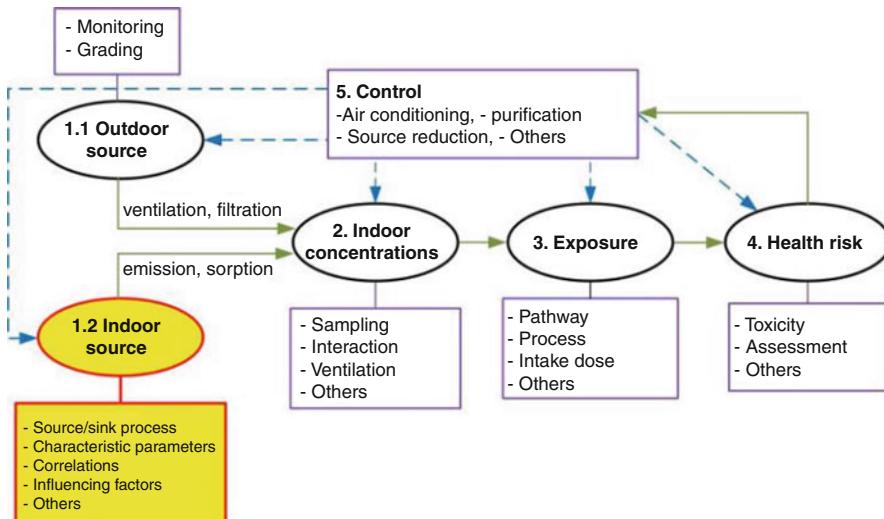

Fig. 1 Schematic showing transport and potential control of indoor chemicals as they move between their sources and the occupants in a building (Zhang et al. 2016)

obtained by direct measurements, they are frequently not applicable to other conditions. In addition, chamber experiments are often expensive, time-consuming, and difficult. Many predictive models have therefore been developed to understand the mechanisms governing VVOC/VOC emissions and transport in the indoor environment. Generally, these models can be categorized into two groups: empirical models and physically based (or mechanistic) mass-transfer models.

Empirical Models

Early models were constructed using statistical analysis of emission chamber test data. Although these models were simple and easy to use, they lacked a physical basis and could not reveal mass-transfer mechanisms and influencing factors, and therefore could not be extended from the test conditions to other conditions.

Dunn (1987) and Clausen (1993) proposed two widely used first-order decay models. The two models assumed that a climatic chamber consists of four (hypothetical) compartments, including source, chamber air, an exit, and a sink, and introduced several first-order rate constants to describe the flows among these compartments as illustrated in Fig. 2. First-order decay models often fit the short-term emissions data very well, but almost always underestimate the long-term emissions. To overcome this problem, higher-order decay models were developed by taking both short- and long-term emissions into account. Clausen et al. (1993) proposed a second-order decay model, and Tichenor et al. (1991a) proposed a more complex model. This model has been applied to many sources that feature rapid

Fig. 2 Schematic showing how two first-order decay models (Dunn 1987; Clausen 1993) are established

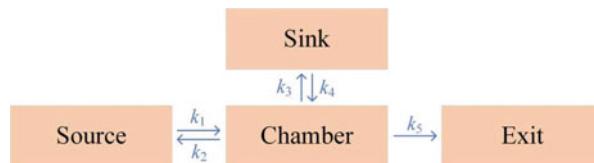

Table 1 List of several empirical models developed by early IAQ modelers

Description	Expression	References
First-order decay model	$E = E_0 e^{-kt}$ $E = M_0 k e^{-kt}$	Dunn (1987) Clausen (1993)
Second-order decay	$E = \frac{E_0}{1 + k_2 t E_0}$	Clausen et al. (1993)
n th-order decay	$E = \frac{E_0}{n-1 \sqrt{1 + (n-1) k_n t E_0^{n-1}}}$	Tichenor et al. (1991a)
Formaldehyde from building materials	$E = E_0 - k_m C$	Mathews et al. (1987)

emissions in the early stage, followed by long-lasting, low-level emissions. In general, it fits long-term data better than the first-order models. On the other hand, higher-order models can sometimes be misused. For example, they allow an infinite amount of pollutant to be emitted from the source, which is physically impossible. Thus, these models may overestimate total emissions.

Building materials have been identified as important indoor pollution sources. For a long time, modelers had to rely on statistical and empirical models. Mathews et al. (1987) developed an empirical model for formaldehyde emissions from particle-board and other engineered wood. Similar to other empirical models, this model lacks a physical basis and provides no insight into the controlling mechanisms. This and the previously mentioned empirical models are summarized in Table 1.

In a useful review, Guo (2002a, b) compiled 52 indoor emission source models found in the literature, which represented the achievements that modelers made in the early years. The review consists of two parts. Part 1 provides an overview of the 52 models, briefly discussing their validity, usefulness, limitations, and flaws. Part 2 focuses on parameter estimation and reviews 48 measurement methods.

Mass-Transfer Models

Compared with empirical models, mass-transfer models are based on valid mass-transfer mechanisms with model parameters that have a clear physical meaning, and therefore can predict emissions for different conditions if the relevant model parameters are known. In this section, we review the development of source/sink models to illustrate the application of mass transfer in addressing problems outlined in Fig. 1: (1) revealing the emission mechanism (or process) of airborne organic compounds released from indoor materials; (2) predicting the concentration of target VVOC/

VOC in indoor air during the emission period; (3) assessing the human exposure and risk to certain airborne chemicals; (4) controlling the source emissions and optimizing the performance of air cleaning equipment/techniques.

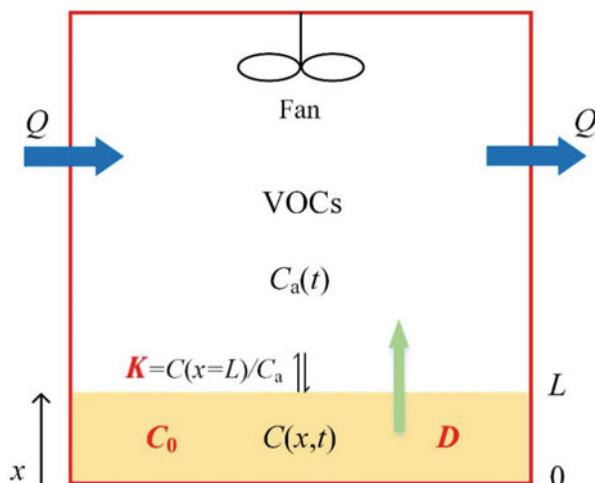

Source/Sink Models for Dry Building Materials

To develop valid source/sink models for dry building materials (e.g., wallboard, wood-based boards, vinyl flooring, etc.), it is necessary to (1) understand the emission mechanisms and behavior of VVOCs/VOCs from indoor materials or products; (2) describe the mass-transfer process using the associated mass-transfer laws or equations (where necessary, rational assumptions can be made to simplify the mass-transfer process); (3) obtain the mathematical solution to the models by various analytical methods; and (4) validate the models and test the applicability of the results.

Considering internal diffusion in the source material and equilibrium partitioning at the material surface, Little et al. (1994) developed a model (Fig. 3) to account for observed emissions of VOCs from new carpets. To simplify the problem, Little et al. assumed that (1) the initial emittable concentration of target pollutant, C_0 , is uniform in the polymer slab; (2) the mass-transfer resistance between the polymer surface and the bulk chamber air is small in comparison to the resistance within the polymer layer itself; (3) the inlet and initial VOC concentrations in the chamber are zero; (4) diffusion inside the polymer slab is one dimensional; (5) the diffusion coefficient D and partition coefficient K are constant and independent of material-phase concentration within low concentration range; (6) the chamber or room air is well mixed; and (7) possible sorption of the VOC to the stainless-steel chamber surface can be neglected.

With these assumptions, the governing equation for internal diffusion based on Fick's second law becomes:

Fig. 3 Schematic of mechanisms governing emissions from a material slab in a chamber or room

$$\frac{\partial C}{\partial t} = D \cdot \frac{\partial^2 C}{\partial x^2} \quad (1)$$

where C is the concentration of the contaminant in the material slab, $\mu\text{g}/\text{m}^3$; D is the diffusion coefficient, m^2/s , assumed to be independent of concentration; t is the emission time, s ; and x is linear distance, m .

Since the material layer is resting on the stainless-steel floor of the chamber, the first boundary condition assumes that there is no flux out of the base of the material slab. Moreover, equilibrium is assumed to exist between the contaminant concentrations in the surface layer of the polymer and the chamber air. Thus, the boundary conditions for Eq. (1) are:

$$\left. \frac{\partial C}{\partial x} \right|_{x=0} = 0, \quad t > 0 \quad (2)$$

$$K = \frac{C|_{x=L}}{C_a}, \quad t > 0 \quad (3)$$

where K is the material/air partition coefficient; C_a is the VOC concentration in the chamber air, $\mu\text{g}/\text{m}^3$; and L is the thickness of the material layer, m .

The initial condition assumes that the compound of interest is uniformly distributed throughout the material layer, or:

$$C(x, t) = C_0, \quad t = 0, \quad 0 \leq x \leq L \quad (4)$$

A second flux boundary condition is imposed through a mass balance on the VOC in the chamber air:

$$V \frac{dC_a(t)}{dt} = -DA \left. \frac{\partial C(x, t)}{\partial x} \right|_{x=L} - QC_a(t), \quad t > 0 \quad (5)$$

where V is the volume of air in the chamber, m^3 ; A is the area covered by the carpet, m^2 ; and Q is the volumetric flow rate of air through the chamber, m^3/s .

The solution to Eqs. (1), (2), (3), (4), and (5) is obtained from an analogous heat-transfer solution, which is first transformed into mass-transfer terms and then adjusted to account for equilibrium partitioning, yielding:

$$C(x, t) = 2C_0 \sum_{n=1}^{\infty} \left\{ \frac{\exp(-Dq_n^2 t)(h - kq_n^2) \cos(q_n x)}{[L(h - kq_n^2)^2 + q_n^2(L + k) + h] \cos(q_n L)} \right\} \quad (6)$$

with

$$h = \frac{Q}{A \cdot D \cdot K} \quad (7)$$

$$k = \frac{V}{A \cdot K} \quad (8)$$

and the q_n are the positive roots of

$$q_n \tan(q_n L) = h - kq_n^2, \quad (n = 1, 2, \dots) \quad (9)$$

Equation (6) gives the contaminant concentration in the polymer slab as a function of linear distance (x) and emission time (t). The concentration of contaminant in the chamber air is obtained by first finding the concentration at the surface of the polymer slab and then substituting this value into Eq. (3).

Analysis reveals that the physical properties D and K and the initial VOC concentration in the material C_0 are the three key parameters, referred to as “emission characteristic parameters,” which collectively characterize the emission behavior of VOCs in indoor environments. Little et al.’s model provides the foundation for the subsequent mechanistic studies of the source/sink characteristics of VVOC/VOCs.

Assumptions (1), (2), and (3) of Little et al.’s model are not always valid in real situations. How can the model be improved when the assumptions do not match the actual situation? How to describe the sorption process with the model? What about a comprehensive prediction for a material with multiple layers? The following research addresses these questions by extending and improving Little et al.’s model.

Single-Layer Source Models. A numerical approach was presented by Yang et al. (2001a) for the simulation of VOC emissions from solid materials. They combined a three-dimensional (3-D) numerical mass-transfer analysis to calculate the external convective mass transfer in chamber air, with the one-dimensional (1-D) approach used in Little et al.’s model for internal diffusion. Because this approach is quite complicated due to the 3-D numerical computation, Huang and Haghighe (2002) developed a numerical and an analytical model to predict the VOC emission rate from dry building materials. Both models consider the mass-diffusion process within the material and the mass-convection and -diffusion processes in the boundary layer. The mass-diffusion process within the material is still described by Eqs. (1) and (2) in Little et al.’s model, while the mass-convection and -diffusion processes in the boundary layer, Eq. (3), is replaced by:

$$-D \cdot \frac{\partial C(x, t)}{\partial x} \Big|_{x=L} = h_m \left(\frac{C(x, t)|_{x=L}}{K} - C_a(t) \right) \quad (10)$$

where C_a is the VOC concentration in the chamber air, $\mu\text{g}/\text{m}^3$, h_m is the convective mass transfer coefficient, m/s . Equation (10) shows how external convective mass transfer is taken into account. Numerical solutions for $C(x, t)$, and $C_a(t)$ were analyzed based on a finite difference method. Under the condition that $C_a(t) \ll C(x = L, t)/K$, which is reasonable for many scenarios, a full analytical solution for $C(x, t)$, and $C_a(t)$ is derived. Because it is assumed that C_a is negligible compared to the VOC concentration adjacent to the material surface, this means that it is not applicable for closed chambers.

Kumar and Little (2003a) validated the strategy to characterize the rate of absorption and desorption of VOCs by diffusion-controlled building materials. An

analytical model for a single-layer homogeneous material with one surface that emits/absorbs a VOC to/from well-mixed air is set up and a fully analytical solution of $C(x, t)$ and $C_a(t)$ is also obtained. This model neglects convective mass-transfer resistance, but considers nonuniform C_0 and included a time-dependent y_{in} . Xu and Zhang (2003) developed an improved generally applicable model for calculating the surface VOC emissions from building materials and instantaneous VOC distributions in materials. They also introduced h_m (estimated from available empirical correlations) instead of the assumptions (2) and (3) of Little et al.'s model. Thus, a semi-analytical (but not fully explicit) solution is analyzed by the variable separation method and computation from the initial condition. The results of using the model were validated with experiments reported in the literature, as shown in Fig. 4.

Deng and Kim (2004) obtained fully analytical solutions of $C_a(t)$, $C(t)$ and $E(t)$ using the Laplace transform, which provides a useful approach to the analytical solution. Compared to other models capable of accounting for those two mechanisms, this model is fully analytical and can be conveniently applied. The analytical solution of $C_a(t)$ derived by Deng and Kim (2004) can be expressed as:

$$C_a(t) = 2C_0\beta \sum_{n=1}^{\infty} \frac{q_n \sin q_n}{G_n} e^{-DL^{-2}q_n^2 t} \quad (11)$$

with

$$Bi_m = h_m L / D \quad (12)$$

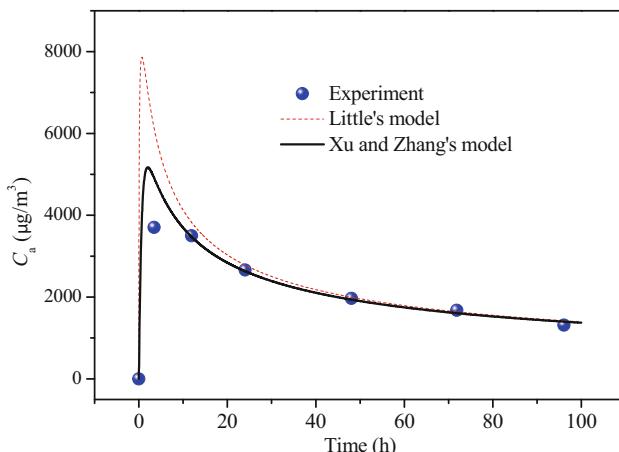

Fig. 4 Comparison of experimental results with emission prediction by Little's model and Xu and Zhang's model. (Reprinted from Xu and Zhang (2003), Copyright 2003, with permission from Elsevier)

$$\alpha = QL^2/VD \quad (13)$$

$$\beta = AL/V \quad (14)$$

$$G_n = \frac{[K\beta + (\alpha - q_n^2)KBi_m^{-1} + 2]q_n^2 \cos q_n + q_n \sin q_n \times}{[K\beta + (\alpha - 3q_n^2)KBi_m^{-1} + \alpha - q_n^2]} \quad (15)$$

and the q_n are the positive roots of

$$q_n \tan q_n = \frac{\alpha - q_n^2}{K\beta + (\alpha - q_n^2)KBi_m^{-1}}, \quad (n = 1, 2, \dots) \quad (16)$$

where C_a is the VOC concentration in the chamber air, $\mu\text{g}/\text{m}^3$, A is the source emission area of the material, m^2 , L is the half thickness of the building material, m , V is the volume of chamber, m^3 , Bi_m is the Biot number for heat transfer, h_m is the convective mass transfer coefficient, m/s , and Q is the volumetric flow rate of chamber air, m^3/s .

However, its application is relatively limited because it is based on assumption (3) of Little et al.'s model.

Taking the external convective mass transfer into account as well as a nonuniform initial material-phase concentration, Xu and Zhang (2004) developed a semi-analytical model focusing on emission behavior of building materials, an extension of their earlier work (Xu and Zhang 2003), and a semi-analytical solution is provided for this model. For the specific case that C_0 is uniform, the proposed model is validated with experimental data. Wang et al. (2006) set up a semi-analytical model for VOC emissions from both surfaces of dry, flat-plate building materials. Based on the analytic model, the influence of several factors on source emission was discussed. In addition, the conditions for simplifying double surface emission into single surface emission were also discussed. Deng and Kim (2007) investigated VOC emission from new carpet and its transport in an aged apartment by using a three-dimensional computational fluid dynamics (CFD) model. A numerical solution for single-layer homogeneous material with one surface emitting is obtained. Compared with the prior studies, this model considers the condition of non-well-mixed air, which is different from assumption (6) of Little et al.'s model. Xiong et al. (2012) further proposed a general fully analytical model to characterize VOC emission/sorption processes under different conditions (airtight or ventilated). These predictive models above generally consider the physical emission process only, but neglect the chemical reaction process, which may cause discrepancy in predicting long-term formaldehyde emissions for the cases where chemical reaction (i.e., hydrolysis) occurs over time. By combining the chemical-reaction process with a physical mass-transfer process, an improved mechanistic model was developed by He et al. (2019) to more accurately predict long-term emission behavior. In this method, a first-order chemical reaction is applied to describe the hydrolysis process between urea-formaldehyde (UF) resin and water vapor inside the material. Thus, the internal diffusion governing Eq. (1) can be rewritten as:

$$\frac{\partial C}{\partial t} = D \cdot \frac{\partial^2 C}{\partial x^2} + R_c \cdot C \quad (17)$$

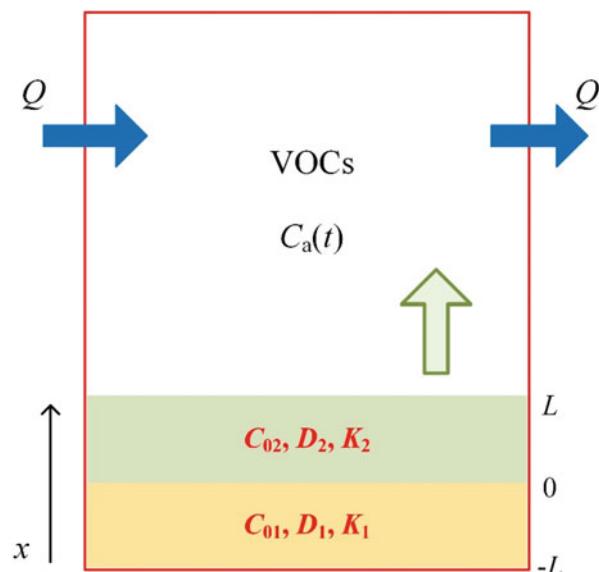

where, R_c is the first-order reaction rate constant, 1/s.

By virtue of the Laplace transform, an analytical solution is derived including four parameters, i.e., C_0 , D , K , and R_c , which comprehensively considers the effect of physical and chemical processes. Chamber experiments under controlled temperature and relative humidity for a laminate flooring product made with high-emitting composite wood core were performed for nearly 1.5 years to examine the long-term formaldehyde emission behavior. The good agreement between mechanistic model prediction and test data validates the effectiveness of the developed model.

Multilayer Source Models. Prior models usually considered the target building material as a single layer. In practice, many indoor furnishings and building structures are comprised of layers of different materials, which may alternatively act as VOC sources or sinks depending on their emission and sorption potentials and the indoor environmental conditions as well. Further model prediction for multilayer emission can be developed building on the well-established single-layer source framework.

Employing the homologous mass-transfer principle as for the single-layer models, a model was developed by Kumar and Little (2003b) to predict the rate of mass transfer between a double-layer material and indoor air, considering diffusion-controlled emissions from the composite material (Fig. 5). The model allows non-uniform initial material-phase concentrations in each of the two layers, while external convective mass transfer was again ignored. An analytical solution to the double-layer model was obtained and a parametric analysis was performed

Fig. 5 Schematic representation of a double-layer model

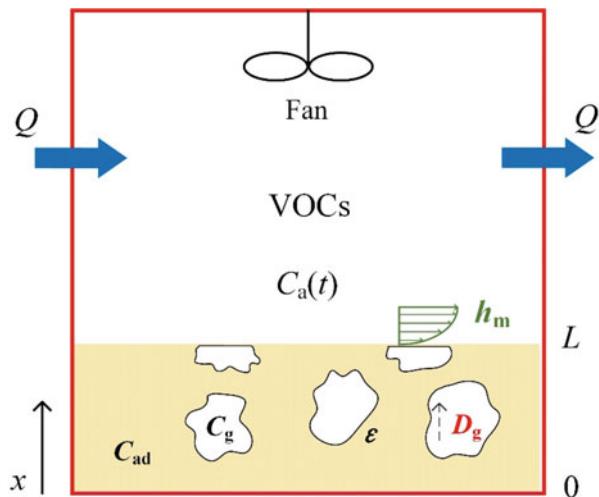

illustrating the behavior of the model as a function of the primary model parameters. In addition, it is a generalized sink/source model, meaning that it is also capable of predicting sorption.

Haghish and Huang (2003) included external convective mass transfer in their numerical integrated IAQ model, which is applied to predict the VOC emission rate of a multilayer material, the VOC sink rate of a material, and the room air VOC concentration with both source and sink materials. Hu et al. (2007) built an analytical mass-transfer model with a semi-analytical solution for predicting emissions of VOCs from multilayer building materials and a nonuniform initial material-phase concentration is included. With the consideration of convective surfaces on both sides, this model does not neglect the mass-transfer resistance through the gas-phase boundary layer. Based upon the model and the dimensionless analysis, the applicable conditions of Kumar and Little (2003b) double-layer model were discussed, but the model is practically limited by the many parameters and complicated forms of semi-analytical solution. Li and Niu (2007) derived a numerical solution of $C_a(t)$ using single-zone method for a whole room IAQ model consisting of multi-phase emission/sorption for wall materials. This model can successfully handle different building scenarios. Deng et al. (2008) presented a fully analytical solution of $C_a(t)$ to describe the emission/sorption of VOCs from/on multiple single-layer materials coexisting in buildings. The study revealed that the coexistence of multiple materials may decrease the emission rate of VOCs from each material. One obstacle to a numerical solution for multilayer composite materials arises from the difficulty in solving sharply discontinuous concentration profiles at the interface of two adjacent materials. Therefore, by considering the flaws existing in the analytical model and conventional numerical methods, the state-space method, widely used in the heat-transfer field, was applied by Yan et al. (2009) to simulate VOC emissions from building materials. Their model assumes that building material is composed of a number of finite layers, in each of which the instantaneous VOC concentration is homogeneous during the entire emission process. Based on this assumption, the method is generally applied to simulate VOC emissions from arbitrary layers of building materials, and the solution is explicit and simple. Wang and Zhang (2011) developed a general mass-transfer model for analyzing VOC emissions from dry multilayer building materials with two emission surfaces. This model adds to an earlier multilayer model by considering chemical reactions within the materials. Consequently, it can be used to analyze the effect of these chemical reactions on removing VOCs, and for characterizing secondary VOC emissions from the building material.

Source Models for Porous Materials. Physical models have been developed to predict VOC source (emission) and sink (sorption) behavior of building materials. Porous building materials (e.g., gypsum, concrete, wood-based products, carpet, wallpaper, etc.) are not only sources of indoor air pollutants such as VOC but they are also strong sinks of these pollutants. The knowledge of VOC transfer mechanisms in these materials is an important step for controlling the indoor VOC concentration levels, and for determining the optimum ventilation requirements for acceptable IAQ.

Generally, a porous building material can be modeled if it consists of pores and solid parts. A VOC in a pore is in the gas phase and/or adsorbed phase on the pore

Fig. 6 Schematic representation of VOC emission from a porous material

surface, as shown in Fig. 6. VOC transport within the building material is mainly by gas-phase diffusion through the pores, and the adsorbed-phase diffusion, or diffusion through the solid part is assumed to be negligible (Tiffonnet et al. 2000; Murakami et al. 2000). Murakami et al. (2003) presented physical models for numerically analyzing the transport of VOCs from porous building material by CFD simulation. Lee (2003) further developed the multi-phase approach, including surface diffusion (adsorbed-phase diffusion) as well as gas-phase diffusion in the pores. Equation (18) is usually used to describe the one-dimensional problem considering only gas-phase diffusion and sorption:

$$\varepsilon \frac{\partial C_g}{\partial t} = D_g \frac{\partial^2 C_g}{\partial x^2} - \frac{\partial C_{ad}}{\partial t} \quad (18)$$

where ε is the porosity of porous media; C_g is the gas-phase concentration of VOC in porous media, $\mu\text{g}/\text{m}^3$; C_{ad} is the adsorbed-phase concentration of VOC in porous media, $\mu\text{g}/\text{m}^3$; D_g is the effective gas-phase diffusion coefficient of VOC within porous media, m^2/s ; and D_{ad} is the diffusion coefficient of adsorbed phase VOC in porous media, m^2/s .

Considering both primary and secondary source/sink behaviors for the first time, a new analytical model was developed by Lee et al. (2005) to predict emission/sorption behaviors of VOCs in porous building materials. The governing equation of one-dimensional gas-phase and surface diffusion within the porous material including physical adsorption/desorption and generation or elimination of VOC due to secondary source or sink behavior is given by:

$$\varepsilon \frac{\partial C_g}{\partial t} + \frac{\partial C_{ad}}{\partial t} = D_g \frac{\partial^2 C_g}{\partial x^2} + D_{ad} \frac{\partial^2 C_{ad}}{\partial x^2} + g(x, t) \quad (19)$$

where D_{ad} is the adsorbed-phase diffusion coefficient of VOC in porous media, m^2/s , and $g(x,t)$ are time and space-dependent VOC generation/elimination due to secondary source/sink behavior, $\mu\text{g}/(\text{m}^3 \cdot \text{s})$. The positive sign (+) for $g(x,t)$ is for the secondary source behavior and the negative (-) is for the secondary sink behavior.

Not fully explicit analytical solutions of $C(x, t)$, $E(t)$, and $C_a(t)$ have been derived, which may require a finite difference method to calculate from initial conditions. Coupled with CFD analysis using the conventional convection approach, the porous emission model can be extended to a more detailed numerical conjugate mass-transfer model developed by Lee et al. (2006), with a numerical solution solved by a combination of 2-D laminar forced convection and unsteady 1-D diffusion and sorption using CFD.

The equations for the porous material are analogous to those described for the single-phase materials. Although some additional parameters are needed for the porous models, it has been shown that these models could be converted from one form to another as long as the linear sorption isotherm is used in both approaches. (Haghighe et al. 2005).

Sink Models. Building materials may act as both sources of and sinks for VOCs in indoor air. Generally, sorption is the reverse process of emission. Almost all existing sink models assume that sorption is fully reversible, and thus, several source models (Kumar and Little 2003a, b; Haghighe and Huang 2003; Li and Niu 2007; Deng et al. 2008; Yan et al. 2009; Xiong et al. 2012) can be used as sink models. Other models, focusing on sink phenomena, have also been proposed.

Based on the linear Langmuir adsorption isotherm (Langmuir 1916), Tichenor et al. (1991b) developed a widely used sorption model to characterize the adsorption/desorption behaviors existing at the material/air interface:

$$V \frac{dC_a}{dt} = k_d A M - k_a A C_a - Q C_a \quad (20)$$

$$\frac{dM}{dt} = k_a A - k_d M \quad (21)$$

where C_a is the concentration in the chamber or room air, $\mu\text{g}/\text{m}^3$; M is the mass on the sink surface, $\mu\text{g}/\text{m}$; k_a is the adsorption rate constant, $1/\text{s}$; and k_d is the desorption rate constant, m/s , A is the sink surface area of the material.

For the Langmuir model, only the adsorption/desorption process at the interface is considered, while internal diffusion is neglected, which is not applicable for long-term prediction. To overcome this, certain physical models have been proposed which not only account for the adsorption and desorption process at the interface, but also include the internal diffusion process.

Little and Hodgson (1996) presented a physical model to characterize and predict the source and sink behavior of homogeneous, diffusion-controlled building materials, but ignored the convective mass-transfer processes outside materials. To extend the prior work, a sink-diffusion model to describe the interaction between material surfaces and VOCs in indoor air was developed by Jørgensen et al. (2000), based on adsorption/desorption on the material surfaces and diffusion into the

materials. In this model, an embedded sink (E) is introduced to represent the diffusion effect inside the materials, so that Eq. (20) is replaced by the following equations:

$$\frac{dM}{dt} = k_a C_a - k_d M - k_{\text{diff}}(M - E) \quad (22)$$

$$\frac{dE}{dt} = k_{\text{diff}}(M - E) \quad (23)$$

The sink-diffusion model gives a better description of the desorption curve than the Langmuir model, especially for prediction with stronger sorption effects. As the adsorption, desorption, and diffusion processes occur simultaneously, it is difficult to propose a method to measure the parameters k_a , k_d , and k_{diff} directly. These parameters are usually determined by nonlinear fitting to experimental data rather than by independent experiments.

Yang et al. (2001b) developed a model to predict the VOC sorption rate into materials, which can be used as a “wall function” in combination with more complex gas-phase models that account for nonuniform mixing to predict the sorption process. The model, however, is inherently complicated due to the CFD approach used to calculate external mass transfer. Deng et al. (2010) introduced a tool called sorption saturation degree (SSD), which can be characterized by dimensionless correlations and parameters to evaluate sorption capacity of building materials. Furthermore, numerical models considering simultaneous source and sink behavior of multilayer materials have been developed, which more closely approximate to the real indoor environment. Yu and Kim (2013) reviewed the state-of-the-art knowledge on characterization of emission behavior of VOCs and formaldehyde from building materials and emphasized the need to consider diffusion and sink effects as an overall strategy for modeling VOC emissions from materials, so as to develop evaluation tools for estimating or predicting VOC concentrations in the indoor environment. The aforementioned VOC emission models for dry building materials with a brief description of their characteristics are listed in Table 2, as well as the model solution approach.

Source/Sink Models for Wet Coating Materials

In addition to the reviewed models for VOC emission/sorption from dry materials, a variety of “wet” products, mostly coatings such as wood stains, varnishes, and paints, are also frequently used indoors (Liu et al. 2013). As suggested in several chamber experiments, VVOC/VOC emission from wet coating materials consist of two stages: (1) the wet stage, in which the material is initially quite wet and characterized by high emission rates and fast decay due to liquid evaporation at the material surface; and (2) the dry stage, in which much of the liquid has evaporated, and the material releases contaminants at a much lower rate, dominated by internal diffusion. A transition phase usually exists between the two stages, which makes the prediction of VOC emissions from wet coating materials more complicated.

Early mass-transfer models for wet coating materials considered emissions as a pure evaporative process. Examples include the vapor pressure and boundary layer

(VB) model (Tichenor et al. 1993) for total volatile organic compounds (TVOCs) and the subsequent VBX model (Guo et al. 1998) employing the same mass-transfer principle. The VB and VBX models assume that the liquid on the substrate is a uniform mixture of VOCs, which evaporate into air and do not penetrate into the substrate. The VB and VBX models ignore the mass transfer between the coating film and the substrate and the diffusion within the film itself, both of which may be negligible at the wet stage when evaporation and external convective mass transfer dominate, but may become important when the film is dry. Thus, the two models can predict short-term emissions with relatively good accuracy, but are not suitable for the dry stage.

Considering the internal diffusion of the liquid film, Sparks et al. (1999) developed a semi-analytical model for evaluating the impact of latex paint emission on IAQ, although it does not have a sound mass-transfer basis. To examine the entire emission process, Yang et al. (2001c) proposed a numerical model to simulate VOC emissions from wet coating materials, with the consideration of the VOC mass-transfer process in the air and at the material/air interface, and diffusion in the material film and also in the substrate. In this model, the material is divided into two separate layers: the upper layer (liquid film) is the substrate infused with liquid, while the lower layer is the substrate (shown in Fig. 7) with both layers treated as a continuum. Fick's law can be used to describe transient diffusion within the liquid film and the substrate, or:

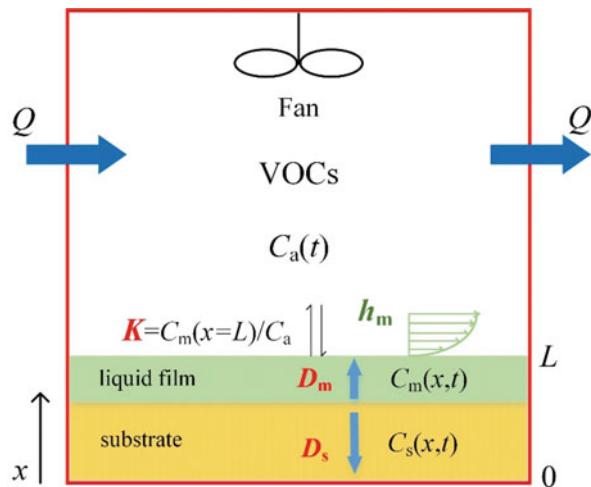

$$\frac{\partial C_m}{\partial t} = \frac{\partial}{\partial x} \left(D_m \frac{\partial C_m}{\partial x} \right) \quad (24)$$

$$\frac{\partial C_s}{\partial t} = \frac{\partial}{\partial x} \left(D_s \frac{\partial C_s}{\partial x} \right) = D_s \frac{\partial^2 C_s}{\partial x^2} \quad (25)$$

where C_m is the material-phase VOC concentration in the liquid film, $\mu\text{g}/\text{m}^3$; C_s is the material-phase VOC concentration in the substance, $\mu\text{g}/\text{m}^3$; D_m is the effective diffusion coefficient in the liquid film, m^2/s ; and D_s is the diffusion coefficient in the substance, m^2/s .

At the film/substrate interface, the flux and the concentration should be continuous:

Fig. 7 Schematic describing the VOC emission from a wet coating material

$$-D_m \frac{\partial C_m}{\partial x} = -D_s \frac{\partial C_s}{\partial x} \quad (26)$$

$$C_m = C_s \quad (27)$$

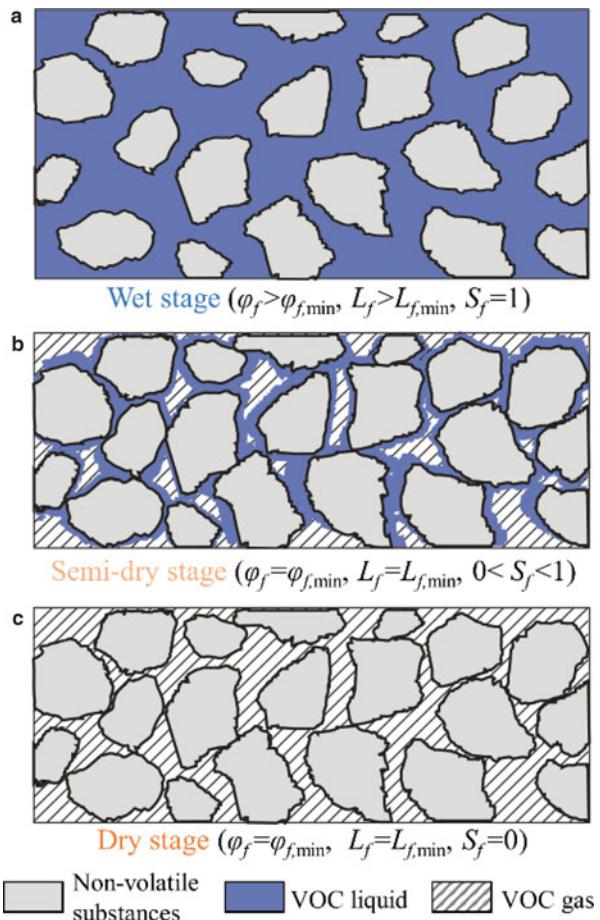

At the bottom of the substrate, zero-flux, or $C_s = 0$, can be taken as the boundary condition. At the material/air interface, an instantaneously reversible equilibrium is assumed, or:

$$C_m|_{x=L} = KC_a \quad (28)$$

Combining Eqs. (24), (25), (26), (27), and (28), a numerical solution is obtained using the CFD calculation of mass transfer in the chamber air. It should be noted that the D_m will change with the decreasing C_m , requiring empirical correlations to quantify the dependence of D_m on C_m , which complicates the process.

The numerical model developed by Haghigat and Huang (2003) is not only used for the emission/sorption behavior of VOCs from dry building material, but also is applicable for the dry/wet or wet/dry material assembly, also under consideration of the dependence of D_m on C_m . To eliminate the complexity due to the concentration dependence, Li et al. (2006) proposed a simplification of the previous model by assuming that the VOC concentration in the material film is always uniform so that diffusion within the film can be ignored. The simplified model should agree well with the cases of thin liquid film, but needs caution in the late emission stage as diffusion inside the liquid film becomes dominant. Altinkaya (2009) developed a mathematical model to describe the emission characteristics of VOCs from homogeneous wet coating materials deposited on impermeable substrates. The model considers mass transfer in the material and in air, boundary layer resistance, and the change in the coating thickness with time

Fig. 8 Schematic of the paint film during drying process (φ_f is the porosity of paint film; L_f is the paint film thickness; S_f is the VOC liquid saturation of the paint film porosity) subscript min. (Reprinted from Zhou et al. (2020), Copyright 2020, with permission from Elsevier)

due to emission of VOCs. However, there is difficulty to obtain most of the model parameters, and the introduction of a moving boundary in the numerical calculation means that the model is inherently more complicated to use. Zhou et al. (2020) proposed a mathematical model for characterizing the full process of VOC emissions from paint film coating on porous substrates. By introducing the saturation of VOC liquid in the pores of the paint film (S_f), this model can give quantitative definitions for three states of the paint film including wet, semi-dry, and dry (Fig. 8). VOC mass transfer in the air, at the air-paint interface, in the paint film, at the paint-substrate interface, and in the porous substrate is mathematically described.

The aforementioned VOC emission models for wet coating materials are listed in Table 3 in chronological order, with a brief introduction of the model characteristics.

Measurement Methods for VVOC/VOC Characteristic Parameters

An important issue for the validation and application of mass-transfer models is the estimation of model parameters. In addition to the easily obtained parameters such as V , Q , A , and L , the key parameters in the solid VOC models primarily include C_0 , D , and K . Besides the inherent errors caused by the assumptions of the models, the accuracy of prediction is greatly dependent on the reliability of model parameters. Therefore, the measurement of model parameters is a prerequisite to apply the models and has resulted in a range of studies. Characterization of model parameters can be specified into two categories: experimental techniques, and correlations between model parameters and physical/chemical properties of target pollutants/materials or the environmental conditions. Therefore, this section will review the developed methods for measuring the source/sink characteristic parameters in

these two categories. Furthermore, the dimensionless analysis of key parameters is also discussed.

Experimental Techniques for Measuring Model Parameters

The Initial Emittable Concentration, C_0

Traditional methods for measuring VOC concentrations in dry materials have used solvents or heat to extract target compounds. Cox et al. (2001a) proposed a fluidized-bed desorption (FBD) method for the determination of initial emittable VOC content (or concentration) in vinyl flooring. Due to the shortening of the mass-transfer path and increasing of the emission area, the experimental time is no more than 7 days. However, there are still some limitations in the FBD method due to the complex experimental system and the fact that the material has to be ground into powder.

Smith et al. (2009) proposed a multi-flushing extraction method for determining C_0 . In this method, material specimens were also ground into powder and then allowed to emit in a recirculation loop. The emission involves multiple equilibrium cycles by multi-flushing the chamber, and continues until the equilibrium VOC concentration in chamber air of the last cycle is less than 10% of the first cycle. Therefore, the initial emittable mass, M_0 , can be calculated as:

$$M_0 = \sum_{i=1}^n VC_{\text{equ},i} + \frac{VC_{\text{equ},n}}{C_{\text{equ},n-1}/C_{\text{equ},n} - 1} \quad (29)$$

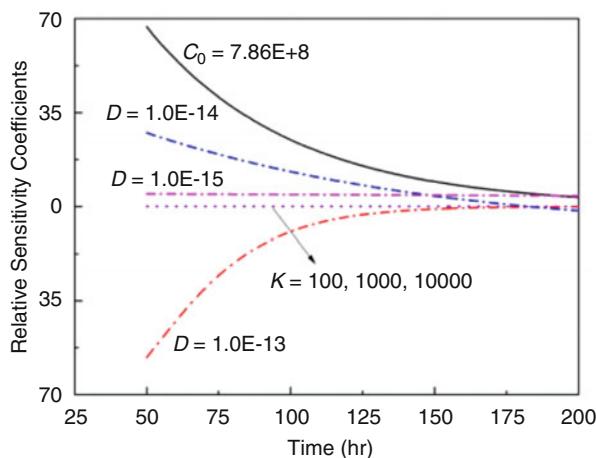

where M_0 is the initial emittable contaminant mass, μg ; V is the volume of the airtight chamber, m^3 ; $C_{\text{equ},i}$ is the equilibrium concentration of VOC in the airtight chamber during the i th period, $\mu\text{g}/\text{m}^3$; and n is the total number of cycles of the experiment. C_0 can be calculated as the ratio of M_0 to the material volume (V_m). Except for grinding, the main drawback is the required time since it may need many cycles to reach the appropriate condition.

Li (2013) presented a novel procedure for estimating C_0 and D in building materials. This new method determines these two parameters by two observations from a chamber test in a non-fitting and sequential way, which defines a well-posed problem and requires no iterative procedure. The most outstanding feature of this method is that multiple estimates of the parameters can be obtained when more than two experimental data points are available. However, the method cannot provide an estimation for K , due to the insensitivity of C_a (air-phase concentration) to K (see Fig. 9).

The Diffusion Coefficient, D

Cup Method. The cup method is one of the simplest techniques to measure D presented by Kirchner et al. (1999). The building material is fixed on the top of a cup containing pure VOC liquid, the system is placed on the electronic balance,

Fig. 9 Sensitivity analysis of C_a to C_0 , D , and K . (Reprinted from Li (2013), Copyright 2013, with permission from American Chemical Society)

and its mass change is recorded with time. According to Fick's diffusion law, D can be calculated as:

$$D = \frac{m}{A} \frac{L}{C_{\text{sat}}} \quad (30)$$

where m is the steady-state mass flux of the VOC through the material, $\mu\text{g/s}$, A is the source emission area of the material, m^2 , L is the thickness of the material, m , and C_{sat} is the saturation concentration of VOC at given temperature, $\mu\text{g/m}^3$.

As D has been shown to be concentration dependent at high concentration levels, the result of the cup method will overestimate D for the saturated concentration of VOC in the cup, which is much higher than the indoor concentration. Furthermore, due to the use of pure VOC liquid, one experiment can only measure the diffusion coefficient of one VOC.

CLIMPAQ Method. To overcome the flaw of cup method, which measures only one VOC at a time, Meininghaus et al. (2000) used the CLIMPAQ method (Chamber for Laboratory Investigations of Materials, Pollution and Air Quality) to determine D of several VOCs simultaneously. The test material is placed between two CLIMPAQs, referred to as the primary and secondary chambers. Air with a constant concentration of VOCs is introduced into the primary chamber while the secondary chamber is ventilated with clean air. The steady-state VOC concentrations in the two chambers are recorded, and D can be calculated as:

$$D = -\frac{m}{A} \frac{\Delta x}{\Delta C} = \frac{Q L}{A} \frac{C_2}{C_1 - C_2} \quad (31)$$

where m is the steady-state mass flux of the VOC through the material, $\mu\text{g/s}$, A is the source emission area of the material, m^2 , Q is the volumetric flow rate of air through the CLIMPAQs, m^3/s , L is the thickness of the material, m , C_1 and C_2 are

the equilibrium VOC concentrations in the primary and secondary chamber, respectively.

The main drawback of this method is that it neglects the external convective mass-transfer resistance at the material surfaces, which may result in an underestimation of D .

Two-Chamber Method. Employing a two-airtight-chamber test, Bodalal et al. (2000) proposed a method to determine D and K simultaneously. The test material, which is free of VOCs, separates two airtight chambers, referred to as a high-concentration chamber and a low-concentration chamber. During the experiment, the target VOCs diffuse from the high-concentration chamber through the test material into the low-concentration chamber. Assuming both chambers are well mixed, an analytical solution is derived as:

$$\ln \left(\frac{y_1 - y_2}{y} \right) = \ln \left[\frac{4K \cdot A \cdot L/V}{q_1^2 + (K \cdot A \cdot L/V)(2 + K \cdot A \cdot L/V)} \right] - \frac{q_1^2 D}{L^2} t \quad (32)$$

where y_1 and y_2 are the VOC concentrations in the high-concentration chamber and in low-concentration chamber, respectively, $\mu\text{g}/\text{m}^3$, and y is the initial VOC concentration in the high-concentration chamber, $\mu\text{g}/\text{m}^3$, A is the source emission area of the material, m^2 , L is the thickness of the material, m , V is the volume of environmental chamber, m^3 .

D and K can be obtained by linear regression of the experimental data. This method also neglects the effect of the external convective mass-transfer process and may have similar limitations as the CLIMPAQ method.

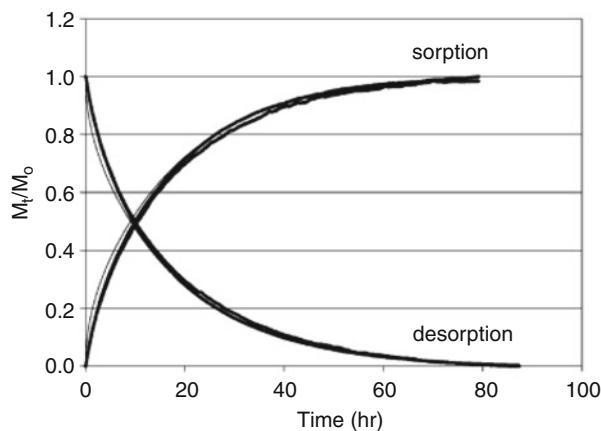

Microbalance Method. A microbalance method was developed by Cox et al. (2001b) to measure D and K separately for vinyl flooring. A thin slab-shaped sample is cut from test material and put into a small glass chamber attached to a high-resolution microbalance. During the experiment, carrier gas with a known concentration of VOC is introduced for sorption until equilibrium, then the desorption test is conducted. The D is determined by fitting Fick's diffusion model to the sorption and desorption curve (see Fig. 10). The samples used for this method are quite small and thin so that it is only applicable to uniform materials.

Inverse Method. Based on Deng and Kim's model (2004), an inverse method was developed by Li and Niu (2005) to estimate the constants D and K of VOCs in the building material. With the use of simulated measurements as input data for the inverse analysis, the parameter-estimation problem was solved by using the Levenberg-Marquardt method (1963) of minimization of the least-squares norm. However, this method cannot solve three key parameters at the same time, and it is necessary to measure at least one key parameter in advance.

The Partition Coefficient, K

Headspace Method. The headspace method developed by Tiffonnet et al. (2002) is a simple and direct method to determine K by measuring both the material-phase concentration and gas-phase concentration at equilibrium. In this method, building materials containing no VOCs are placed in an airtight environmental chamber and

Fig. 10 Fitting transient sorption/desorption data (symbols) to a diffusion model (lines) for determination of D . (Reprinted from Cox et al. (2001b), Copyright 2001, with permission from Elsevier)

then injected with a certain mass of acetone, M_s . When the adsorption equilibrium is reached, K can be calculated by the following equation:

$$K = \frac{C_m}{C_a} = \frac{M_s - C_{\text{equ}}V}{C_{\text{equ}}V} \quad (33)$$

where M_s is the known mass of VOC injected in headspace method, μg , C_{equ} is the gas-phase concentration of acetone in equilibrium, $\mu\text{g}/\text{m}^3$, V is the volume of environmental chamber, m^3 .

Several sensitive methods (e.g., Xiong et al. 2009, 2011a; Wang and Zhang 2009; Wang et al. 2008), which employ the basic idea of the headspace method to measure K and C_0 simultaneously, have been developed.

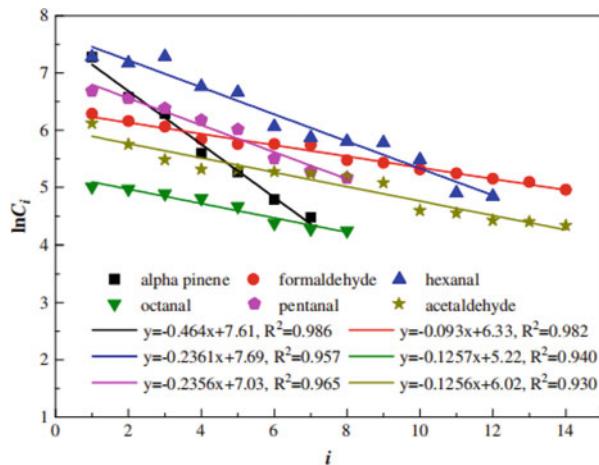

Multi-emission/Flush Regression Method (MEFR). Based on the extraction method presented by Smith et al. (2009), an improved method, the multi-emission/flush regression method, was proposed by Xiong et al. (2009) to simultaneously determine K and C_0 . In this method, a piece of particle board is placed in the closed chamber where it freely emits until equilibrium is established. Then multiple equilibria are formed by duplicate emission/flushing cycles, and the gas-phase concentration in the chamber air at equilibrium is noted. Based on mass conservation and Henry's linear sorption law, for the i th equilibrium state, we get:

$$\ln C_{\text{equ},i} = \ln \frac{K}{R_v + K} \cdot i + \ln \frac{C_0}{K}, \quad (i = 1, 2, \dots) \quad (34)$$

where $C_{\text{equ},i}$ is the equilibrium VOC concentration in the chamber during the i th period, $\mu\text{g}/\text{m}^3$, R_v ($= V/V_m$) is the ratio of chamber volume (V) to material volume (V_m).

Then, C_0 and K can be simultaneously obtained through linear regression of the experimental data (see Fig. 11). Compared to the extraction method, this method has

Fig. 11 Regression for six VOCs in the tested particle board. (Reprinted from Xiong et al. (2009), Copyright 2009, with permission from Elsevier)

the following advantages: (1) it is unnecessary to emit completely from the material, thus greatly reducing experimental time; (2) it can avoid the measurement uncertainties at low VOC concentrations; and (3) it does not require grinding the building material and is thus more convenient to use. However, the proposed method is also somewhat time-consuming due to several emission/flushing cycles.

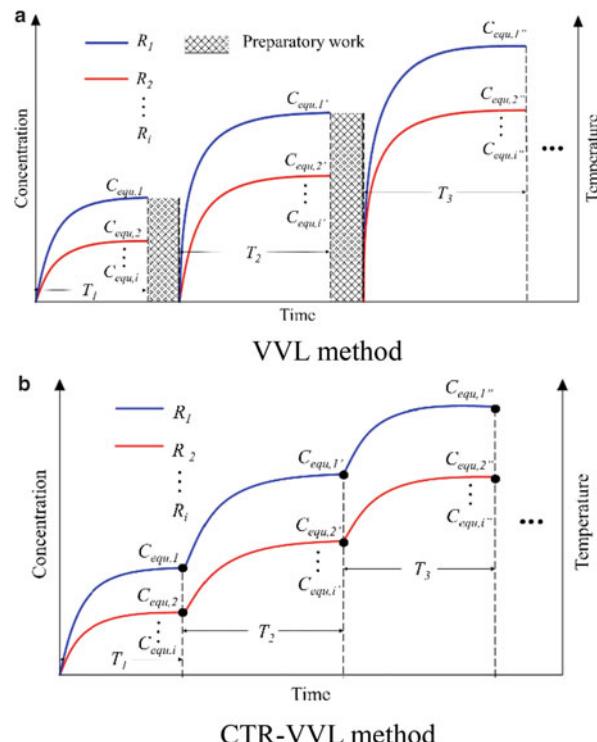

Variable Volume Loading Method (VVL). Xiong et al. (2011a) developed a convenient and rapid method for simultaneously measuring C_0 and K of formaldehyde and other aldehydes in building materials. In this method, the building material is placed in the closed chamber where it freely emits until equilibrium is reached, as shown in Fig. 12a. Then multiple equilibria are formed by changing the volumetric air/material phase ratio, and the gas-phase concentration in the chamber air at equilibrium is measured. A regression method can be applied by using more than two sets of experiments with different volumetric air/material phase ratios (designated as R_i , $i = 1, 2, \dots$). The regression formula is:

$$\frac{1}{C_{\text{equ},i}} = \frac{1}{C_0}R_i + \frac{K}{C_0}, \quad (i = 1, 2, \dots) \quad (35)$$

where $C_{\text{equ},i}$ is the equilibrium VOC concentration in the chamber during the i th period, $\mu\text{g}/\text{m}^3$, $R_i (= V/V_m)$ is the different ratio of chamber volume (V) to material volume (V_m).

Thus, C_0 and K can be obtained from the slope and intercept of the regression line by applying Eq. (35) to the experimental data. This method has the following features: (1) it requires a relatively short experimental time (less than 24 h for the cases studied); and (2) is convenient for routine measurement. It should be pointed out that the proposed method does not consider the chemical state of the formaldehyde and VOCs in the building material. In addition, it is also only applicable for homogeneous building materials.

Fig. 12 Schematic diagrams of the (a) VVL and (b) CTR-VVL methods.
 (Reprinted from Liu et al. (2015a), Copyright 2015, with permission from Elsevier)

CTR-VVL Method. Based on the VVL method, a CTR-VVL method was proposed by Liu et al. (2015a) to simultaneously measure K and C_0 . By linearly fitting $C_{equi,i}$ and R_i using Eq. (35), C_0 and K can be obtained from the slope and intercept. In an airtight space, the equilibrium VOC concentrations of the same material are distinct at different temperatures. Based on the emission characteristics of formaldehyde, for an identical piece of material and corresponding to a fixed R_i , continuous measurements of the equilibrium concentrations of formaldehyde were made at temperature ranging from low to high. The environmental chamber was not opened until all measurements of one R_i were completed under multiple sets of temperatures. The measurements of another R_i began when the background concentration fell below the limit. This experimental method is known as the CTR-VVL method, with a schematic diagram shown in Fig. 12b. There are several advantages compared with the VVL method: (1) An identical piece of material is tested under multiple working conditions to reduce the measuring error as well as the material consumption; and (2) CTR-VVL method sets the previous equilibrium concentration as the initial environmental concentration of the following temperature condition, which accelerates the process to reach the equilibrium concentration.

Rapid and Accurate Measurement Method

The aforementioned measurement methods are used for the determination of one or two emission parameter(s), but are not able to measure three key parameters simultaneously. Based on the work performed by Xu and Zhang (2003, 2004) and Deng and Kim (2004), a series of rapid and accurate methods to simultaneously measure the three key parameters have been developed, and are introduced as follows:

A Simple Method to Measure C_0 , K , and D Simultaneously. This method was developed by Wang and Zhang (2009) to determine C_0 under conditions similar to those in common indoor environments, together with K and D . The tested materials are placed in an airtight environmental chamber where the air is well mixed. A water-bath jacket is used to control the air temperature in the chamber. The materials undergo a multi-sorption/emission process and the instantaneous formaldehyde concentration in the chamber is recorded. At equilibrium, after the emission or sorption process, the following equation can be derived:

$$(C_{a,0} - C_{\text{equ}}) \cdot V/V_m = K \cdot C_{\text{equ}} - C_0 \quad (36)$$

where $C_{a,0}$ is the initial formaldehyde concentration in the chamber, $\mu\text{g}/\text{m}^3$, and C_{equ} is the equilibrium formaldehyde concentration in the chamber after an emission or sorption process, $\mu\text{g}/\text{m}^3$, V is the volume of environmental chamber, m^3 , V_m is the volume of tested material, m^3 .

If a series of $C_{a,0}$ and C_{equ} are measured, the parameters K and C_0 can be obtained by linear regression. Then D can be obtained by fitting the concentration at the emission stage into a mass-transfer-based model developed by Xu and Zhang (2003). Thus, all three key emission characteristic parameters, C_0 , K , and D , can be determined in one experiment. Because only D is determined by nonlinear least-squares regression, the relative error of regression can be decreased.

This study indicated that the room temperature sorption/emission method is practical to measure C_0 , D , and K with the important advantages of the experimental system and the measuring procedure being simple. Also, the method simultaneously determines the three key parameters of dry building materials in a short time (about 7 days). However, as the peak concentration after injection is hard to detect, the measurement accuracy will be affected.

C-History Method. This method focuses on the emission process of VOCs from some building materials in a closed chamber. Because of the shortcomings for the aforementioned methods, Xiong et al. (2011b) developed a novel method to rapidly and simultaneously determine C_0 , D , and K of formaldehyde and VOCs in building materials.

Based on several assumptions widely adopted in previous studies, the analytical solution describing VOC emission is:

$$C_a(t) = \frac{C_0\beta}{K\beta + 1} + 2C_0\beta \sum_{n=1}^{\infty} \frac{\sin q_n}{q_n A_n} e^{-DL^{-2}q_n^2 t} \quad (37)$$

with

$$A_n = (K\beta - q_n^2 K B_i m^{-1} + 1) \cos q_n - (1 + 2 K B_i m^{-1}) q_n \sin q_n, \quad (n = 1, 2, \dots) \quad (38)$$

where C_a is the formaldehyde concentration in chamber air, $\mu\text{g}/\text{m}^3$, $\beta = AL/V$, A is the source emission area of the material, m^2 , L is the half thickness of the building material, m , V is the volume of chamber, m^3 , $B_i m$ is the Biot number for heat transfer ($= h_m L/D$); h_m is the convective mass transfer coefficient, m/s , and q_n are the positive roots of

$$\frac{\tan q_n}{q_n} = \frac{1}{q_n^2 K B_i m^{-1} - K \beta}, \quad (n = 1, 2, \dots) \quad (39)$$

When the emission process reaches the equilibrium state, the equilibrium chamber VOC concentration, C_{equ} , can be represented as:

$$C_{\text{equ}} = \frac{C_0 \beta}{K \beta + 1} \quad (40)$$

For the infinite exponential series of Eq. (37), the terms decay very fast. Therefore, for a sufficiently long emission time, t , only the first term ($n = 1$) is significant, meaning that:

$$\ln \left(\frac{C_{\text{equ}} - C_a(t)}{C_{\text{equ}}} \right) = -DL^{-2} q_1^2 t + \ln \left(-\frac{2(K\beta + 1) \sin q_1}{q_1 A_1} \right) \quad (41)$$

where q_1 is the first root of Eq. (39), and A_1 is the first term of A_n .

If we denote the slope and intercept of Eq. (41) as SL and INT, this equation can be rewritten as:

$$\ln \left(\frac{C_{\text{equ}} - C_a(t)}{C_{\text{equ}}} \right) = -SL \cdot t + INT \quad (42)$$

where SL and INT are both functions of D and K .

Therefore, if the VOC concentration in the chamber versus time is treated as the form of Eq. (42), the SL and INT can be obtained by linear curve fitting. The two parameters D and K can be obtained directly because they are functions of SL and INT, and we have two equations with two unknown parameters. Combining Eq. (40) and the known value of K , C_0 can be calculated. Since the main characteristic of this method is to apply the concentration history of VOCs in a closed chamber, it is called the C-history method.

Compared to the available methods of determining the three parameters described in the literature, this approach has the following salient features: (1) The three parameters can be simultaneously obtained; (2) it is time-saving, generally taking

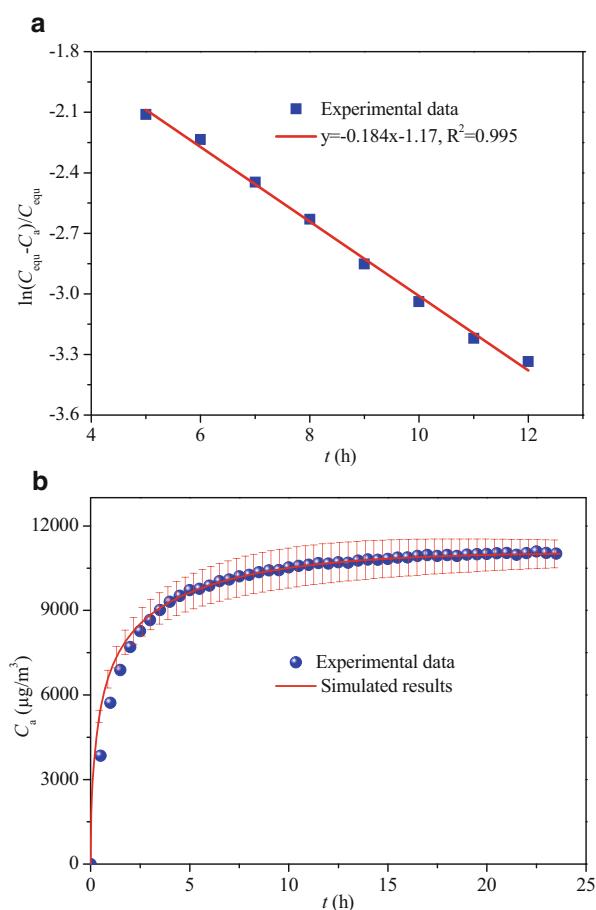

less than 3 days for the cases studied; and (3) the maximum relative standard deviations of the measured C_0 , D , and K are all less than 10%, which are acceptable for engineering applications.

The results using C-history method to chamber formaldehyde concentration data are shown in Fig. 13.

In the application of the proposed C-history method, the choice of time interval by using Eq. (42) to fit experimental data is very important. Further analysis reveals that when the test period is within the linear region (i.e., $t_1 < t < t_2$, $t_1 = 0.125 L^2/D$, $t_2 = 1.50 L^2/D$), then Eq. (42) can be rationally applied.

In this method, considering the VOC concentration in a closed chamber should be sampled multiple times, it is required that chamber volume should be not too small, otherwise multiple sampling might destroy the formaldehyde/VOC mass conservation in the closed chamber, which would result in deviations of measured parameters.

Ventilated-Chamber C-History Method. In order to overcome the problems in C-history method, Huang et al. (2013) developed a novel method, the ventilated-chamber C-history method, to rapidly and accurately measure the three emission characteristic parameters.

This method involves two physical processes: the building material first emits formaldehyde/VOCs in a chamber under airtight conditions until equilibrium is reached; then, clean air is introduced into the chamber, causing the decrease of the concentration in the chamber. The latter process is regarded as emission in a ventilated chamber ($N > 0$). The concentration curve versus time of the chamber formaldehyde/VOC concentration (C_a) during the two processes is shown in Fig. 14.

Based on mass-transfer analysis presented by Deng and Kim (2004) and Xiong et al. (2011b), an analytical solution to the whole physical process can be derived as:

$$\ln \frac{C_a(t)}{C_{\text{equ}}} = \text{SL} \cdot t^* + \text{INT} \quad (43)$$

$$\text{SL} = -DL^{-2}q_1^2 \quad (44)$$

$$\text{INT} = \ln \left(2\alpha \cdot \frac{\cos q_1 - KBi_m^{-1}q_1 \sin q_1}{G_1} \right) \quad (45)$$

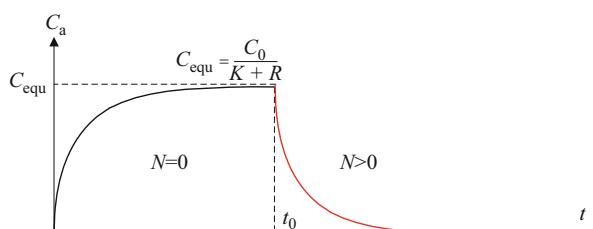

with the mass conservation relationship:

$$C_{\text{equ}} = \frac{C_0}{K + R_v} \quad (46)$$

where t^* is defined as $t-t_0$, representing the emission time under ventilated conditions, C_a is the formaldehyde/VOC concentration in chamber air, $\mu\text{g}/\text{m}^3$, C_{equ} is the equilibrium concentration in the chamber air, $\mu\text{g}/\text{m}^3$, Bi_m is the Biot number ($= h_m L/D$); L is the thickness of the tested material, m, h_m is the convective mass transfer coefficient, m/s , R_v ($= V/V_m$) is the ratio of chamber volume (V) to material volume (V_m).

The SL and INT can be obtained by linear curve fitting once the chamber formaldehyde/VOC concentration is treated as the form of Eq. (43). After that, the D and K can be determined directly because there are two Eqs. (44) and (45) containing the two unknown parameters (D and K). Combining the determined K and Eq. (46), C_0 can be calculated.

Fig. 14 Formaldehyde/VOC concentration in chamber air in two process steps.
(Reprinted from Huang et al. (2013), Copyright 2013, with permission from Elsevier)

For small chamber tests, the ventilated-chamber C-history method is more suitable than the C-history method, and some commonly used measurement instruments (e.g., GC/MS, HPLC) can be applied. In addition, the proposed method can be very time-saving and accurate, with an experimental time of less than 12 h and R^2 ranging from 0.96 to 0.99 for the cases studied, because it is not necessary to reach emission equilibrium in the ventilated chamber for linear regression.

Improved C-History Method. Both types of C-history methods (using either closed or ventilated chambers) mentioned above require the emission time (t) within a specific range, which may prolong experimental time and reduce method accuracy. In order to overcome this limitation, Zhang et al. (2018) propose an improved C-history method based on the full analytical solution of the mass-transfer model describing the VOC emission process.

For the ventilated chamber C-history method, the analytical solution of the mass-transfer model describing emission process of the targeted compound during the ventilated chamber emission process is

$$\frac{C_a(t)}{C_{\text{equ}}} = 2\alpha \sum_{n=1}^{\infty} \frac{\cos q_n - KBi_m^{-1} q_n \sin q_n}{G_n} e^{-DL^{-2}q_n^2 t} \quad (47)$$

and q_n are the positive roots of

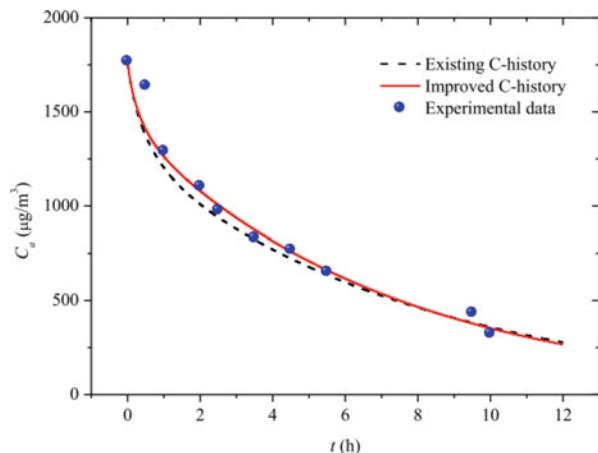

$$q_n \tan q_n = \frac{\alpha - q_n^2}{K\beta + (\alpha - q_n^2)KBi_m^{-1}}, \quad (n = 1, 2, \dots) \quad (48)$$

where C_a is the VOC concentration in chamber air, $\mu\text{g}/\text{m}^3$, C_{equ} is the equilibria concentration in the chamber air, $\mu\text{g}/\text{m}^3$, Bi_m is the Biot number ($= h_m L/D$); L is the thickness of the tested material, m, h_m is the convective mass transfer coefficient, m/s.

As C_{equ} can be directly measured in the closed chamber and h_m can be determined using empirical correlations, the remaining unknown parameters in Eq. (47) are D and K . The Levenberg-Marquardt algorithm is chosen for the nonlinear fitting in MATLAB. Then, C_0 can be obtained by using Eq. (46). To summarize, this method uses a ventilated chamber to measure a C-history series, and then simultaneously determines C_0 , D , and K . Instead of the simplified solution used in existing methods, the full analytical solution is adopted for determining parameters, meaning that the measured data matching the time interval discussed in previous C-history methods ($t > 0.125 L^2/D$) are also applicable.

Figure 15 shows the comparison between experimental data and simulated results (which are obtained by substituting the emission parameters determined by both methods into Eq. (47)). The simulated results agree well with experiment data, implying both methods are likely accurate enough. Furthermore, results have shown that the improved method is more rapid and accurate than the existing methods.

Fig. 15 Comparison between the experimental data and simulated results obtained using the improved C-history method. (Reprinted from Zhang et al. (2018), Copyright 2018, with permission from Elsevier)

Measurement methods for the three key emission parameters are listed in Table 4, with a brief introduction to the characteristics of each method.

Correlations Between Model Parameters and Physical/Chemical Properties

The Initial Emittable Concentration, C_0

The initial emittable concentration of formaldehyde (C_0) in building material has been found to be much lower than the concentration measured by the perforator method (C_{total}) at room temperature (Wang and Zhang 2009). Xiong and Zhang (2010) found that the C_0 at room temperature is far less than the value measured by the perforator method recommended by the Chinese National Standard GB/T 17657-1999, which measures the total concentration of formaldehyde in medium density board. This means most of formaldehyde in the building material cannot be emitted at room temperature.

Heterogeneous adsorption theory of porous media is applied to explain the above phenomena by statistical physics (Huang et al. 2015). The emission of formaldehyde and VOCs from building materials is mainly a physical process for short-term emissions. From the microscopic perspective, the formaldehyde and VOC molecules are bonded to the material surface by adsorption, and a molecule is emittable only when the kinetic energy of this molecule is high enough to overcome the bonding forces, that is, to overcome an energy barrier, the adsorption energy. The sum of these molecules constitutes the initial emittable concentration (C_0), which is clearly lower than the total concentration (C_{total}). Zhou et al. (2016) systematically analyzed the multi-scale desorption mechanism of VOCs, and then proposed the mathematical characterization of the distribution law of adsorption potential in porous building materials. An analytical formula for the distribution of multiple initial emittable concentrations was derived based on the nonuniform desorption criterion.

The Diffusion Coefficient, D

From the mesoscale perspective, most building materials are porous media. Therefore, the mesoscale structure plays an important role in the diffusion coefficient of VOC inside the pores of the material.

Treybal (1981) found that surface diffusion is several orders of magnitude smaller than molecular diffusion and Knudsen diffusion, and the contribution of surface diffusion to mass transfer can be ignored under this condition. Carniglia (1986) proposed a model to calculate the effective diffusion coefficient (D_e) by simultaneously considering the contribution of molecular and Knudsen diffusion and the microstructure parameters. The parameters ε and τ can be directly calculated using the data from mercury intrusion porosimetry (MIP) experiments:

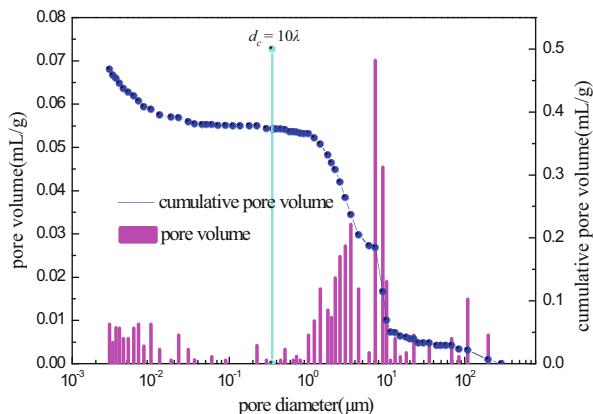

$$D_e = D_r \frac{\varepsilon}{\tau} \quad (49)$$

where ε is the porosity; τ is the tortuosity factor; and D_r is the mean (reference) diffusion coefficient in the porous material, m^2/s .

Blondeau et al. (2003) developed a parallel pore model to calculate D_r by assuming that the pores involve many parallel connections. Seo et al. (2005) used a mean pore model to calculate D_r by simplifying all types of pores as an average pore with equivalent diameter.

In many cases, neither treatment characterizes the features of diffusion paths in porous materials very well, resulting in large errors. By virtue of an MIP experiment, a side face image of REV (representative elementary volume) in a piece of fiberboard is observed by scanning electron microscope (shown in Fig. 16); it was found that

Fig. 16 Pore size distribution of a medium-density fiberboard. (Reprinted from Xiong et al. (2008), Copyright 2008, with permission from Elsevier)

the connection between the macro- and mesopores in a REV is in series. The pore size distribution of porous building materials shows that its internal structure conforms to the fractal theory, which was proposed by Mandelbrot in 1967. The pore size distribution of several kinds of fiberboard and particleboard was observed by mercury porosimetry, showing that their fractal dimension conforms to the fractal criterion. Based on the fractal theory and mercury porosimetry, a macro-meso two-scale model was proposed by Xiong et al. (2008) to determine D_r assuming that the macro- and mesopores are connected physically, thus the D_r can be derived as:

$$\frac{1}{\varepsilon D_r} = \frac{\alpha^2}{\varepsilon_1 D_1} + \frac{(1 - \alpha)^2}{\varepsilon_2 D_2} \quad (50)$$

where ε is the total porosity of the material; ε_1 , ε_2 are the porosities of the macro- and mesopores, respectively; d_1 and d_2 are average diameters of the macro- and mesopores, respectively, m; α is defined as $\alpha = \varepsilon_1 d_2^2 / (\varepsilon_1 d_2^2 + \varepsilon_2 d_1^2)$; D_1 is Fick's diffusion coefficient, m^2/s ; and D_2 is transitional diffusion coefficient, m^2/s .

Equation (50) establishes the relationship between mesoscale structure parameters and the macroscale diffusion coefficient. The diffusion process of the VOC inside the pores can be controlled by changing the mesoscale structure. The effective coefficients calculated using this model come within 20% of the values obtained by Qian et al. (2007) from experimental data using the same material.

Zheng et al. (2012) developed a capillary bundle model for gas diffusion through fractal porous media based on fractal characteristics of porous media and rarefied gas effect of small-size pores/capillaries. It is found that the proposed gas-diffusivity model is expressed as a function of micro-structural parameters (the pore area fractal dimension, the tortuosity fractal dimension, porosity, and pore sizes) of porous media.

Liu et al. (2015b) proposed a multistage series-connection fractal capillary-bundle (MSFC) model, which assumed that the variable-diameter capillaries formed by macropores connected in series as the main mass-transfer paths in porous building materials. An analytical solution of D_e was deduced from the MSFC model, which included a detailed description of the fractal structures in porous building materials.

The Partition Coefficient, K

It has been reported that the characteristic parameters D and K are related to the chemical and physical properties of a VOC, for example, the molecular weight (M) and the vapor pressure (P). Based on the experimental data, correlations between diffusion coefficient and molecular weight, partition coefficient and vapor pressure, were separately derived by Bodalal et al. (2001):

$$D = a/M^{n_1} \quad (51)$$

$$K = b/P^{n_2} \quad (52)$$

where, a , b , n_1 , and n_2 are constants for a specific chemical class in target material.

The results indicate that the diffusion coefficient is inversely proportional to the molecular weight. Also, the partition coefficient is inversely proportional to vapor pressure at a given temperature.

Wang et al. (2008) derived a correlation between K and the VOC liquid molar volume based on the theory of adsorption potential, expressed as follows:

$$\ln K = c_1 v_l + c_2 \quad (53)$$

where v_l is the VOC liquid molar volume, and c_1 and c_2 are constants for a specific chemical class in the material.

Liu et al. (2015a) deduced that a dual-scale calculation model of K based on the Dubinin-Radushkevich and Freundlich adsorption theory (Freundlich and Hatfield 1926), respectively, corresponded with micropores and macro-mesopores in porous materials. The model considers several factors that affect the partition coefficient, such as pore scale, porosity, temperature, VOC properties, and other parameters.

Dimensionless Analysis of Characteristic Parameters

Dimensionless analysis is a powerful approach to solving the two aforementioned problems. Xu and Zhang (2003) normalized the equations in Little et al.'s model by using dimensionless analysis without the assumption that h_m is infinitely large. They found that the dimensionless emission rate of VOCs is a function of Bi_m/K and Fo_m , where Bi_m is the Biot number for mass transfer, and Fo_m is the Fourier number for mass transfer. The result reveals general emission characteristics of VOCs from building materials. Based upon their dimensionless analysis, the applicable

condition of Little et al.'s model was derived as: $Fo_m > 10^{-4}$, and $Lt > 35$. Using this condition, the relative error of the emission rate calculated is less than 5%. To simplify the analysis, Bi_m/K , is suggested as the Little number, Lt . The physical meaning of Lt is the ratio of diffusion mass-transfer resistance in material to convective mass-transfer resistance in air with mass transfer expressed as chemical potential or fugacity. This study is the first approach using dimensionless analysis to obtain generalized VOC emission correlations for building materials by fitting the experimental data. For VOC emissions from building materials, the material/air partition coefficient is generally in the range of 10^2 – 10^5 , which results in Lt greater than 10. This means that the emission characteristics are mainly controlled by internal diffusion, and that external convection only occurs during the initial period of the emission process (Xu and Zhang 2003).

Qian et al. (2007) presented a detailed dimensionless analysis of VOC emissions. Based on the associated mass-transfer model, they obtained dimensionless correlations between VOC emission rate and total VOC emission quantity and found that the dimensionless emission rate and total emission quantity are functions of just four dimensionless parameters, Bi_m/K or Lt , Fo_m , the dimensionless air exchange rate (NL^2/D), and the ratio of building material volume to chamber or room volume (AL/V). Using the correlations, the VOC emission rate from dry building materials can be conveniently calculated without having to solve the complicated mass-transfer equations. Thus, it is very simple to estimate VOC emissions for a given condition. The relationship also explicitly explains the impacts of air velocity, load ratio, and air exchange rate on the VOC emission rate.

It should be noted that the correlations of Qian et al. (2007) are applicable only to ventilated conditions. To obtain dimensionless correlations for airtight conditions, Xiong et al. (2011c) derived empirical correlations to predict the dimensionless rate, $E(t)$, based on dimensionless parameters, βK , Fo_m , and Bi_m/K . The predicted correlation is in quite good agreement with the experimental results. Based on the model presented by Little and Hodgson (1996), empirical correlations are derived by Deng et al. (2010) to predict the sorption behavior of VOC in solid material, associated with the dimensionless parameters α , βK , and Fo_m .

Source Control to Reduce the VVOC/VOC Emissions

Compared with other common VOC reduction measures (e.g., ventilation dilution, air purification), source control is a more straightforward and better approach to reduce indoor VOC emission rates or concentrations. Considering that the emission rate or concentration is a function of the three emission parameters C_0 , D , and K , methods for source control are focused on restraining one or more characteristic parameters, as the following examples show:

Yuan et al. (2007) proposed a low diffusive barrier layer (clay/polyurethane composite layer) to reduce emissions. The existence of nanoparticles results in a highly tortuous diffusion path, which greatly reduces D , thus decreases the emission rate. Using a low diffusion-coefficient film as a decorative layer in flooring material,

VOC emissions from flooring material were greatly reduced by He et al. (2010). By lowering the ratio of formaldehyde to urea in the resin, and adding formaldehyde scavengers during the panel manufacturing process, formaldehyde emissions have also been reduced by Roffael (2006).

Influencing Factors on VVOC/VOC Characteristic Parameters

The Initial Emittable Concentration, C_0

Temperature and relative humidity can simultaneously change in indoor environment, which significantly affects the emission rate of formaldehyde and VOCs from building materials. Xiong and Zhang (2010) found that C_0 of formaldehyde in building material changes with environmental conditions, in particular with temperature. A similar phenomenon was investigated by Crawford and Lungu (2011), i.e., that C_0 of styrene from a vinyl ester resin thermoset composite material changed with temperature. To quantify the relationship between the C_0 and environmental temperature, theoretical correlations between the proportion of emittable amount to the total amount ($P = C_0/C_{\text{total}}$) and temperature was obtained by Huang et al. (2015):

$$\ln P \sqrt{T} = -\frac{H_1}{T} + H_2 \quad (54)$$

$$C_0 = \frac{H_3}{\sqrt{T}} \exp\left(-\frac{H_1}{T}\right) \quad (55)$$

where P is the proportion of emittable amount (C_0) to the total amount (C_{total}), T is the temperature, K, $H_3 = C_{\text{total}} \exp(H_2)$, H_1 and H_2 are constants independent of temperature and are related to the physical properties of the material-formaldehyde combinations.

The derived correlations (Eqs. (54) and (55)) quantitatively establish the relationship between P , C_0 , and T for formaldehyde emissions from building materials. When the parameters H_1 and H_2 (or H_3) are obtained from available results, the derived correlations can be used to predict P and C_0 at other temperatures. This is very helpful and should be useful for engineering applications.

Linear curve fitting by applying Eq. (54) to the experimental data of formaldehyde emissions at different temperatures, as well as data from previous research (Huang et al. 2013) is shown in Fig. 17. The results indicate that both R^2 are about 0.97, demonstrating a high accuracy.

Prior studies generally focused on the single effect of temperature or relative humidity, and the combined effect was not considered. Xiong et al. (2016) investigated the comprehensive influence of temperature and relative humidity on the C_0 and on the emission rate of pollutants from building materials, and derived correlations between C_0 and combined environmental factors theoretically, or:

Fig. 17 Comparison of theoretical correlations and experimental data. (Reprinted from Huang et al. (2015), Copyright 2015, with permission from American Chemical Society)

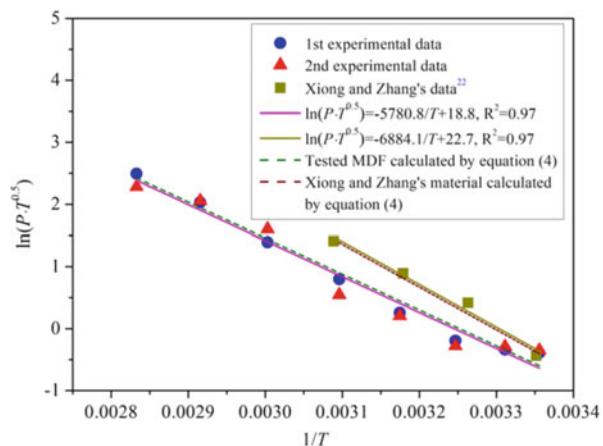

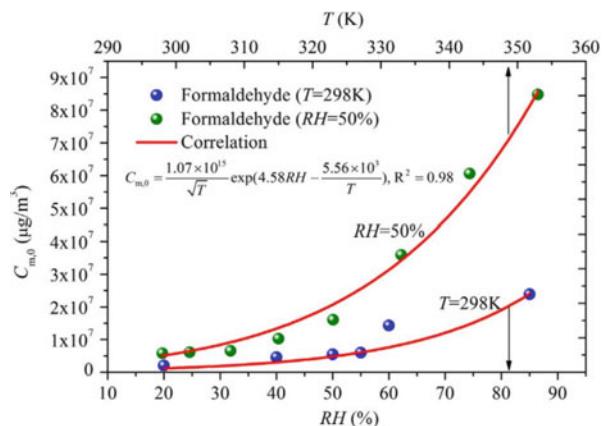

Fig. 18 The correlation between C_0 and T , RH for formaldehyde emissions from medium density fiberboard. (Reprinted from Xiong et al. (2016), Copyright 2016, with permission from Elsevier)

$$C_0 = \frac{H_1}{\sqrt{T}} \exp \left(H_2 \cdot RH - \frac{H_3}{T} \right) \quad (56)$$

where T is the environmental temperature, K ; RH is the relative humidity; and H_1 , H_2 , and H_3 are positive constants, which do not change with temperature and relative humidity, but are only related to the physical and chemical properties of the material-pollutant combinations.

Regression results of the correlation between C_0 and the comprehensive effect are shown in Fig. 18. The fitting degree (R^2) is 0.98, indicating acceptable regression accuracy.

The Diffusion Coefficient, D

Diffusion of VOCs in building materials is a function of molecular motion, so the diffusion coefficient is strongly dependent on temperature. For VOC diffusion in porous materials, when molecular diffusion is dominant, Deng et al. (2009) derived a theoretical correlation to characterize the influence of temperature on D :

$$D = H_1 T^{1.25} \exp\left(-\frac{H_2}{T}\right) \quad (57)$$

where H_1 and H_2 are positive constants, which are not related to temperature, but are only related to the physical and chemical properties of the material-pollutant combinations.

Calculations using Eq. (57) agree well with experimental data for four types of building materials. Huang et al. (2015) measured the C_0 , D , and K of formaldehyde from a medium density fiberboard (MDF) at eight different temperatures, and found that if the temperature is below 50 °C, the D increases with increasing T , while if the temperature is above 50 °C, the D may decrease with the increase of T . The possible explanation given by Huang et al. (2015) is that when the temperature is relatively high, the diffusion may change from Fickian diffusion to transition diffusion or Knudsen diffusion, resulting in the decrease of D .

The Partition Coefficient, K

The Arrhenius relation is used for some sorption transport phenomena (e.g., chemical engineering sorption separation) to characterize the impact of temperature on the partition coefficient (Ruthven et al. 1984):

$$K = K_0 \exp\left(-\frac{U}{RT}\right) \quad (58)$$

where U is internal energy of desorption; R is the universal gas constant, and K_0 is a constant independent of temperature.

Based on the Langmuir equation, Zhang et al. (2007) derived a correlation between partitioning coefficient and temperature as follow:

$$K = H_1 T^{0.5} \exp\left(-\frac{H_2}{T}\right) \quad (59)$$

where H_1 and H_2 are positive constants, which are not dependent on temperature, but are only related to the physical and chemical properties of the material-pollutant combinations.

The correlation derived by Zhang et al. (2007) is similar to the Arrhenius equation. However, the correlation derived in this study has one more term, $T^{0.5}$. Experiments for formaldehyde emissions from four types of building materials at

different temperatures ranging from 18 °C to 50 °C were performed by Zhang et al. (2007), and the results validated the reliability of the temperature correlation. For the experiments conducted by Huang et al. (2015), it was found that if the temperature is below 50 °C, the K decreases with a decrease of T , while if the temperature is above 50 °C, K may increase with an increase of T . The mechanistic reason for explaining this phenomenon requires further study.

Conclusions

Investigating the source/sink characteristics of VVOCs and VOCs in building materials is a prerequisite for understanding emission mechanisms to achieve improved source control of indoor pollutants. This chapter reviewed research on predictive models for VVOC/VOC source/sink characteristics and highlighted methods for measuring the source emission parameters of indoor materials, providing the foundation for comprehending the mass-transfer principle and improving indoor air quality.

There remain many issues that require further investigation, including: (1) When multiple source or sink materials exist simultaneously in indoor environments, the emission/sorption behaviors from/to materials become more complicated, which requires more complex models to describe the mass-transfer process; (2) more attention should be paid to long-term contaminant emission behaviors and relevant modeling; (3) the emission characteristics of VOCs from human skin due to the use of personal care products or chemical reactions with chemicals in ambient air; and (4) the mechanisms underlying the influence of temperature, humidity, and timing on key emission characteristic parameters, especially factors varying in a wide range.

Besides the building materials, residents also contribute to indoor air pollution. The metabolic products of the human body are generally released into ambient air through the skin or breath, and may react with oxidized media in the environment to generate new pollutants (e.g., VOCs). The impact of human occupancy on the indoor environment is far more important than initially imagined and further investigations are likely to uncover additional impacts. Research on the reaction between the human body and the ambient air may significantly enrich the knowledge of VOC mass transfer behavior in the indoor environment.

Nomenclature

A	Source emission area, m ²
Bi_m	Biot number for mass transfer
C	Material-phase contaminant concentration, µg/m ³

C_0	Initial emittable contaminant concentration, $\mu\text{g}/\text{m}^3$
C_1	Equilibrium contaminant concentration in the primary chamber, $\mu\text{g}/\text{m}^3$
C_2	Equilibrium contaminant concentration in the secondary chamber, $\mu\text{g}/\text{m}^3$
C_a	Contaminant concentration in chamber air, $\mu\text{g}/\text{m}^3$
$C_{a,0}$	Initial chamber contaminant concentration, $\mu\text{g}/\text{m}^3$
C_{ad}	Adsorbed-phase concentration of VOC in porous media, $\mu\text{g}/\text{m}^3$
C_{equ}	Equilibrium contaminant concentration in the chamber, $\mu\text{g}/\text{m}^3$
$C_{equ,i}$	Equilibrium contaminant concentration in the chamber during the i th period, $\mu\text{g}/\text{m}^3$
C_g	Gas-phase concentration of VOC in porous media, $\mu\text{g}/\text{m}^3$
C_{in}	Inlet contaminant concentration, $\mu\text{g}/\text{m}^3$
C_m	Material-phase contaminant concentration in the liquid film, $\mu\text{g}/\text{m}^3$
C_s	Material-phase contaminant concentration in the substrate, $\mu\text{g}/\text{m}^3$
C_{sat}	Saturation concentration of contaminant at given temperature, $\mu\text{g}/\text{m}^3$
C_{total}	The total contaminant concentration in the material, $\mu\text{g}/\text{m}^3$
D	Diffusion coefficient, m^2/s
D_1	Fick's diffusion coefficient, m^2/s
D_2	Transitional diffusion coefficient, m^2/s
d_1	Average diameter of macropores, m
d_2	Average diameter of mesopores, m
D_{ad}	Adsorbed-phase diffusion coefficient of VOC in porous media, m^2/s
D_e	Effective diffusion coefficient in the porous material, m^2/s
D_g	Effective gas-phase diffusion coefficient of VOC within porous media, m^2/s
D_m	Effective diffusion coefficient in the liquid film, m^2/s
D_r	Mean (reference) diffusion coefficient in the porous material, m^2/s
D_s	Diffusion coefficient in the substrate, m^2/s
Fo_m	Mass transfer Fourier number
$g(x,t)$	Time and space dependent VOC generation/elimination due secondary source/sink behavior, $\mu\text{g}/(\text{m}^3 \cdot \text{s})$
h_m	Convective mass transfer coefficient, m/s
K	Partition coefficient
k_a	Adsorption rate constant, $1/\text{s}$
k_d	Desorption rate constant, m/s
L	Thickness of the material, m
L_f	Paint film thickness
m	Steady-state mass flux of contaminant through the material, $\mu\text{g}/\text{s}$
M	Contaminant mass on sink surface, $\mu\text{g}/\text{m}$
M_0	Initial emittable contaminant mass, μg
M_s	Certain mass of contaminant injected in headspace method, μg
n	Total number of emission cycles
P	Proportion of emittable contaminant amount in the total amount
Q	Ventilation rate, m^3/s
R	Universal gas constant
R_c	Reaction rate constant, $1/\text{s}$

R_v	Ratio of chamber volume to the material volume
S_f	Saturation of VOC liquid in the pores of paint film
T	Temperature, K
t	Emission time (s)
U	Internal energy of desorption
v_l	Contaminant liquid molar volume
V	Volume of environmental chamber, m^3
x	Linear distance, m
y	Initial contaminant concentration in the high-concentration chamber, $\mu\text{g}/\text{m}^3$
y_1	Concentration in the high-concentration chamber, $\mu\text{g}/\text{m}^3$
y_2	Concentration in the high-concentration chamber, $\mu\text{g}/\text{m}^3$

Greek Letters

α	Dimensionless air exchange rate
β	Ratio of material volume to chamber volume
ε	Porosity of porous media
ε_1	Porosity of the macropores
ε_2	Porosity of the mesopores
τ	Tortuosity factor
φ_f	Porosity of the paint film

Abstract

Semivolatile organic compounds (SVOCs) are ubiquitous and persistent in indoor environments. It is important to understand the mechanisms governing their emission, sorption, and transport. This article reviews the source and sink characteristics of SVOCs, including their emission from source materials, sorption to sink surfaces, and sorption to particles or dust, as well as the experimental and modeling methods to determine key parameters that control these processes.

Keywords

SVOC · Emission · Sorption · Modeling, Chamber test

Introduction

Semivolatile organic compounds (SVOCs) are a group of organic compounds with vapor pressures ranging from 10^{-9} Pa to ~ 10 Pa (Weschler and Nazaroff, 2008) and boiling points ranging from 240 °C to 400 °C (WHO 2010). They are extensively used as additives in building materials and consumer products to enhance product performance. For example, polybrominated diphenyl ethers (PBDEs) and phthalate esters are the most typical flame retardants and plasticizers, respectively. Since they are not chemically bound to the polymer matrix, they can slowly emit from source materials to the surrounding environment (Kemmlein et al. 2003; Xu and Little 2006; Xu et al. 2009, 2010). In addition, combustion by-products, such as nicotine and polycyclic aromatic hydrocarbons (PAHs), as well as pesticides and biocides, such as organophosphates, carbamates, and pyrethroids, are also SVOCs.

SVOCs are ubiquitous and persistent in the indoor environment. Because of their low vapor pressure, they tend to partition/sorb onto airborne particles, dust, and interior surfaces, including windows, mirrors, dishware, furniture, clothes, and even human skin (Weschler and Nazaroff 2008; Wang et al. 2010; Nazaroff and Goldstein 2015). Weschler and Nazaroff (2008) showed that if ventilation serves as the only removal mechanism, SVOCs with a moderate sorption capacity can remain indoors for hundreds to thousands of hours, while those with strong sorption capacity can persist for years, so that sinks such as furniture may even become secondary sources.

The presence of SVOCs in indoor environments may lead to significant human exposure through inhalation, ingestion, and dermal uptake. Airborne SVOCs including gas-phase and particle-phase SVOCs are inhaled by residents. Ingestion may occur with intake of dust and food contaminated by SVOCs. Children are the main target for this exposure pathway due to frequent hand-to-mouth contact. Dermal uptake usually results from direct contact with SVOCs on sink surfaces and as a result of SVOC transport from contaminated air directly to skin. Some studies have suggested that longtime exposure to SVOCs will lead to adverse health effects (Shelby 2006). For example, many studies reported that exposure to several kinds

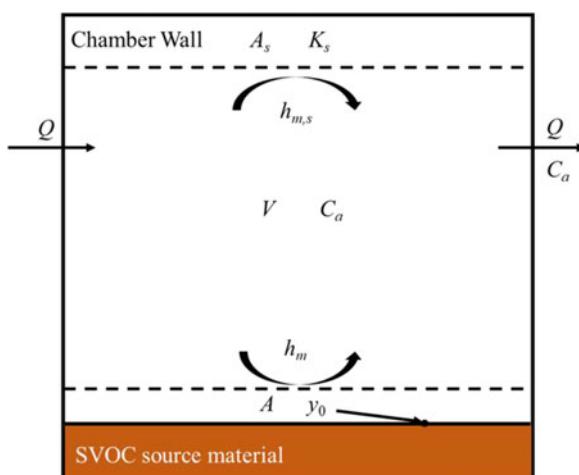

of phthalates including butyl benzyl phthalate (BBzP), di-n-butyl phthalate (DnBP), and di-(2-ethylhexyl) phthalate (DEHP) is associated with irreversible changes in reproductive tract development (Kay et al. 2013, 2014; Zarean et al. 2016; Hoyer et al. 2018). Other serious health concerns such as autism spectrum disorders, disruption of hormones, prenatal mortality, reduced growth and birth weight, allergy and childhood asthma, thyroid function alteration, decreased semen quality, and permanent learning and memory impairment were also found to be associated with phthalate and organophosphate exposure (Meeker and Stapleton 2010; Dishaw et al. 2014; Miodovnik et al. 2014; Ferguson et al. 2016; Hoffman et al. 2017; Zhao et al. 2017). Therefore, it is of great necessity to investigate the emission/sorption behavior (source/sink characteristics) of SVOCs and evaluate the potential human exposure levels and risks.

SVOC Emissions from Source Materials

Emission Model

Similar to (Volatile organic compounds) VOCs, the emission of SVOCs from building materials, consumer products, and articles consist of two processes: molecular diffusion in the source material and surface convective mass transfer to the surrounding air. These processes are illustrated in Fig. 1, with an SVOC source material slab placed in a chamber. Xu and Little (2006) proposed a mathematical model that describes these processes and predicts the emission rate of SVOCs from polymeric materials. In the model, the transient diffusion of SVOCs in the source material is expressed by Fick's second law:

Fig. 1 Schematic of SVOC mass transfer in a chamber (in the absence of suspended particles). (©With permission of Cao et al. 2017)

$$\frac{\partial C(x, t)}{\partial t} = D \frac{\partial^2 C(x, t)}{\partial x^2} \quad (1)$$

where $C(x, t)$ ($\mu\text{g}/\text{m}^3$) is the SVOC material-phase concentration, D (m^2/s) is the material-phase diffusion coefficient, x (m) is the vertical distance from the bottom of the slab, and t (s) is elapsed time. At the beginning, the SVOC concentration is assumed to be uniform throughout the material, which leads to the initial condition:

$$C(x, t) = C_0 \text{ for } t = 0, 0 \leq x \leq L \quad (2)$$

where C_0 ($\mu\text{g}/\text{m}^3$) is the initial material-phase concentration and L (m) is the vertical length of the slab. The boundary condition at the base of the slab is

$$\frac{\partial C(x, t)}{\partial t} = 0 \text{ for } t > 0, x = 0 \quad (3)$$

The boundary condition of the top of the slab is

$$-D \frac{\partial C(x, t)}{\partial x} = h_m(y_0(t) - y(t)) \text{ for } t > 0, x = L \quad (4)$$

where y_0 ($\mu\text{g}/\text{m}^3$) is the SVOC gas-phase concentration in equilibrium with the material phase and immediately adjacent to the slab surface, y ($\mu\text{g}/\text{m}^3$) is the SVOC gas-phase concentration in the chamber air, and h_m (m/s) is the external convective mass-transfer coefficient. An instant partition equilibrium is assumed to exist between the material surface and the air near the surface, or

$$C(x, t) = K_{ma}y_0(t) \text{ for } t > 0, x = L \quad (5)$$

where K_{ma} is the source surface/air partition coefficient.

After emission from the source material, gas-phase SVOCs will sorb to the chamber surfaces, with sorption potentially expressed by Langmuir or Freundlich isotherms, both of which are characterized by the sink surface/air partition coefficient, or

$$q(t) = K_s y(t) \quad (6)$$

$$q(t) = K_s y(t)^n \quad (7)$$

where q ($\mu\text{g}/\text{m}^2$) is the sink surface-phase concentration of SVOC, K_s (m) is the sink surface/air partition coefficient, and n is the Freundlich isotherm parameter.

The SVOC accumulated in a chamber obeys the following mass balance:

$$\frac{dy(t)}{dt}V = Qy_{in}(t) + A\dot{m}(t) - A_s \frac{dq(t)}{dt} - Qy(t) \quad (8)$$

$$\dot{m}(t) = h_m(y_0(t) - y(t)) \quad (9)$$

where V (m^3) is the chamber volume, Q (m^3/s) is the air flow rate, y_{in} ($\mu\text{g}/\text{m}^3$) is the gas-phase concentration of SVOC at the inlet, A (m^2) is the source surface area, \dot{m} ($\mu\text{g}/(\text{m}^2\text{s})$) is the emission rate, and A_s (m^2) is the sink surface area.

The above model clearly shows that the emission rate of SVOCs is influenced by the partition and sorption behavior. Based on the model, Xu and Little (2006) conducted sensitivity analysis to identify the most important parameters that influence SVOC emission. They found that emissions of SVOCs are subject to “external” control (partitioning from the material into the gas phase, convective mass transfer through the boundary layer, and strong sorption onto interior surfaces including airborne particles). The main difference between VOC and SVOC emissions is mainly due to their different physicochemical properties. Compared to VOCs, the vapor pressures of SVOCs are much lower, which results in their strong sorption to surfaces. Therefore, external gas-phase resistance and exterior sinks dominate the emission behavior of SVOCs. Moreover, the initial material-phase concentration C_0 of SVOCs is usually much higher than that of VOCs, making the material-phase concentration effectively constant, meaning that diffusion is not an important mechanism.

Existing Methods for Measuring Key Emission Parameter (y_0)

CLIMPAQ and FLEC Chamber Methods

Clausen et al. (2004) applied CLIMPAQ (Chamber for Laboratory Investigations of Materials, Pollution, and Air Quality) and FLEC (Field and Laboratory Emission Cell) to investigate the emission of DEHP from PVC flooring. Air in both chambers was sampled at the outlet and analyzed to obtain the DEHP concentration ($\mu\text{g}/\text{m}^3$). The entire emission experiment lasted for almost 400 days. At the beginning of the experiment, the gas-phase concentration increased over time, but after 150 days, the concentration tended to remain stable, which indicated that the emission process had reached steady state. To characterize the emission behavior, the specific emission rate (SER , $\mu\text{g m}^{-2} \text{h}^{-1}$) was calculated using the steady-state data:

$$SER = C \cdot N / L \quad (10)$$

where C ($\mu\text{g}/\text{m}^3$) is gas-phase concentration at steady state, N (h^{-1}) is the air exchange rate, and L (m^2/m^3) is the test pieces loading factor. The $SERs$ in CLIMPAQ are in the range of 0.2–0.4 $\mu\text{g}/\text{m}^2/\text{h}^1$, approximately 5–10 times lower than that in FLEC, with 1–1.6 $\mu\text{g}/\text{m}^2/\text{h}^1$. The inconsistency may be explained by the five times higher L/N ratio in CLIMPAQ. Therefore, SER changes with the design of

the chamber, which means it is not an ideal parameter to characterize emission of SVOCs from various materials.

As mentioned earlier, the emission rate of SVOCs from a material is calculated by Eq. (9) using the mass-transfer coefficient and the concentration difference between indoor (bulk) air and y_0 . Therefore, y_0 has to be considered as the key parameter that characterizes SVOC emission. In recent years, most experimental studies and efforts were directed toward the determination of y_0 values for different SVOC/material combinations. The following sections summarize the existing methods for measuring y_0 .

Sandwich-like Chamber Method

The emission of SVOCs in CLIMPAQ and FLEC requires extremely longtime periods of time (almost 150 days) to reach steady state because of the strong sink effect of SVOCs on internal chamber walls, which demonstrates that CLIMPAQ and FLEC may not be suitable for the measurement of characteristic parameters of SVOCs. For this reason, Xu et al. (2012) developed a “sandwich-like” chamber to characterize SVOC emissions. The chamber is composed of two pieces of test material and a thin stainless steel chamber “ring,” which forms a cylindrical chamber cavity by placing the “ring” in between the two test material pieces and then pressing them tightly together (Fig. 2). In this way, the emission area is maximized, and the sorption area is minimized to reduce the impact of SVOC sorption to the chamber surfaces. Using this chamber to test the emission of DEHP from PVC flooring, the time for gas-phase DEHP to reach steady state is considerably reduced to about 20 days, which is a significant improvement compared to the CLIMPAQ and FLEC chambers.

Based on this sandwich-like chamber, Liang and Xu (2014a, b) further improved the performance of the chamber by changing the chamber shape from cylindrical to half-cylindrical (Fig. 3), with three inlets and six outlets to increase air flow mixing

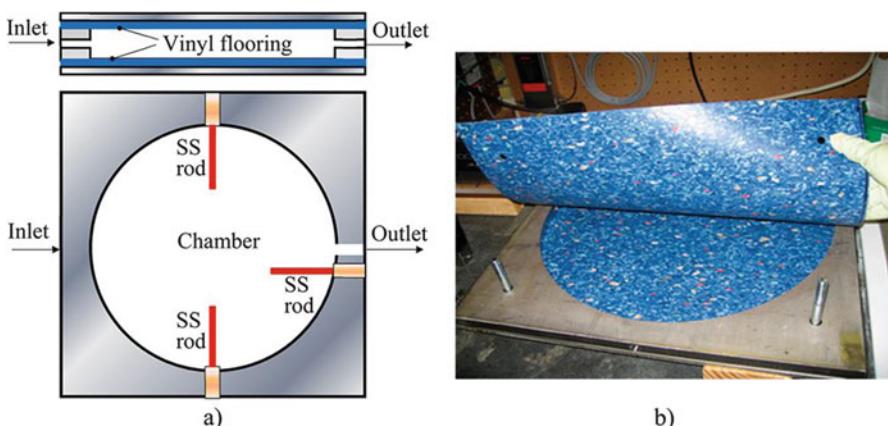

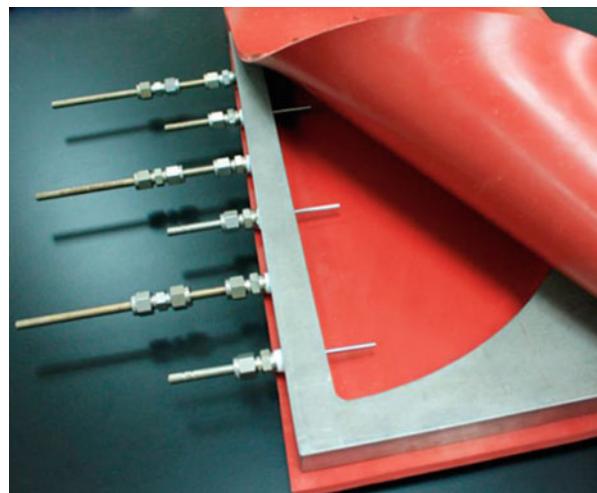

Fig. 2 Configuration of the chamber; (a) side and top view, (b) photo. (©With permission of Xu et al. 2012. Copyright 2021 American Chemical Society)

Fig. 3 The specially designed sandwich-like chamber. (©With permission of Liang and Xu 2014a. Copyright 2021 American Chemical Society)

and to increase the air flow rate. With the improved method, the time to reach steady state was shortened to less than 5 days. In addition, they measured the y_0 values of a range of phthalates from various vinyl floorings based on the following equation, which is obtained by applying the steady-state condition to Eq. (8):

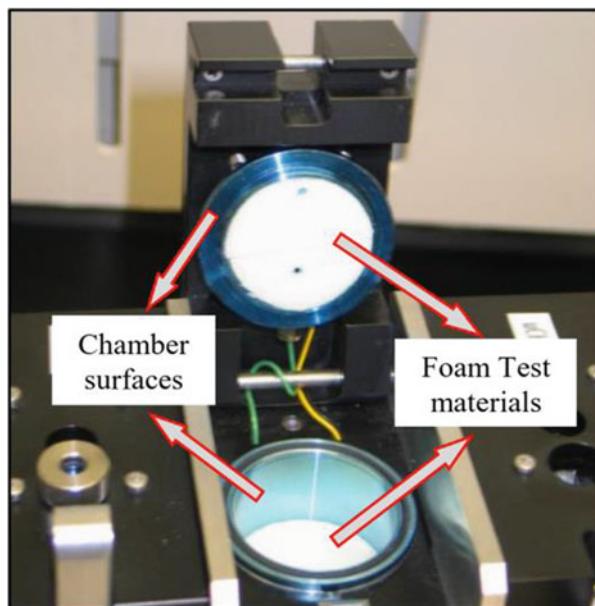

$$y_0 = \frac{y_{ss} \cdot Q}{h_m \cdot A} + y_{ss} \quad (11)$$

where y_{ss} is the gas-phase concentration of SVOC at steady state. Although this specially designed chamber is a significant improvement from the earlier SVOC emission tests, it still has some limitations. For example, since the gas tightness is formed by the test material itself, it is required to be flat, impervious, and flexible, which limits the applicability of this emission chamber to certain materials.

To overcome the abovementioned limitation, Liang et al. (2018a, b) developed a material-air-material (M-A-M) open-ended cylinder microchamber to measure y_0 of organophosphate flame retardants (OPRFs) from a polyisocyanurate rigid foam. When conducting emission experiments, two pieces of foam are attached to the bottom and the top of the chamber using double-sided tape. As shown in Fig. 4, unlike the sandwich-like chamber developed by Xu et al. (2012), the M-A-M emission chamber is self-sealed rather than being sealed by the test materials. Therefore, it broadens the scope of application to pervious materials.

Furthermore, it is also “sandwich-like,” so that the ratio of emission to sorption surface area is also large. Using this chamber, the gas-phase concentration of OPRFs (TCEP and TCPP) reaches steady state within 40 h. However, the common drawback of the sandwich-like methods is that the convective mass-transfer coefficient h_m at the source surface is required to be measured independently, which results in additional experiments and brings potential errors to the measured y_0 .

Fig. 4 The M-A-M microchamber with source materials. (©With permission of Liang et al. 2018b. Copyright 2021 American Chemical Society)

Yang et al. (2019) applied the sandwich-like emission chamber developed by Xu et al. (2012) to simultaneously determined y_0 and h_m values of DEHP emission from vehicle cabin materials. Yang et al. (2019) used different calculation methods to obtain y_0 . Equation (11) is still used in the determination of y_0 , but it is transformed into:

$$\frac{1}{y_{ss}} = \frac{Q}{h_m A y_0} + \frac{1}{y_0} \quad (12)$$

Since h_m can be expressed as a function of Q , or $h_m = C_1 Q^{0.5}$, Eq. (12) can be rewritten as:

$$\frac{1}{y_{ss}} = \frac{Q^{0.5}}{C_1 A y_0} + \frac{1}{y_0} \quad (13)$$

where C_1 is a constant related to the size of the test material and the physical properties of SVOCs. A series of experiments were conducted at different ventilation rates and the respective y_{ss} values were measured to obtain the slope and intercept by linear curve fitting (varied ventilation rate [VVR] method). By this means, C_1 , y_0 , and h_m were derived simultaneously, and the potential errors of y_0 caused by h_m can be avoided. Solid-phase microextraction (SPME) was used for steady-state chamber air sampling instead of Tenax thermal desorption (TD) tubes. SPME possesses the virtue of nonexhaustive and small-volume sampling, leading to shorter extraction

time compared with other methods. However, because this is a passive sampling method, the amount of SVOC extracted by SPME cannot reflect the gas-phase SVOC concentration directly, and calibration is needed, which may result in further experiments and errors. In addition, there are some other limitations in Yang's method. The determination of one y_0 value requires at least four different flow rate experiments, and for each flow rate experiment, the SPME method needs to be calibrated again, because the extraction amount of SPME at equilibrium varies with ventilation rate. Therefore, the test process is complicated, and the experimental time is hardly reduced. Moreover, the regression method has a risk of multiple solutions since more than one parameter is determined simultaneously (He and Yang 2005).

A microemission cell (μ EC) chamber (Fig. 5), which can be easily held in one hand, was developed by Li et al. (2022, *in preparation*) to characterize the emission of multiple SVOCs from various consumer products. Combined with a novel active air sampling technique, the needle trap device (NTD), the time for gas-phase SVOCs in the μ EC to reach steady state was significantly reduced. For example, DEHP emitted from car interior can be characterized within 10 min. This is attributed to the high ratio of emission to sorption surface area, no loss of SVOCs in sampling pathways, the high mass transfer enhanced by using a fan, and the improvement of the sensitivity of the sampling device.

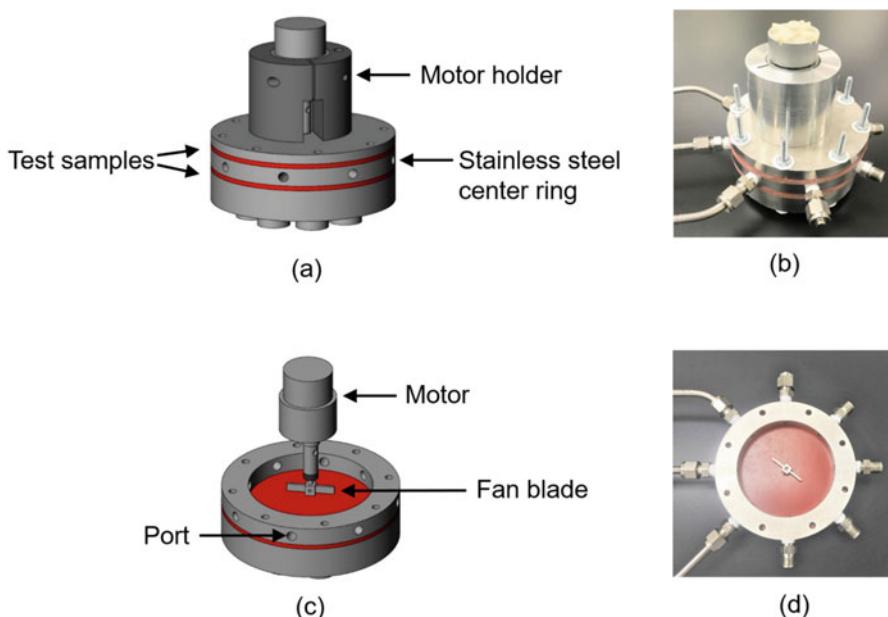

Fig. 5 (a) Configuration of microemission cell; (b) photo of microemission cell; (c) configuration of open microemission cell; and (d) photo of top view of open microemission cell. (Li et al. 2022, *in preparation*)

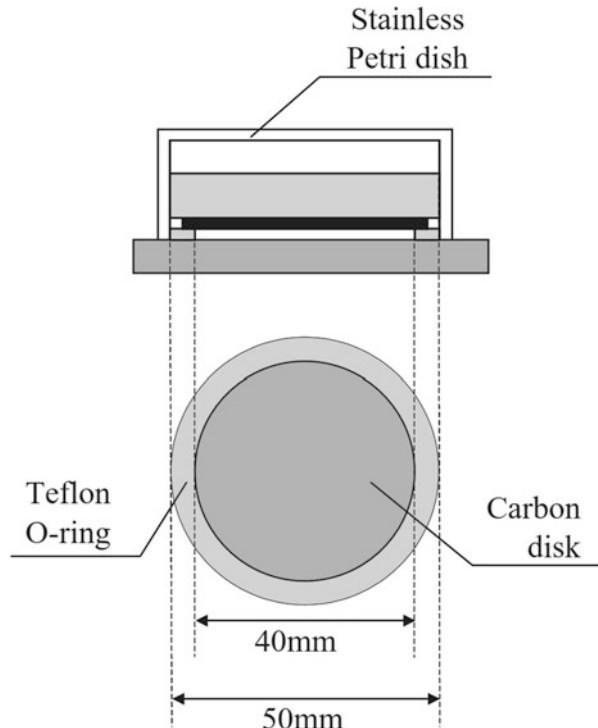

Passive Flux Sampler (PFS) Method

A diffusion-based passive flux sampler for measuring the emission flux of phthalate esters was first developed by Fujii et al. (2003). The configuration of the sampler is displayed in Fig. 6. The phthalate esters emitted from the test materials diffuse through the O-ring and adsorb directly onto the carbon disk. After several days of exposure, the carbon disk is removed for chemical analysis, and the flux can be calculated by Fick's law.

Based on the PFS developed by Fujii et al. (2003), a series of investigations (Ni et al. 2007; Noguchi and Yamasaki 2016) concerning SVOC emissions under different temperature conditions was conducted. Moreover, the relationship between emission flux and chemical content in the materials was examined.

Wu et al. (2016) also proposed a simple diffusion-based passive flux sampler method to measure y_0 . Standard stainless steel thermal desorption tubes (Tenax TA tubes) are employed in this method. As shown in Fig. 7, the test material that is perpendicular to and placed at the opening of the Tenax TA tube serves as the SVOC source. Tenax TA packed in the upper section of the tube serves as a perfect and instantaneous SVOC sink. A large and a small cylinder are used to hold the tube in place. Corresponding to this method, a mechanistic model was developed to describe the transport of gas-phase SVOCs in the tube (Fig. 8). Gas-phase SVOC transient

diffusion in the tube is characterized by Fick's second law, and the analytical solution is derived as:

$$C(x, t) = y_0 \left(1 - \frac{x}{L}\right) + \frac{2}{\pi} \sum_{n=1}^{\infty} \left(-\frac{y_0}{n}\right) \cdot \sin\left(\frac{n\pi x}{L}\right) \cdot \exp\left(-\frac{D_a n^2 \pi^2 t}{RL^2}\right) \quad (14)$$

where $C(x, t)$ ($\mu\text{g}/\text{m}^3$) is the SVOC gas-phase concentration in desorption tube at location x and time t , D_a (m^2/s) is the SVOC diffusion coefficient in air, R is a retardation factor caused by tube surface adsorption, and L (m) is the length of the air diffusion path.

This mathematical model assumes that SVOC gas-phase concentration is evenly distributed at the cross-section of the desorption tube. However, while SVOCs diffuse in the tube, they will be adsorbed by the inner tube surface, and this process is described by an instantaneous linear partition equilibrium:

$$q(x, t) = K_s C(x, t) \quad (15)$$

where $q(x, t)$ is the surface-phase concentration of SVOC and K_s (m) is the surface/air partition coefficient. By integrating $q(x, t)$ over distance x , the adsorbed amount of SVOCs on the tube surface versus time can be expressed as:

$$M_q(t) = \int_0^x q(x, t) \pi d dx \quad (16)$$

For the perfect sink at the top of the tube ($x = L$), the mass flux diffused into it can be represented by:

$$J(t)|_{x=L} = \frac{D_a y_0}{L} \left(1 + 2 \sum_{n=1}^{\infty} \cos(n\pi) \cdot \exp\left(-\frac{D_a n^2 \pi^2 t}{RL^2}\right) \right) \quad (17)$$

By integrating $J(t)|_{x=L}$ over time t , the amount of SVOCs absorbed by the perfect sink M_j versus time is:

$$M_j(t) = \int_0^t J(t) dt \Big|_{x=L} \quad (18)$$

The total amount of SVOC emitted from source material is equal to the sum of M_q and M_j :

$$M(t) = M_q(t) + M_j(t) \quad (19)$$

By fitting the model to experimental data $M(t)$, y_0 and K_s can be simultaneously derived.

When applying the model, there is an assumption that the gas-phase concentration of SVOCs is uniform on the transversal surface of the tube. However, it may not be applicable to those SVOCs with large K_s , since the tube surface is a strong sink for these SVOCs. To this end, the authors developed a two-dimensional (2-D) model based on cylindrical coordinate to characterize these cases:

$$\frac{\partial C(r, z, t)}{\partial t} = \frac{1}{r} \frac{\partial}{\partial r} \left(r D_a \frac{\partial C(r, z, t)}{\partial r} \right) + D_a \frac{\partial^2 C(r, z, t)}{\partial z^2} \quad (20)$$

where r and z are the radius and height of the tube, respectively. The numerical solution of the 2-D model can be derived by finite difference methods, and y_0 and K_s can therefore be obtained. Wu et al. (2016b) found that for SVOCs with K_s larger than 1000 m, the 2-D model is more reliable.

Applying this method, emissions of DEHP, DnBP, and DiBP from PVC flooring were tested, and the results are comparable to those reported in the previous study (Liang and Xu 2014a). The experimental time of this diffusion-based PFS method is approximately 180 h. This method is much simpler compared with the aforementioned ventilated chamber methods, and because it is a sealed chamber, it does not need to consider the mass-transfer coefficient of the tube surfaces. However, there

are still some limitations. The 2-D mass-transfer model is complicated, and there are possibilities of multiple solutions when fitting two parameters simultaneously via nonlinear regression (Liang et al. 2018b). Liang et al. (2018a, b) used this method to determine the y_0 values of organophosphate flame retardants (TCEP, TCPP, and TDCPP) from PIR foam material, and found that the y_0 values obtained by PFS method are 48–54% lower compared with those obtained using the M-A-M method. For the limitation of complicated 2-D mass-transfer model, Eichler et al. (2018) modified the diffusive sampler by changing the thermal desorption tubes to a circular stainless steel washer with thickness of 0.254 mm. Because the diffusion distance of SVOCs was extremely short (0.254 mm), the sorption of SVOCs on inner surfaces of the washer was negligible and therefore the 1-D mass-transfer model is enough to characterize the transport of SVOCs.

SPME-Based Sealed Chamber Method

Cao et al. (2017) developed a SPME-based sealed chamber (Fig. 9) method to measure y_0 . A SPME fiber is inserted into the chamber to sample air through the holes drilled in the side of the stainless steel ring separating the two pieces of source

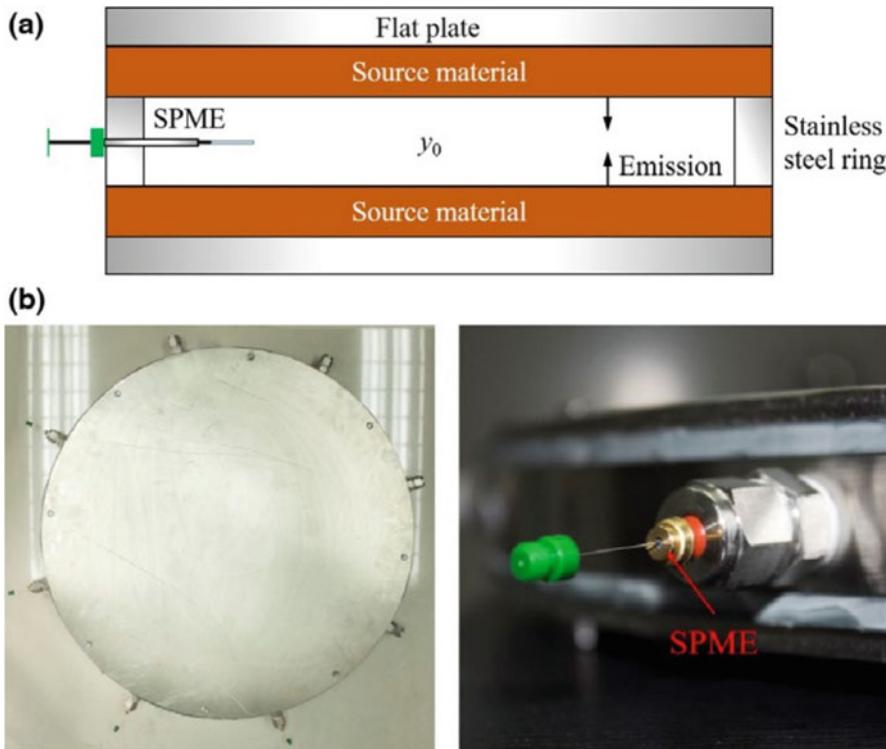

Fig. 9 (a) Schematic of the experimental system and (b) photographs. (©With permission of Cao et al. 2017)

material (Fig. 9b). The steady-state SVOC concentration in the chamber air is considered as y_0 when $Q = 0$ in Eq. (11) and it is determined by the following procedure. Ouyang and Pawliszyn (2008) recognize that the adsorption rate of SVOCs on SPME coating is constant in a short enough sampling duration (it is defined as the early stage where the adsorbed mass is less than 50% of the equilibrium mass):

$$M = D_a S C_g t \quad (21)$$

where M (μg) is the SVOC mass adsorbed on the coating, D_a (m^2/s) is the SVOC diffusion coefficient in the air, and S is the shape factor related to the length and external diameter of SPME coating. Assuming that steady state can be achieved quickly, C_g , SVOC concentration in the chamber air is substituted by y_0 :

$$M = D_a S y_0 t \quad (22)$$

Therefore, by monitoring the adsorbed mass of SVOC on the SPME coating with respect to time, y_0 can be obtained by linear curve fitting.

Cao et al. (2017) used this method to determine the y_0 of DEHP emitted from PVC floorings and the duration of the experiment was about 1 day (26 h), which is a great improvement compared to previous methods (several days or even several months). In addition, this sealed chamber method also overcomes the liability that the h_m on the source surface will cause inaccuracy in y_0 because it is often estimated. Although this method is rapid and accurate, it still has some limitations. First, it is restricted to flat and relatively soft materials. Second, the adsorption rate of SPME coating defined as $D_a S$ (Eq. 22) is irrelevant to the properties of target SVOCs, which may not hold true for all the SVOCs. For example, for SVOCs with relatively low vapor pressures, the adsorption rate of SPME coating should be smaller than for those with higher vapor pressures. Third, because the sampling must be conducted before reaching sorption equilibrium, and different SVOCs may have different sorption characteristics with respect to the SPME coating, it is necessary to investigate the sampling time in advance. Last, calibration of SPME may be time consuming and could result in substantial uncertainty.

Other Methods

Xiong et al. (Xiong et al. 2016) solved the mass-transfer model of SVOC emission (Eqs. 8 and 9) in a much simpler way compared with traditional partial differential equation-based analytical or numerical solutions. With this approach, an exponential relationship between the gas-phase SVOC concentration and elapsed time was established, by which y_0 and h_m can be derived simultaneously. Moreover, unlike most of the sandwich-like methods applying the steady-state gas-phase concentration to obtain y_0 (Eq. 11), this method does not require that steady state has been reached, but utilizes the data of the early stage of the experiment, which means the experimental duration can be shortened, and therefore it is called the “early stage C-history method.”

So far, the abovementioned methods were mainly used to measure the y_0 values of phthalates. Chemicals like flame retardants (e.g., organophosphates and PBDEs) were rarely tested due to their strong affinity to chamber surfaces and the difficulties associated with determining low concentrations. Only a few studies (Kemmlein et al. 2003; Salthammer et al. 2003; Bakó-Biro et al. 2004; Ni et al. 2007) focused on developing experimental chamber methods to measure their specific emission rates from a broad range of consumer goods (e.g., insulating materials, foams, TVs, computers, printed circuit boards, etc.). Glass tubes packed with PUF plugs and Tenax tubes were used to sample gas-phase flame retardants in a chamber (Kemmlein et al. 2003; Salthammer et al. 2003). However, as previously mentioned, these chemicals have an extremely strong sink effect, which results in very low concentrations that are difficult to be accurately detected. Therefore, it is of great importance to develop more sensitive and reliable sampling techniques for these chemicals. The NTD-GC/MS sampling and analysis technique developed by Li et al. (2022, *in preparation*) may be a potential method.

All the experimentally determined y_0 values of a variety of SVOCs emitted from different materials are summarized in Table 1.

Equilibrium Relationship Between Source Materials and Air

Relationship Between y_0 and Temperature

Several studies have found that y_0 increases rapidly with increasing temperature (Clausen et al. 2012; Liang and Xu 2014b; Bi et al. 2015; Wu et al. 2016). The relationship between temperature and the ratio of C_0 ($\mu\text{g}/\text{m}^3$) (the material-phase concentration of SVOCs in the source material) to y_0 can be characterized by the van't Hoff equation (Cao et al. 2017):

$$\ln \left(\frac{C_0}{y_0} \right) = \frac{\Delta H_p}{RT} + Y \quad (23)$$

where ΔH_p (J/mol) is the enthalpy of SVOC phase change from source material phase to gas phase, R (J/(mol · K)) is the universal gas constant, T (K) is the temperature, and Y is a constant. Because C_0 is constant for many SVOCs, Eq. (23) can be transformed into:

$$\ln y_0 = -\frac{\Delta H_p}{RT} + \ln C_0 - Y \quad (24)$$

where ΔH_p is relatively constant within a range of temperature, and in this case it can be seen from Eq. (24) that y_0 increases with increasing temperature.

Relationship Between y_0 , SVOC Weight Fraction, and Vapor Pressure

Liu and Zhang (2016) found that for DEHP emitted from PVC floorings, when the DEHP weight fraction of source material increases from 13% to 23% at 23 °C, the

^bMean value of two tests

^cMean value of the results of three positions on the test sample

ratio of y_0 to saturated gas-phase concentration of pure DEHP, y_{sat} , increases from 69% to 74%. y_{sat} is calculated as $y_{sat} = \frac{P_{sat} \cdot MW}{RT}$, where P_{sat} is the saturated vapor pressure, and MW is molecular weight. Cao et al. (2017a) observed a similar result, and derived a mathematical expression of the relationship:

$$\frac{y_0}{y_{sat,DEHP}} = 1.00 - e^{-0.0860m} \quad (25)$$

where m is the DEHP weight fraction of source material. Moreover, the relationship between $y_{sat,DEHP}$ and temperature was measured using their SPME-based sealed chamber:

$$\ln y_{sat,DEHP} = -1.00 \times 10^3 \times \frac{103.67}{RT} + 42.80 \quad (26)$$

By combining Eqs. (25 and 26), the relationship between y_0 and weight fraction can be represented as:

$$\ln y_0 = -\frac{104}{RT} + \ln(1.00 - e^{-0.0860m}) + 42.80 \quad (27)$$

It should be noted that Eq. (27) only holds true for chemicals whose enthalpy of phase change from material phase to air is approximately equal to enthalpy of vaporization for its pure liquid. Otherwise, the temperature effect on $\frac{y_0}{y_{sat,DEHP}}$ should be incorporated in Eq. (25).

The abovementioned equilibrium relationship between y_0 , y_{sat} , and m is for DEHP and PVC floorings, and whether the relationship can be applied to other chemical/material combinations remains uncertain. Eichler et al. (2018) investigated the equilibrium relationship for phthalates and their alternatives and different source materials including backpack, toys, vinyl flooring, table cloth, wall paper, and crib mattress cover. Distinct from Cao's result (2017a, b) (Eq. 25), the ratio of y_0 to y_{sat} is positively proportional to weight fraction at 25 °C:

$$\frac{y_0}{y_{ss}} = 5.12 \cdot m \quad (28)$$

Furthermore, Liang et al. (2018a, 2018b) explored the relationship for phthalates, organophosphates flame retardants, and various source materials (e.g., PVC flooring, polyisocyanurate rigid foam) with relatively low weight fraction (<15%). The result at temperature ranging from 23 °C to 25 °C is:

$$\frac{y_0}{y_{ss}} = 3.40 \cdot m \quad (29)$$

Similar to the results of Eichler (2018) and Liang et al. (2018a, b), Li et al. (2022, in preparation) also found a linear relationship between $\frac{y_0}{y_{ss}}$ and m for additional

chemical/material combinations (phthalates and their alternatives from crib mattress covers, wall covering, infant changing pads, children's backpack, etc.; organophosphates from portable crib foam, insulation board, and foam spray; dihydroxy alcohol from paints, etc.). The slope is 4.87 in Li et al. (2022, *in preparation*). The slopes obtained from these three studies are slightly different, this may be due to experimental uncertainties and variations in chemical/material combinations used in data processing. Both the structure of materials (e.g., porous or impermeable) and the type of SVOC influence the emission process because of different chemical bond interactions.

Sorption by Sink Materials

Sorption Processes and Models

Impermeable Surfaces

Because of their extremely low vapor pressure, many SVOCs prefer to sorb to the surface phase rather than remain in the gas phase, and for this reason it is important to investigate the sorption behavior of SVOCs. In ventilated environments, a boundary layer is assumed to exist between the sink material surface and bulk air. The sorption process consists of two stages: mass transfer of SVOCs from bulk air to the boundary layer and partitioning between boundary layer and sink material surface. For the first stage of mass transfer, we have:

$$\frac{dq_s(t)}{dt} = h_{m,s}(y(t) - y_s(t)) \quad (30)$$

where q_s ($\mu\text{g}/\text{m}^2$) is the sink surface-phase concentration, $h_{m,s}$ (m/s) is the convective mass-transfer coefficient near sink surface, y ($\mu\text{g}/\text{m}^3$) is the bulk air concentration, and y_s is gas-phase concentration in the boundary layer. As the mass transfer proceeds, y_s will gradually increase to y , which means that sorption equilibrium has been reached. In a quiescent environment without ventilation, there is no boundary layer and there is no difference between gas-phase concentration near the sink surface (y_s) and bulk air (y).

As for the second stage of partitioning, various models have been developed to represent the relationship between y_s and q_s . In the simplest case, a linear isotherm can be established under the following two assumptions (Schwarzenbach et al. 2016). First, the attraction of the sorption sites on surfaces to molecules remains constant throughout the entire concentration range; second, the sorption sites are far from saturated with regard to the low gas-phase concentration of chemicals (Schwarzenbach et al. 2016). The linear isotherm can be presented as:

$$q_s = K_s y_s \quad (31)$$

where q_s is the equilibrium concentration of chemical on solid surface ($\mu\text{g}/\text{m}^2$), or in the solid phase ($\mu\text{g}/\text{m}^3$), and K_s (m or dimensionless) is the partition coefficient.

However, if the sorption sites are limited and can gradually become saturated as the amount of gas-phase chemicals increases, there should be a maximum value of q_s . The linear isotherm is no longer applicable in these cases and a Langmuir isotherm (Langmuir 1916) should be adopted, expressed as (Nazaroff and Alvarez-Cohen 2001):

$$q_e = q_{max} \frac{K_L y_e}{1 + K_L y_e} \quad (32)$$

where q_{max} ($\mu\text{g}/\text{m}^2$) is the maximum equilibrium surface-phase concentration, and K_L ($\text{m}^3/\mu\text{g}$) is the equilibrium Langmuir isotherm constant. There are some assumptions that should be satisfied when applying this isotherm. First, all the sorption sites on a homogeneous surface are equally likely to be occupied by any molecules, which means each site has the same sorption-free energy. Second, the likelihood of a molecule being attached to a sorption site is independent of whether the adjacent site has been occupied by other molecules. Third, sorption is a monolayer process, with no other molecules overlaying. However, for air contaminants whose partial pressure in the air is extremely low, the sorption sites for the chemical are rarely saturated, in this case, the Langmuir isotherm can be simplified to a linear isotherm (Liang et al. 2018a).

The two abovementioned isotherms are used to describe linear sorption processes. Compared to these two, an empirical relationship referred to as the Freundlich isotherm (Freundlich 1906) is widely applied as the mathematical model for nonlinear, heterogeneous, and multilayer sorption. In these cases, the sorption sites are of different types and possess different sorption-free energies. The equation of Freundlich isotherm is:

$$q_s = K_F y_s^n \quad (33)$$

where K_F ($\text{m}^{3n-2} \times \mu\text{g}^{1-n}$) is the Freundlich constant, and n is the Freundlich exponent, which serves as an indicator of free energy potential (Weber Jr and DiGiano 1996). When $n = 1$, the equation transforms into a linear isotherm and the free energies of different sorption sites are considered as constant over the chemical concentration range. When $n > 1$, as the chemical concentration increases, the free energies increase for further sorption. Last, when $n < 1$, in contrast to the previous situation, the free energies are weakened with enhanced sorbate amount.

Linear, Langmuir, and Freundlich isotherms are the earliest, most classic, and commonly used models for the characterization of sorption. However, there exist some cases where none of these three isotherms are sufficient to describe the sorption process. To improve the effectiveness and reliability of data fitting, different combinations of these three isotherms can be developed, e.g., the Sips model (Sips 1948) and the Koble-Corrigan model (Koble and Corrigan 1952). In general, the

development of these models paved the way for establishing models specifically for SVOC sorption.

For the sorption of SVOCs, Xu and Little (2006) first proposed the use of the Freundlich equation to characterize SVOC sorption between chamber air and stainless steel chamber surfaces, while for sorption from chamber air to airborne particles, a linear relationship was adopted (Xu and Little 2006). These equations are incorporated in the SVOC emission model they developed. Later, they simplified the emission model and in this updated model, the Freundlich equation was replaced by a linear isotherm to clarify the sorption relationship of SVOCs between gases and chamber surfaces (Xu et al. 2012). Since then, the linear equilibrium relationship gained its popularity in being used to depict the partition behavior of SVOCs in either surface/air or particle/air. For example, Bi et al. (2015) adopted a linear equilibrium partition coefficient to investigate the sorption strength of phthalates on indoor surfaces such as windows, dish plates, mirrors, fabric cloths, etc. However, the author also found that a thin organic film developed at the interface between impervious surfaces and indoor air (Bi et al. 2015). This was verified by the approximation between dimensionless partition coefficients and phthalates' octanol-air partition coefficients, K_{oa} . In addition to this study, many other studies of SVOC surface sorption have demonstrated the growth and existence of organic films (Diamond et al. 2000; Liu et al. 2003; Butt et al. 2004; Wu et al. 2008). The organic films developed on impervious surfaces are formed by the dry deposition of airborne particles and the partitioning between gas-phase chemicals and film (Liu et al. 2003; Butt et al. 2004). The films comprise of condensed organic matter, inorganic molecules and ions, moisture and settled particles, and generally have a thickness of 5–20 nm (Liu et al. 2003) and grow at a rate of 0.11–0.31 nm/day (Wu et al. 2008). The surfaces coated with organic films can continuously accumulate SVOCs (Wu et al. 2017), which means that no longer a monolayer of SVOCs can be assumed, and the widely used linear model cannot reasonably explain the development of and SVOC partitioning to organic films. Therefore, the Freundlich model should be adopted in these cases. Wallace et al. (2017) quantitatively measured the amount of organic matter accumulated on petri dishes or foils, which also illustrates the necessity of applying multilayer models when organic films exit on the sorption surfaces.

Weschler and Nazaroff (2017) proposed a model accounting for the film growth contribution of SVOCs across a wide range of $\log K_{oa}$ values. The model characterizes the dynamic process, the surface/volumetric concentration changes of SVOCs sorbed to the film, and the increase of film thickness:

$$\frac{dM_{fi}}{dt} = v_{di} \left(C_{gi} - \frac{M_{fi}}{XK_{oai}} \right) \quad (34)$$

where M_{fi} is the surface concentration of sorbed SVOCs of group i (the sorbed SVOCs in the organic film are divided into several groups according to $\log K_{oa}$), v_{di} is the deposition velocity of SVOCs of group i , C_{gi} is the gas-phase concentration of

SVOCs of group i , and X is film thickness, which is coupled with the SVOC concentration in the film:

$$X = X_0 + \sum_{i=1}^n \frac{M_{fi}}{\rho_i} \quad (35)$$

where X_0 is the initial film thickness, and ρ_i is the density of the sorbed SVOCs of group i . Based on the model simulation, the authors found that at the beginning of the buildup of organic film, SVOCs adsorbed to the surface at the maximum rate and SVOCs with lower $\log K_{oa}$ ($\log K_{oa} \approx 8\text{--}10$) contribute more to film growth. However, from the perspective of film thickness, these SVOCs are not dominant. After they equilibrate with the surface film, SVOCs with $\log K_{oa} \approx 11\text{--}13$ dominate film growth and make up the majority of film components. SVOCs with $\log K_{oa} > 13$ tend to remain in the gas phase and scarcely contribute to film growth.

Permeable Surfaces

For permeable materials, an instantaneous linear isotherm is used to describe SVOC partitioning behavior:

$$C_m = K_s y_s \quad (36)$$

where C_m is the equilibrium concentration of the chemical in the solid material ($\mu\text{g}/\text{m}^3$), and K_s (dimensionless) is the partition coefficient. Fick's second law is applied to describe the diffusion of a chemical into the solid phase:

$$\frac{\partial C_m(x)}{\partial t} = D \frac{\partial^2 C_m(x)}{\partial x^2}, 0 < x < \delta \quad (37)$$

where D (m^2/s) is the diffusion coefficient of SVOCs in material phase and δ (m) is the thickness of material.

Existing Methods for Measuring Key Sorption Parameters (K_s and D)

Ventilated Chamber Method

As previously mentioned, all the sorption models involve critical parameters, which characterize sorption capacity, such as K_s and D . The usefulness of the sorption models depends on the reliability and availability of the model parameters. For this reason, it is important to develop techniques to measure key model parameters. The most common approach is to measure the absorbed mass of SVOCs in materials at different exposure times, then fit the sorption model to the experimental data to obtain K_s and D .

Liu et al. (2014) developed a ventilated dual chamber method (Fig. 10) to determine K_s and D of five PCB congeners in eight materials including polypropylene, polyether ether ketone, glass, and stainless steel. The dual chambers were divided as source and test chambers, and throughout the experiment, the gas-phase

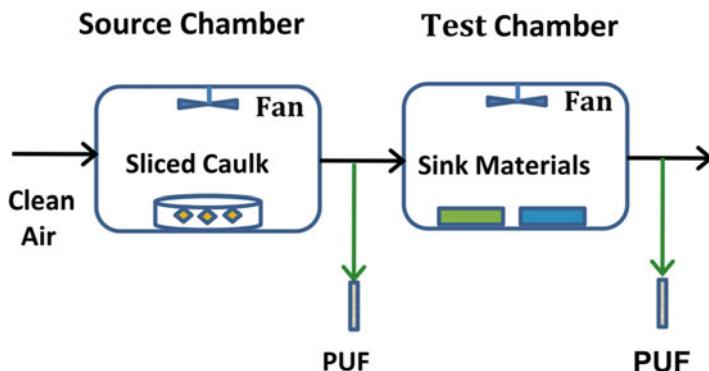

Fig. 10 Schematic of the dual chamber. (©With permission of Liu et al. 2014)

concentration at the outlet of the two chambers was monitored using polyurethane foam (PUF), and test materials were taken out from the test chamber at different time intervals to measure the amount of sorbed PCBs. The entire test lasted for at least 18 days. These data were fitted with the mathematical sorption model. There are some limitations in this method. For example, K_s and D were determined simultaneously with one dataset, which may lead to the risk of multiple solutions. Moreover, it is hard to guarantee that the air in the test chamber is fully mixed since the chamber size is relatively large, which may result in potential errors.

Liang and Xu (2014a) applied the specially designed sandwich-like chamber (Fig. 3 in “SVOC Emissions from Source Materials”) to characterize surface sorption of DEHP, DINP, DnBP, BBP, and Iso-DEHP. Unlike Liu’s method (2014), the partition and diffusion coefficients were determined by linear isotherm and Fick’s law, respectively, which avoids the multisolution problem since K_s and D were obtained independently. However, because K_s was obtained based on the equilibrium surface concentration and the steady-state gas-phase concentration, a longer test duration (more than 30 days) was needed for SVOCs to reach equilibrium.

As mentioned earlier, the linear isotherm is not capable of explaining the partition effects of multilayer sorption, and Liang et al. (2018a) adopted both linear isotherm (simplified Langmuir isotherm) and Freundlich isotherm models to investigate the sorption dynamics of organophosphate flame retardants (OPFRs) on impervious surfaces using similar chambers to Liu’s study (2014). The model parameters K_L , K_F , and n were fitted in desorption stage. Although both the isotherms provided similar fitting results for the gas-phase OPFR concentrations, the Freundlich isotherm was more advantageous in describing surface-phase OPFR concentrations, which suggest the possibility of an organic film forming on the chamber surfaces, thus leading to multilayer adsorption.

All the abovementioned methods applied ventilated chambers and the test materials must be taken out at different times to measure the accumulated mass of SVOCs. This interrupts the fate and transport of SVOCs in the chamber and introduces uncertainty in the results. To overcome this problem, Yang et al. (2020)

developed a sandwich-like chamber based on Liang and Xu's design (2014a). However, unlike the previous ventilated methods, the gas-phase SVOCs concentration instead of test material-phase concentration were measured versus time to avoid interference. In addition, this method not only simultaneously determines K_s and D , but also another important parameter, y_0 , which is the gas-phase concentration immediately adjacent to the source material surface. Nevertheless, there still exists the drawback of a nonunique solution.

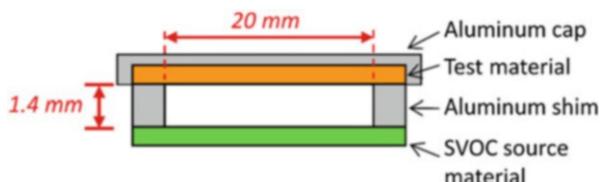

Sealed Chamber Method

Apart from ventilated chambers, sealed chambers using passive sampling techniques are also widely used in the determination of K_s and D . The sealed chamber is often designed with the source material serving as the base and test (or sink) material serving as the top of the chamber. A circular shim/ring is placed between these two materials and determines the diffusion distance (Wu et al. 2017). According to this design, molecular diffusion of SVOCs driven by the concentration gradient between source materials and chamber air is the only mechanism that governs the mass flux (Wu et al. 2017). Therefore, Fick's law can be employed to describe the transport of SVOCs, and the sorption linear isotherm is used in the boundary condition of the model. Multiple sets of this kind of small chamber are prepared and the mass of SVOCs collected on the test materials are periodically measured. Using the sealed chamber method can avoid the effects of not knowing the accurate values of convective mass-transfer coefficients of different surfaces and air flow rates (Cao et al. 2016a), and also shortens the experimental time because the kinetic stage of sorption process is often used to obtain key parameters. Wu et al. (2017) modified their diffusion-based PFS chamber (Fig. 11) to measure the K_s values of DEHP on impervious surfaces (aluminum, glass, etc.) and explore the effects of surface roughness on the sorption process.

Cao et al. (2016) designed a symmetrical sealed chamber (Fig. 12) to determine the y_0 values of three phthalates in PVC floorings and their K_s values on pure cotton shirts. In this method, the test period is substantially shortened because it only uses the early-stage concentration of the sorption process. However, it is hard to examine the impact of environmental conditions since the chamber is sealed. Additionally, the test materials need to be of regular shape, which constrains the applicability of the method.

Cao et al. (2017) developed a SPME-based C_a -history method to measure D of DiBP, DnBP, and TCPP in clothing. The chamber used in this method is the same as that used for y_0 measurements (Cao et al. 2017), with a slight difference in the configuration of source and sink materials. For this method, source and sink

materials are pressed together tightly (Fig. 13). In this way, the mass-transfer process from source to sink materials is markedly improved and the experimental duration can be shortened.

If the gas-phase SVOC concentration versus time is measured during the experiment, D can be obtained by linear fitting within 16 days. However, the experimental time will be longer for chemicals with smaller D and for thick sink materials (Cao et al. 2017).

All the experimentally determined K_s and D values of a variety of SVOCs and materials combinations are summarized in Table 2.

Prediction of the Key Sorption Parameters

Gas/Surface Partition Coefficient (K_s)

The binding forces that cause sorption behavior originating from intermolecular attraction consist of nonspecific van der Waals interactions and specific electron donor–acceptor (EDA) interactions (Goss 2004). For polar SVOCs such as nicotine, they undergo both van der Waals interactions and EDA interactions (Petrick et al. 2010), while for nonpolar SVOCs, which comprise the majority of SVOCs, their molecular interactions are mainly governed by van der Waals forces. These intermolecular interactions and the molecules' freedom of orientation, configuration, and translation constitute the free energy of transfer, which defines the potential of sorption (Schwarzenbach et al. 2016). The sorption behavior is correlated with free energy of transfer. Therefore, the partition coefficients can be estimated using substance descriptors representing molecular properties (Stenzel et al. 2013). Poly-parameter linear free energy relationships (pp-LFERs) developed by Goss (2005) and based on Abraham's two linear solvation energy relationship (LSER) can be applied to various environmental systems, if the system constants and the values of substance descriptors are accessible. The form of the pp-LFERs is:

$$\log K = sS + aA + bB + vV + lL + c \quad (38)$$

where the capital letters on the right side of the equation are the substance descriptors, and the small letters are the system constants that describe the properties of the two partition phases. S represents the dipolarity/polarizability of the substance, A and B denote the hydrogen bond donor and acceptor properties, respectively. These three descriptors are the measures of molecular specific interactions. V refers to the McGowan volume of the substance, and L is the logarithmic hexadecane-air partition coefficient. V and L are the measures of the cavity energy and nonspecific van der Waals interactions. As long as the substance and system descriptors are established, the partition coefficient can be predicted with high reliability. Stenzel et al. (2013) determined the substance descriptors of 40 flame retardants by measuring the gas-chromatographic retention times and liquid/liquid partition coefficients with multiple linear regression analysis. The pp-LFERs were also used to evaluate the partition coefficients of polyurethane foams (PUFs) under different temperature and humidity conditions for a wide range of organic compounds (Kamprad and Goss 2007).

Diffusion Coefficient (D)

The diffusion coefficient in the sink material, D , is influenced by several factors, e.g., temperature and porosity. D can be estimated by the following equation (Morrison et al. 2017):

$$D = D_a \varepsilon^n / K_m \quad (39)$$

where D_a (m^2/s) is the diffusion coefficient in air, ε is the porosity of the sink material, and n is a constant always assigned as 3/2 or 4/3 (Armitage et al. 2013; Cao et al. 2016a, 2016b). Furthermore, D_a is dependent on temperature and pressure according to the semi-empirical relation established by Fuller et al. (1966):

$$D_a = 10^{-3} \frac{T^{1.75} \left[\left(\frac{1}{M_{air}} \right) + (1/M) \right]^{1/2}}{p \left[\bar{V}_{air}^{1/3} + \bar{V}^{1/3} \right]^2} \quad (\text{cm}^2 \text{s}^{-1}) \quad (40)$$

where T (K) is temperature, p (atm) is the gas-phase pressure, M_{air} (28.97 g/mol) is the average molar mass of air, M (g/mol) is the molar mass of the target SVOC, \bar{V}_{air} ($\approx 20.1 \text{ cm}^3/\text{mol}$) is the average molar volume of the gases in air, and \bar{V} (cm^3/mol) is the molar volume of the target SVOC. Therefore, D is dependent on temperature and gas-phase pressure, in which case D is positively proportional to $T^{1.75}$ and inversely proportional to p . However, several studies on volatile organic compounds (VOCs) have found that D estimated using this empirical formula are vastly different from those experimentally measured (Blondeau et al. 2003; Cao et al. 2017). Xiong et al. (2008) explored the reason for this inconsistency and pointed out that researchers' different understanding of material pore structure leads to the inconsistency. If the macropores (pores with diameter larger than 10λ , where λ is the mean free path of the VOC molecule) and mesopores (pores with diameter less than 10λ) are treated as in series connection, the mesopores play a more important role in the determination of diffusion rate of chemicals. On the contrary, if the macro- and mesopores are treated as in parallel connection, the macropores dominate, and D will be overestimated. Based on these findings, Xiong et al. (2008) established a macro-meso two-scale model to predict the diffusion coefficient of VOCs in porous materials. However, its suitability to estimate diffusion coefficients of SVOCs has not been evaluated.

Relationship Between K_s and Temperature, Surface Roughness, Vapor Pressure, and Other Potential Impact Factors

Apart from the pp-LFERs, K_s can also be estimated by other physical or chemical properties of substances. Wu et al. (2017) revealed that surface roughness has a significant effect on the adsorption process of DEHP. K_s is linearly correlated with the roughness factor of material surfaces. In this case, Wu et al. (2017) proposed the possibility that the K_s values of some SVOCs can be easily determined by measuring the surface roughness rather than conducting time-consuming experiments. Xu et al. (2009) pointed out that K_s of phthalates on various surfaces are related to vapor

pressures. The relationship was derived for BBP, DBP, and BPA. Although only three chemicals were applied to obtain the relationship, which cannot yield a definite conclusion, with more datasets used to validate the relationship, it will also serve as a convenient method to estimate K_s . Linear relationships between the logarithm of vapor pressures and partition coefficients of DEHP, DINP, and DnBP on stainless steel were also found (Liang and Xu 2014a).

Sorption to Particles/Dust

SVOCs emitted from source materials not only sorb to common surfaces indoors, but also partition to settled dust and suspended particles (Bi et al. 2018). Considering the potential toxicity of SVOCs to human health and the fact that particles and dust can be ingested by people, especially children who frequently put their hands in mouths, it is important to investigate SVOC sorption by particles and dust.

Interaction Between Gas-Phase SVOCs and Suspended Particles

The Equilibrium Model

There are both equilibrium models and dynamic models to describe the mass-transfer process of gas-phase SVOCs sorbing to particles. For equilibrium model, an instant partition equilibrium is assumed between gas phase and particle surface (Yamasaki et al. 1982; Finizio et al. 1997):

$$F = K_p \cdot C_a \cdot TSP \quad (41)$$

where F ($\mu\text{g}/\text{m}^3$) is the particle-phase concentration of SVOCs, K_p ($\text{m}^3/\mu\text{g}$) is the gas/particle partition coefficient, C_a ($\mu\text{g}/\text{m}^3$) is the gas-phase concentration of SVOCs, and TSP ($\mu\text{g}/\text{m}^3$) is the total suspended particle mass concentration.

The Dynamic Model

In real indoor environments, the partitioning process seldom reaches equilibrium due to the nearly constant removal of suspended particles through ventilation and deposition. In addition, the instant equilibrium model is more appropriate for relatively volatile chemicals such as pyrene, and particles with relatively small diameter (0.01–10 μm), but is not reasonable for less volatile chemicals such as DEHP, and particles with a diameter larger than 2.5 μm (Liu et al. 2013). Otherwise, pronounced deviation (a two orders of magnitude error in gas-phase concentration and a factor of two error in particle-phase concentration) will be generated if the equilibrium model is used (Liu et al. 2013). For this reason, it is necessary to use dynamic models to characterize the gas/particle partitioning of SVOCs.

An important point for accurately establishing the dynamic model is to determine what the rate limiting process regarding the mass transfer is, either external (mass transfer from bulk air to particle surface) or internal (diffusion in and out of the

particle). Typically, this is determined by comparing the timescale of each process (Strommen and Kamens 1997).

For the description of particles, Liu et al. (2013) proposed a physically based model of a particle, which possesses the essential feature of typical particles containing organic components. The representative particle consists of an impermeable core and a permeable homogenous outer layer (Fig. 14). Corresponding to this physical model, a mathematical model to describe the diffusion in the particle was developed:

$$\frac{\partial F}{\partial t} = D_{sp} \left(\frac{\partial^2 F}{\partial r^2} + \frac{2}{r} \frac{\partial F}{\partial r} \right), R_1 < r < R_2 \quad (42)$$

where F ($\mu\text{g}/\text{m}^3$, mass of SVOC per volume of particle) is the particle-phase SVOC concentration, D_{sp} (m^2/s) is the intraparticle diffusion coefficient of SVOC, and r (m) is the diffusive distance. The boundary conditions are:

$$\frac{\partial F}{\partial r} = 0, r = R_1 \quad (43)$$

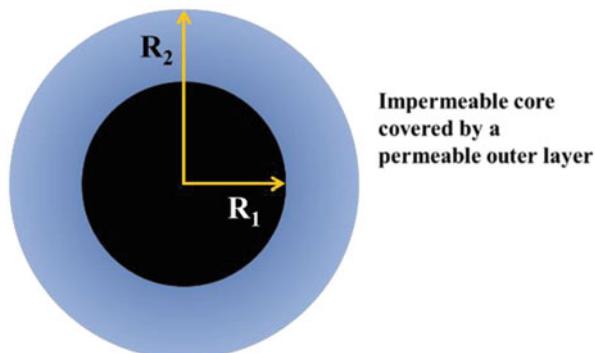

$$D_{sp} \frac{\partial F}{\partial r} = v_t \left(C_a - \frac{F}{K_p} \right), r = R_2 \quad (44)$$

where v_t (m/s) is the mass-transfer coefficient at gas/particle interface, C_a ($\mu\text{g}/\text{m}^3$, mass of SVOC per volume of air) is the gas-phase concentration of SVOCs in bulk air, and K_p is the gas/particle partition coefficient. The initial condition is:

$$F(r, t = 0) = 0 \quad (45)$$

To determine the rate-limiting process of mass transfer, the above model (Eqs. 42–45) is normalized by defining the following dimensionless parameters:

Fig. 14 The physically based model of particles with organic matter. (©With permission of Liu et al. 2013)

$$F^* = \frac{(K_p C_a - F)}{(K_p C_a)}, R_p = \frac{r}{R_2}, R_{12} = \frac{R_1}{R_2}, Fo_m = \frac{(D_s p t)}{(R_2^2)}, Bi_m = \frac{(v_t R_2)}{D_s p}$$

In this way, the dimensionless particle-phase concentration, F^* , is a function of:

$$F^* = f\left(\frac{Bi_m}{K_p}, Fo_m, R_p, R_{12}\right) \quad (46)$$

where $\frac{Bi_m}{K_p}$ indicates a ratio of internal mass-transfer resistance to external mass-transfer resistance. As $\frac{Bi_m}{K_p}$ increases, the internal mass-transfer resistance is stronger. To evaluate which resistance is more significant for the gas/particle dynamic interaction, a parameter, ε , is established:

$$\varepsilon = \frac{F^*(R_p = 1)}{F^*(R_p = R_{12})} \quad (47)$$

As $\frac{Bi_m}{K_p}$ decreases, which means external resistance plays a more important role in the mass-transfer resistance, ε increases. When $\frac{Bi_m}{K_p}$ decreases to a critical value, ε increases to 95% and the internal resistance can be neglected; the complicated intraparticle diffusion process (Eqs. 42–45) is not necessary for describing the gas/particle interaction. Instead, the lumped-parameter method is sufficient to describe the interaction between gas-phase SVOCs and particles. In addition, ε is also subject to the fraction of impermeable volume of the particle, f_v :

$$f_v = 1 - R_{12}^3 \quad (48)$$

Therefore, f_v and $\frac{Bi_m}{K_p}$ together determine whether the internal mass-transfer resistance can be ignored. The critical $\frac{Bi_m}{K_p}$ decreases with increasing f_v . With the commonly identified SVOCs (Pyrene, DEHP, DnBP, BaP, BDE-47, and BDE-99) and porous and nonporous particles with diameter varying from 0.01 to 10 μm , their $\frac{Bi_m}{K_p}$'s are smaller than the critical $\frac{Bi_m}{K_p}$, in which case the concentration gradient within the particle can be ignored, and for convenience, the lumped-parameter method may be applied for the characterization of gas/particle partition process.

Another important point for dynamic gas/particle modeling is to determine the time required to attain partition equilibrium. Based on the above analysis, the lumped parameter method is used:

$$V_p \frac{dF}{dt} = v_t A_p \left(C_a - \frac{F}{K_p} \right) \quad (49)$$

where V_p is the volume of the particle and A_p is the surface area of the particle. The analytical solution of Eq. (49) is:

$$F = K_p C_a (1 - e^{-\varphi t}) \quad (50)$$

$$\varphi = \frac{v_t A_p}{V_p K_p} = \frac{6 v_t}{d_p K_p} \quad (51)$$

where φ is the characteristic parameter concerning the timescales of gas/particle partitioning of SVOCs. If it is assumed that the partition equilibrium is achieved when the particle concentration F reaches 95% of the equilibrium concentration $K_p C_a$, then the critical time for attaining gas/particle partition equilibrium is:

$$t_c = 3\varphi^{-1} \quad (52)$$

The criterion, which establishes whether the gas/particle interaction can be described as instantaneous partition equilibrium, is based on a comparison between equilibrium timescales and the residence time of particle indoors (which is mainly controlled by air exchange rate [on the order of 1 h^{-1}]). If the equilibrium timescale is one order shorter than the residence time, then the instant partition equilibrium is reasonable for the modeling (Eq. 41). Otherwise, it is necessary to adopt a dynamic model to characterize gas/particle interaction:

$$\frac{dF}{dt} = \frac{TSP \cdot A_p}{V_p} v_t \left(C_a - \frac{F}{TSP \cdot K_p} \right) - \frac{Q}{V} F \quad (53)$$

It can be seen from Eq. (51) that the critical time for attaining partition equilibrium is a function of the mass-transfer coefficient on the particle surface, v_t , the particle diameter, d_p , and the gas/particle partition coefficient K_p . v_t varies with SVOCs and the composition of particles, but the variation can be neglected compared to that in K_p , which varies by several orders of magnitude (Liu et al. 2013). Therefore, t_c is mainly governed by K_p and d_p .

Role of Aerosols in Enhancing SVOC Flux Between Air and Indoor Surfaces

Xu and Little (2006) investigated the impact of particles on SVOC emission and they found that because of the presence of particles, the bulk gas-phase concentration of SVOCs will decrease, leading to a larger concentration gradient between surface boundary layer and bulk air, and therefore enhancing the SVOC emission rate. Through conducting experiments, Benning et al. (2013) reached a similar conclusion that particles can enhance DEHP flux from a material surface.

For SVOC sorption to surfaces, Liu et al. (2012) found that SVOC transport in the boundary layer between air and surfaces is significantly enhanced in the presence of particles, and the sorption rate is thereby increased. This is because particles transport SVOCs to surfaces through eddy and Brownian diffusion, and in the boundary layer, particles can release SVOCs and decrease the mass-

transfer resistance between air and surfaces (Weschler and Nazaroff 2008). The flux enhancement is influenced by particle diameter (d_p), gas/particle partition coefficient (K_p), and air velocity near surfaces (Liu et al. 2012). As d_p decreases, flux enhancement is inclined to increase. However, for particles with extremely small diameters (e.g., $d_p < 0.05 \mu\text{m}$) and SVOCs with $\log K_p = 13$, the enhancement will drop somewhat. The flux enhancement is more pronounced for chemicals with lower volatility; it is not significant if the $\log K_p$ value of SVOCs is lower than 10, but as the K_p value increases, the flux enhancement increases.

Existing Methods for Measuring Key Sorption Parameter (K_p)

Existing Methods Used in Atmospheric Field (Equilibrium Model)

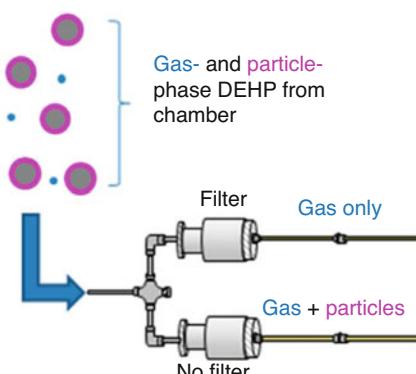

In field test, Eq. (41) was first proposed by Yamasaki (1982) to depict the partition behavior of PAHs on particles in ambient air, and now it is widely applied to determine K_p by monitoring the particle- and gas-phase concentration of SVOCs and the total suspended particle mass concentration.

Sandwich-like Chamber Method

Benning et al. (2013) applied the sandwich-like chamber method developed by Xu et al. (2012) to measure K_p of DEHP to ammonium sulfate particles. The airborne (particle- and gas-phase) concentration and gas-phase concentration of DEHP at the outlet of the chamber were measured together by controlling the loading of polytetrafluoroethylene (PTFE) membrane filter on different sampling trains of the chamber outlet (Fig. 15). In this way, the particle-phase concentration of DEHP can be calculated as the concentration difference between the two sampling trains, and the gas/particle partition coefficient can be derived as:

$$K_p = \frac{F}{C_a \cdot TSP} \quad (54)$$

Fig. 15 Experimental sampling setup for the measurement of gas-phase and airborne DEHP. (©With permission of Benning et al. 2013. Copyright 2021 American Chemical Society)

where C_a ($\mu\text{g}/\text{m}^3$) is the long-term average steady-state gas-phase concentration of DEHP, and TSP is the average measured total suspended particle mass concentration of both before and after passing through the chamber.

Using this method, K_p of DEHP on ammonium sulfate particles was determined to be $0.032 \pm 0.003 \text{ m}^3/\mu\text{g}$. The K_p of DEHP can also be estimated by empirical relationship based on vapor pressure (Pankow 1987, 1994; Naumova et al. 2003) or the octanol-air partition coefficient (Finizio et al. 1997; Harner and Bidleman 1998; Cousins and Mackay 2001). The result obtained by Benning et al. (2013) is one order of magnitude lower than that obtained based on the vapor pressure, i.e., $0.25 \text{ m}^3/\mu\text{g}$. However, it is only a factor of two lower than that obtained based on the octanol-air partition coefficient, i.e., $0.64 \text{ m}^3/\mu\text{g}$. This discrepancy may be due to the difference of particle composition (organic/inorganic), particle mass concentration, particle size, and the uncertainties of DEHP's vapor pressure. Benning's method (2013) was the first chamber experiment to quantify K_p .

Tube Chamber

Wu et al. (2018) developed a long tube chamber (Fig. 16) method to determine the K_p of DEHP on one inorganic particle (ammonium sulfate) and two organic particles (oleic acid and squalane). Similar to the sandwich-like chamber, the tube chamber is designed to maximize the ratio of SVOC source area to sink area. A thin layer of pure DEHP liquid was coated on the internal surface of the tube to serve as the emission source. Air mixed with particles at a specific concentration was introduced into the tube at a controlled flow rate to guarantee a laminar flow in the tube, avoiding inaccuracy caused by complex flow field in the chamber. The K_p value of DEHP on inorganic particles reported by Wu et al. (2018) is $0.011 \pm 0.10 \text{ m}^3/\mu\text{g}$, which is slightly lower than that reported by Benning et al. (2013). For organic particles, the measured K_p value is $0.23 \pm 0.13 \text{ m}^3/\mu\text{g}$ for oleic acid and $0.11 \pm 0.10 \text{ m}^3/\mu\text{g}$ for squalane.

Fig. 16 Photo of experimental setup of the long tube chamber method.
(© With permission of Wu et al. 2018. Copyright 2021 American Chemical Society)

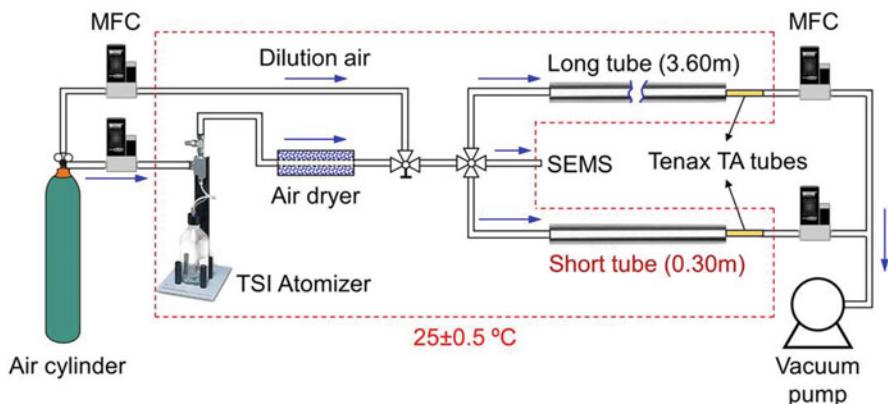

Fig. 17 Experimental system. (© With permission of Cao et al. 2019)

The two abovementioned chamber methods require that the sorption equilibrium between gas-phase SVOCs and particles has to be attained, which may increase inaccuracy and uncertainty, especially for SVOCs with larger K_p and particles with larger diameter. Furthermore, the gas-phase concentration of SVOCs may be underestimated because they are inclined to sorb to the filter during sampling (Fig. 15), and measurement errors are generated. To overcome these two problems, Cao et al. (2019) improved the method of Wu et al. (2018) and determined the K_p of DEHP on ammonium sulfate. The tube chamber method was modified from one tube to two tubes of different lengths (3.60 and 0.30 m) in parallel (to both conducted equilibrium and dynamic methods) (Fig. 17). A mass-transfer model of SVOCs in the tube chamber was established, and unlike the previous methods (Benning et al. 2013; Wu et al. 2018), only the total airborne SVOC concentration needed to be measured by Tenax tubes and gas-phase and particle-phase DEHP were not separated. K_p values were derived by fitting the mass-transfer model to the measured total airborne SVOC concentration, which agreed well with the previous studies (Benning et al. 2013; Wu et al. 2018).

All the experimentally determined K_p values of SVOCs are summarized in Table 3.

Prediction of the Key Sorption Parameter (K_p)

Junge-Pankow Method: K_p - P_s Relationship and K_p - K_{OA} Relationship

Apart from using experimental methods to quantify K_p , empirical relationships are also widely used to predict K_p for SVOCs. The Junge-Pankow model (Junge 1977; Pankow 1987) and the K_{oa} absorption model (Finizio et al. 1997; Harner and Bidleman 1998; Weschler and Nazaroff 2010) are most frequently applied. In the Junge-Pankow model, the particle fraction of chemical, φ , which is calculated as the

Table 3 Key parameters of SVOC particle sorption (K_p)

Chemical	Particle	Median particle diameter (nm)	K_p	Testing method	Temperature (°C)	References
DEHP	Ammonium sulfate	40–50	0.032 ± 0.003 (m ³ /μg)	Modified sandwich-like chamber	22 ± 0.3	(Benning et al. 2013)
	Ammonium sulfate	70–80	0.011 ± 0.004 (m ³ /μg)	Long tube chamber	25 ± 0.5	
Oleic	40–130	0.23 ± 0.13 (m ³ /μg)				(Wu et al. 2018)
	110–170	0.11 ± 0.10 (m ³ /μg)				
DEHP	Ammonium sulfate	50–60	260 ± 80 (m) (surface-area-normalized partition coefficient)	Dynamic long tube chamber	25	(Cao et al. 2019)

particle-phase concentration over the total airborne concentration, is correlated with the subcooled liquid vapor pressure of chemical, P_s (Junge 1977; Pankow 1987):

$$\varphi = \frac{c\theta}{P_s + c\theta} \quad (55)$$

where c is a constant related with the desorption heat of particle surface, vaporization heat of the chemical, and the number of adsorption sites on the particle, and θ is the surface area of the particle.

According to the definition of φ , it can be derived as:

$$\varphi = \frac{F}{F + C_a} \quad (56)$$

Substituting Eqs. (54 and 56) into (55) gives an equation of the following form:

$$\log K_p = -\log P_s + b \quad (57)$$

The intercept ($b = \log \frac{c\theta}{TSP}$) is dependent on the inherent properties of the particles, and the slope is required to be close to -1 for true equilibrium partitioning as described in Pankow (1994). However, this may not be satisfied for all regression cases of different SVOCs. The possible reasons are the artificial errors in sampling and kinetic effects. However, the slope may still not be -1 , even if the above two problems are avoided, due to the thermodynamic effect, which means that the difference between desorption heat and vaporization heat does not remain constant within a class of chemicals (Pankow and Bidleman 1992). Wei et al. (2016) reviewed the empirical equations of K_p and P_s for a wide range of SVOCs and they used all the published equations to derive the K_p distribution of numerous SVOCs. This way, the deviation related to the selection of a particular equation can be diminished.

Another generally used empirical correlation for K_p prediction is the K_{oa} absorption model, which indicates that K_{oa} and P_s are most relevant (Cousins and Mackay 2001). Finizio et al. (1997) first proposed K_{oa} to be a predictor for K_p of SVOCs in two forms:

$$\log K_p = a + b \log K_{oa} \quad (58)$$

where a and b are constants and a is related to the inherent properties of the chemical and b . When b is assigned to be 1.0, Eq. (58) is transformed to be:

$$\frac{K_p}{K_{oa}} = B$$

where B is within the order of 10^{-12} and decreases with increasing K_{oa} , which may be due to the kinetic effect (Finizio et al. 1997).

Following Finizio et al. (1997), other researchers began to investigate the relationship between K_p and K_{oa} , and empirical equations for PAHs (Weschler et al. 2008),

PCBs (Harner and Bidleman 1998; Kaupp and McLachlan 1999), organochlorine pesticides (Kaupp and McLachlan 1999), and PCNs (Harner and Bidleman 1998) were established.

Pp-LFER Method

Both the estimation from P_s and K_{oa} are single parameter approaches. It is unclear whether one descriptor is enough to characterize the comprehensive chemical diversity due to van der Waals and H-bond interactions (Salthammer and Goss 2019). As mentioned in the section of “Prediction of the Key Sorption Parameters” the poly-parameter linear free energy relationship (pp-LFER) may overcome this limitation and can be adopted to estimate K_p . Using this method, Salthammer and Goss (2019) determined the K_p values of 14 SVOCs (mostly phthalates) on water-insoluble organic matter (WIOM), for which the dominant mechanism is absorption. The results derived from pp-LFERs are significantly lower than those based on P_s and K_{oa} in most cases (Salthammer and Goss 2019). Although pp-LFER appears to be a more comprehensive method for K_p estimation, it is challenging to obtain the precise values of multiple descriptors (e.g., van der Waals interactions, L ; polarizability, S ; hydrogen bond acidity, A ; and hydrogen bond basicity, B). Therefore, the uncertainties arising from parameterization should be carefully taken into account.

Conclusion

Many efforts have focused on exploring the mechanisms governing SVOC source and sink behavior (i.e., emission, sorption, and partitioning) and developing methods to determine the key parameters that control these processes. The substantial achievements have been reviewed in this chapter. However, there still are many topics that require further investigation to improve our understanding of SVOC fate and transport in indoor environments and their impacts on human health, such as standard methods to determine key parameters, insight into the SVOC source and sink processes at the molecular level, the influence of environmental conditions, and different mechanisms that may occur in new source and sink materials.

Abstract

Building products contain volatile organic compounds (VOCs), which can be emitted into indoor air and result in human exposures in the indoor environment. The emission rate, commonly measured in environmental chambers, is a key parameter to characterize the emission of a chemical of interest from materials in

a building. Reference materials with known emission rates can be used to characterize the uncertainty associated with building product emission testing. This chapter describes VOC emission testing and explores the types of reference materials that have been used to validate product emission testing. Detailed descriptions of five types of reference materials are presented, addressing their emission mechanisms, production methods, application protocols, and use in inter-laboratory emission tests. This chapter also describes some of the causes of uncertainty associated with reference materials, emission testing systems, analytical measurement methods, and inter-laboratory study procedures.

Volatile organic compounds · Formaldehyde · Chamber · Inter-laboratory · Concentration

Introduction

Airborne emission testing is the quantification of the migration of chemicals from a building material or product into the gas phase. In general, a building material or product is placed in an environment at a controlled temperature, relative humidity, airflow rate, and pressure. The gas phase concentration of the chemical of interest is measured after certain conditions are met (e.g., the concentration of the chemical reaches steady state in the controlled environment). Some regulations or product labeling schemes define emission limits from tested materials as steady state gas-phase concentrations (mass per volume) under specified conditions. Under steady-state conditions the emission rate is the mass of chemical (concentration multiplied by the sample volume) emitted during the sampling period.

Why Test Material Emissions?

The concentration of most chemicals in indoor air is higher than outdoor air (Weschler 2006). The source of elevated indoor airborne chemical concentrations can be building materials, consumer products, occupants, and occupant activities, along with chemical reactions in the air. Quantifying the emissions of chemicals from building materials and consumer products into indoor spaces can increase the accuracy of indoor chemical concentration and exposure modeling. This improved exposure modeling may provide opportunities to reduce indoor chemical exposures.

There are two primary drivers for airborne emission testing of materials and products. First, some countries set regulatory maximum emission limits for chemicals or classes of chemicals from specific products (e.g., formaldehyde from wood products; Table 1). Second, voluntary product labeling schemes, or product certifications, and industry consensus standards can encourage producers to test products to gain market advantages. Product certification programs can be regulatory or voluntary.

Table 1 Examples of Emission Regulations

Country	Identification	Regulation Name
United States (USEPA)	Title VI TSCA	Formaldehyde Emission Standards for Composite Wood Products Rule (Title VI of the Toxic Substances Control Act (TSCA))
United States (CARB)	CWP ATCM	Composite Wood Products Airborne Toxic Control Measure (ATCM)
China	GB 18580-2017	Indoor Decorating and Refurbishing Materials – Limit of Formaldehyde Emission of Wood-Based Panels and Finishing Products
Germany	ChemVerbotsV	German Chemicals Prohibition Ordinance
France	Décret n°2011-321	Labeling of Construction and Decoration Products Regarding VOC Emissions
Japan	JIS A 5905	Fiberboards
Japan	JIS A 5908	Particleboards

Each regulation or certification label scheme requires a test protocol to determine emission rates from a specific product (Table 2). Many of the test methods have been developed and maintained by nongovernmental consensus-based organizations (e.g., the International Organization for Standardization (ISO) and ASTM International). The methods have varying degrees of parameter and measurement specificity (e.g., ASTM guides give information or series of options, while ASTM test methods require specific steps that produce a result). Some methods are specific to a product type (e.g., ANSI/BIFMA M7.1 focuses on furniture). Many methods are based in part on or refer to ISO 16000-9 (Indoor air – Part 9: Determination of the emission of volatile organic compounds from building products and furnishing – Emission test chamber method), for example, EN 16516. As described below methods can be either static (sealed chamber) or dynamic (flow-through chamber).

What Chemicals are Analyzed in Emission Testing?

Emission testing is used to quantify emission of an individual chemical, a group of chemicals or both. Due to regulatory requirements (e.g., USEPA Formaldehyde Emission Standards for Composite Wood Products Rule) formaldehyde is the most often targeted individual chemical for emission testing. Emissions of other volatile organic compounds (VOCs) are often covered by product emission labeling programs. There are many different definitions for VOCs and semi-volatile organic compounds (SVOCs) (ASTM 2017), with definitions using chemical boiling point, vapor pressure, and/or retention time on a gas chromatogram (GC) analytical column or combinations of these three. The total emitted mass of VOCs can be quantified in multiple ways: (1) as the sum of individually quantified chemicals within a range of boiling points, vapor pressures, and/or retention times, or (2) as an approximate quantification of components by integrating peaks using toluene equivalents (Oppel et al. 2020).

Table 2 Examples of Testing Standards

Test Method ID	Region	Type	Method Name	Chemicals
ISO 16000-9	International	Dynamic	Indoor air – Part 9: Determination of the Emission of Volatile Organic Compounds from Building Products and Furnishing – Emission Test Chamber Method	VOCs
ISO 16000-10	International	Dynamic	Indoor Air – Part 10: Determination of the Emission of Volatile Organic Compounds from Building Products and Furnishing – Emission Test Cell Method	VOCs
ASTM D5116	US	Dynamic	Standard Guide for Small-Scale Environmental Chamber Determinations of Organic Emissions from Indoor Materials/Products	VOCs
ASTM D6670	US	Dynamic	Standard Practice for Full-Scale Chamber Determination of Volatile Organic Emissions from Indoor Materials/Products Emission Rate	VOCs
ASTM D7706	US	Dynamic	Standard Practice for Rapid Screening of VOC Emissions from Products Using Micro-Scale Chambers	VOCs
ASTM D6007	US	Dynamic	Standard Test Method for Determining Formaldehyde Concentrations in Air from Wood Products Using a Small-Scale Chamber	Formaldehyde
ASTM E1333	US	Dynamic	Standard Test Method for Determining Formaldehyde Concentrations in Air and Emission Rates from Wood Products Using a Large Chamber	Formaldehyde
ASTM D5582	US	Static	Standard Test Method for Determining Formaldehyde Levels from Wood Products Using a Desiccator	Formaldehyde
CDPH Standard Method V1.2	US	Dynamic	Standard Method for the Testing & Evaluation of VOC Emissions from Indoor Sources Using Environmental Chambers	VOCs
ANSI/BIFMA M7.1	US	Dynamic	Testing for VOC Emissions from Office Furniture and Seating	VOCs and Formaldehyde

Test Method ID	Region	Type	Method Name	Chemicals
UL 2821	US	Dynamic	GREENGUARD Standard for Building Materials, Finishes and Furnishings	VOCs and Formaldehyde
EN 16516	EU	Dynamic	Construction Products: Assessment of Release of Dangerous Substances – Determination of Emissions into Indoor Air	VOCs
EN 717-1	EU	Dynamic	Wood-based Panels – Determination of Formaldehyde Release – Formaldehyde Emission by the Chamber Method	Formaldehyde
EN 717-3	EU	Static	Wood-based panels – Determination of formaldehyde Release – Formaldehyde Release by the Flask Method	Formaldehyde
GEV	EU	Dynamic	GEV – Testing Method Determination of Volatile Organic Compounds for Evaluation of Emissions Controlled Products for Flooring Installation, Adhesives, Construction Products, as well as Lacquers, Finishes and Oils for Parquet, for Mineral Floorings and for Resilient Floorings	VOCs
GB/T 17657-2013	China	Dynamic	Test Methods of Evaluating the Properties of Wood-based Panels and Surface Decorated Wood-based Panels	Formaldehyde
JIS A 1911: 2015	Japan	Dynamic	Determination of the Emission of Formaldehyde by Building Materials and Building Related Products – Large Chamber Method	Formaldehyde
JIS A 1901: 2015	Japan	Dynamic	Determination of the Emission of Volatile Organic Compounds and Aldehydes by Building Products – Small Chamber Method	VOCs
JIS A 1460	Japan	Static	Determination of the emission of Formaldehyde from Building Boards – Desiccator Method	Formaldehyde

Formaldehyde and other VOC emission rates are quantified by determining the mass of the chemical in the air per time (chemical concentration multiplied by flow rate). The VOC emission rate is often controlled by the chemical diffusion through a material. In contrast, the SVOC emission rate is usually determined by the

convective mass transfer above the surface of the material, which is dependent on the airflow rate and the SVOC concentration in the bulk air. Since these two parameters can vary with time, with variations between different chambers and built environments, mass per time emission rates are not useful parameters for quantifying SVOC emissions from indoor materials. For SVOCs, a mass transfer approach as described in ASTM D8141 (ASTM 2017) needs to be used to quantify emissions from products indoors. For this reason, there are few SVOC test standards, regulations, labeling programs, or reference materials. The remainder of this document will focus on VOC emission testing (both individual and total) and reference materials.

How Does Emission Testing Work?

There are a variety of approaches to measure VOCs emissions from materials. Broadly, they can be broken down into three types: extractor methods, static methods, and dynamic methods.

Extractor or perforator methods directly quantify the amount of chemical present in the product. For example, formaldehyde perforator methods (e.g., EN 120: Wood-based panels; determination of formaldehyde content) involve boiling a wood product sample in toluene to remove formaldehyde (Risholm-Sundman et al. 2007; Roffael et al. 2010). The collected formaldehyde is then transferred to water for optical analysis.

Static methods often involve placing wood products in closed systems in the presence of water at a constant temperature. The formaldehyde migrates through the air phase from the test specimen into the water. After a defined time, the water is analyzed for the presence of formaldehyde. Static methods include flask (EN 717-3) and desiccator methods (JIS A 1460). The relative humidity in these methods is high due to the presence of liquid water in the system. The high humidity may impact the measured emission rate.

The reference materials reviewed for this document have not been tested using static or extractor methods. Rather, most reference materials to date highlighted in academic publications have been used with dynamic chamber methods. In these methods, a test specimen is placed in a chamber held at a constant temperature and relative humidity. Pre-humidified air is supplied to chamber at a defined airflow rate. The concentration of the chemical(s) of interest is measured in the chamber exhaust air. Some methods are performed at elevated temperatures and/or at a low relative humidity. There is a wide range of dynamic testing methods (Table 2) that vary in requirements, including chamber volume, temperature, relative humidity, air velocity, air change rate, loading rate, exposed edges, pre-chamber conditioning, duration of exposure of the test specimen in the chamber, and sample time (Poppendieck and Gong 2020).

Dynamic Emission Test System Components

Dynamic emission chamber test systems consist of a chamber, a temperature control system, an airflow control system, and a relative humidity control system (Fig. 1). In addition, temperature, airflow, pressure, and relative humidity are monitored.

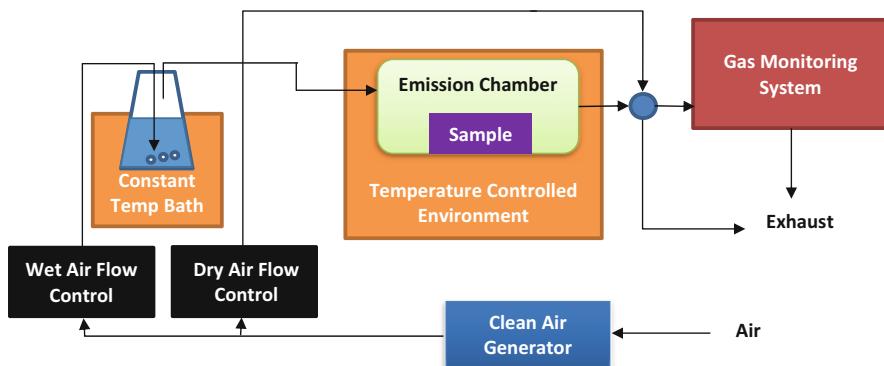

Fig. 1 Example schematic for an emission test system

There is a wide range of chamber sizes used depending on the purpose of the test method. Chamber sizes can vary from 0.00003 m^3 for screening emission testing of a portion of a product (ASTM D7706) to 30 m^3 for testing a complete product (e.g., full sheet of plywood, ASTM E1333 or ASTM 6670). Smaller chambers can be enclosed in external temperature control systems (e.g., incubators). Larger chambers can have dedicated heating, ventilation, and air conditioning systems to control temperature and relative humidity.

Since dynamic emission chambers use concentration measurements and airflow rates to determine the emitted mass, dynamic chamber systems employ mass flow controllers or mass flow meters to accurately measure the airflow rates. To control relative humidity, many chamber systems smaller than 1 m^3 split the incoming chamber airflow between a dry line and wet line (Fig. 1). The wet line is bubbled through water to increase the relative humidity. The two lines are then mixed in a controlled manner prior to entering the chamber to achieve the desired relative humidity. Most dynamic emission methods specify a maximum pressure in the chamber, which can be controlled with the exhaust system.

Dynamic Emission Testing Variability

Given the potential for systematic errors (e.g., an incorrectly calibrated temperature probe) to influence the reported emission rates, inter-laboratory (among laboratories) comparison studies can be performed to ensure the accuracy of emission testing systems. The California Composite Wood Products Airborne Toxic Control Measure (ATCM) requires third-party emission certification laboratories to participate in inter-laboratory studies for at a minimum of every 2 years. The uncertainty of measured concentrations or emission rates in dynamic emission testing is a function of three factors: (1) sample variation of the material being tested, (2) the emission testing system, and (3) the analytical concentration measurement.

The analytical concentration measurements have been historically performed in dynamic emission chambers by either trapping the analyte on a sorbent followed by thermal desorption and quantification in a thermal desorption gas chromatograph (TD-GC) or derivatization followed by extraction and analysis with high-performance

liquid chromatography (HP-LC) system. The uncertainty associated with these analytical measurements can be determined by conducting inter-laboratory studies using spiked sorbent tubes or extraction liquids. Kirchner (2007) demonstrated that for 10 out of 11 chemicals analyzed on spiked Tenax tubes, the relative standard deviations (RSDs) were less than 4% ($n = 6$), demonstrating small analytical uncertainty in inter-laboratory studies is possible.

It is difficult to distinguish emission testing system uncertainty from sample variation and analytical uncertainty. The tested sample (either a building material or designed reference material) can be heterogeneous at the scale tested. In addition, shipping, storage, and handling issues can influence the emission rate of a sample. Each emission test system design can also vary. Finally, the airflow rate, temperature, relative humidity, and pressure can all impact the actual chemical concentration in a chamber. These contributions to uncertainty are described in more detail in the section “Uncertainties in Emission Testing when Using Reference Materials.”

Reference Materials

The development of emission testing reference materials is intended to reduce uncertainty related to sample variation of the material being tested, specifically sample heterogeneity and handling issues. An ideal emission testing reference material emits the target compound at a predictable rate in quantities sufficient for detection and quantification over the required period of time while being independent of age and handling of the material (Cox et al. 2010; Uhde and Aksteiner 2018; ISO 2015).

Definitions

According to the International Bureau of Weights and Measures (BIPM) international vocabulary of metrology, a reference material is defined as a “material sufficiently homogeneous and stable with reference to specified properties, which has been established to be fit for its intended use in measurement” or in examination of nominal properties (ISO 2015). There are many kinds of reference materials created for specific uses.

For example, the US National Institute of Standards and Technology (NIST) has six different categories of reference materials that are intended for different specified purposes, for example, primary standards (PSs), standard reference materials (SRMs), research gas mixtures (RGMs), NIST traceable reference materials (NTRMs), reference materials (RMs), and research-grade test materials (RGTM) (Beauchamp et al. 2021). The reference values assigned to PSs, SRMs, and RGMs are metrologically traceable to internationally recognized higher-order reference systems, for example, the International System of Units (SI). The reference values assigned to NTRMs are traceable to existing PSs and SRMs. The reference values assigned to RMs are determined following

between-method harmonization, within-method precision assessment, and process stability assessment. RGTMs are a subset of the exploratory materials undergoing the first step of development towards reference materials and are prepared to be fit-for-purpose, homogeneous, and stable.

Types of Reference Materials

A certified reference material (CRM) is a reference material that has been characterized by a “metrologically valid procedure” to determine the “associated uncertainty” and includes a statement of metrological traceability (Beauchamp et al. 2021; ISO 2015, 2016). CRMs are metrologically traceable and produced by a responsible reference material producer (ISO 2016). All CRMs are reference materials, but not all reference materials are CRMs. For example, four of the six NIST reference material types are CRMs (PSs, SRMs, RGMs, and NTRMs). Reference materials need only to be homogeneous, stable, and fit for use; they do not need to be traceable. Traditionally, reference materials used for emission testing have not been certified (CRMs) or traceable.

True Values, Traceability and Consensus Approaches

There are multiple means that can be used to establish the mass value emitted from an emission testing reference material. The true mass value is the mass that would be the emitted mass if there was no measurement error (Beauchamp et al. 2021), but the exact true mass value is impossible to measure. CRM certificates report estimates of the true mass value with a specified uncertainty and stated confidence.

Ideally, measurement results from CRMs are traceable to the SI reference system using two or more independent methods (Beauchamp et al. 2021). This makes the stated CRM reported value method independent. In other words, chamber flow measurements would be directly traceable to the primary and secondary values. A certificate attached to a CRM would account for all uncertainty in that traceability train to estimate the true emission value.

Alternatively, consensus values can be used to estimate the emitted mass true value for reference materials that are not CRMs through inter-laboratory studies with enough participants (Beauchamp et al. 2021). Reference materials whose true values are estimated via consensus efforts do not need to be traceable. However, consensus values can only be established during inter-laboratory studies that have enough participants. The required number of participants is a function of spread in the results, the data analysis methods, and if a control material was used. To date, all emission testing reference materials have used a consensus value to estimate the true value. This means there are no commercial emission testing products that can be used independently of an inter-laboratory study campaign that could be used to evaluate the performance of an emission testing system.

Types of Emission Testing Reference Materials

To date, there is a limited number of published inter-laboratory studies for the measurement of VOCs emissions from materials in emission test chambers (De Bortoli et al. 1999; Risholm-Sundman et al. 2007; Wilke et al. 2009; Yrieix

et al. 2010; Howard-Reed et al. 2011; Wilke et al. 2011; Howard-Reed et al. 2014; Horn et al. 2018; Oppl et al. 2020).

Historically, inter-laboratory studies used building material samples as the reference material (De Bortoli et al. 1999; Kirchner 2007; Risholm-Sundman et al. 2007; Wilke et al. 2009; Yrieix et al. 2010). For this discussion, building product reference materials are defined as any emission testing material typically used as a building product that has not been spiked with compounds (described in section “Building Product Reference Materials Used in Emission Testing”). More recently, reference materials have been designed specifically for emission testing purposes. These systems (described in section “Designed Reference Materials Used in Emission Testing”) either spike chemicals of interest into various materials or they emit chemicals of interest from a designed liquid source.

Building Product Reference Materials Used in Emission Testing

Inter-laboratory studies that have used building product reference materials have included carpet, carpet cushion, paint, particleboard, polyvinyl chloride (PVC) flooring, rubber flooring, and sealants. Summaries of these studies follow.

De Bortoli et al. (1999) conducted an inter-laboratory study with 18 laboratories from 10 European countries. Five VOCs (*n*-decane, *n*-undecane, *n*-dodecane, 2-phenoxy ethanol, *n*-tridecane) from carpet, eight VOCs (phenol, 2-(2-butoxyethoxy)ethanol, C7 benzene, C8 benzene-1, C8 benzene-2, *n*-tetradecane, C9 benzene and 2,2,4-trimethyl-1,3-pentanediol diisobutyrate) from PVC cushion, and two VOCs (2-(2-ethoxyethoxy)ethanol and Texanol) from paint were evaluated. The RSDs of area-specific emission rates for carpet, PVC cushion, and paint ranged from 25% to 91%, 27% to 83%, and 21% to 69%, respectively. The intra-laboratory (same lab) variance (range 0% to 38%, mean 2.3% to 10% depending on the chemical) was smaller than the inter-laboratory variance. Analytical errors, losses of the heaviest compounds due to sorption on the chamber wall and non-homogeneity of the materials were suggested as the main reasons for inter-laboratory discrepancies.

Risholm-Sundman et al. (2007) conducted an inter-laboratory study with six laboratories. Formaldehyde emission from particleboards was tested with three replicate samples in each laboratory. The 16% variation in inter-laboratory tests was larger than the 6% intra-laboratory variation. Edge sealing, conditioning of the sample before the test, and test temperature were cited as potential reasons for the discrepancies.

Kirchner (2007) conducted an inter-laboratory study with 11 laboratories. Three VOCs emitted from PVC flooring (cyclohexanone, 2-methoxy-1-methylethylacetate, and diethylene glycol monobutyl ether) and five VOCs from rubber flooring (styrene, cyclohexanone, benzaldehyde, benzothiazole, and 2,6-di-*t*-butyl-4-methylphenol) were evaluated. RSDs ranged from 64% to 87% for PVC flooring and from 22% to 43% for rubber flooring. The variability in the PVC emissions was attributed to damage of the material in packaging for shipping.

The intra-laboratory variation for spiked VOCs on sorbent tubes was between 2% to 10% for the PVC flooring chemicals and 6% and 15% for the rubber flooring chemicals. Hence, the inter-laboratory variation was not limited to the analytical discrepancies.

Wilke et al. (2009) conducted an inter-laboratory study with 37 laboratories from Europe. Seven VOCs (butanol, butyl acetate, dibutylether and butyl acrylate, ethandiol, propanoic acid butyl ester, and butanoic acid butyl ester) emitted from a sealant were evaluated. Test chamber volumes ranged between 0.02 m³ and 1.0 m³. RSDs ranged from 17% to 61%. The 61% RSD for ethanediol was attributed to poor adsorption onto Tenax and a poor peak shape influencing quantification with gas chromatography.

Yrieix et al. (2010) conducted an inter-laboratory study with six European laboratories. Six VOCs (formaldehyde, acetaldehyde, pentanal, hexanal, alpha-pinene, and beta-pinene) emitted from urea-formaldehyde particleboard were measured. RSDs ranged from 17% to 45%. The lower RSD for formaldehyde emissions (17%) compared to other non-aldehyde emissions (27% to 45%) was attributed to the higher heterogeneity of natural wood compounds than of the urea formaldehyde resin of the tested product.

Combined these historical studies on building materials indicate that the uncertainty attributed to analytical concentration measurement (Kirchner 2007) and sample variation of the material being tested (Risholm-Sundman et al. 2007) are likely lower than uncertainty related to the emission testing system. However, the range of uncertainty related to emission testing using building materials for inter-laboratory studies (conducted between 1999 and 2010, RSD 16% to 91%) indicated that improvements to all three factors impacting emission testing (sample variation of the material being tested, the emission testing system, and the analytical concentration measurement) were needed.

Designed Reference Materials Used in Emission Testing

A range of emission testing reference materials have been developed since 2010. Unlike the previously described building product reference materials, these specifically designed materials either spike chemicals of interest into materials or involve evaporation of the chemicals from a liquid solution. These materials include lacquers, films, molded thermoplastic polyurethane plates, liquid-diffusion-film-emissions systems, and temperature-controlled diffusive evaporators.

To use these materials as a reference material in a chamber test, the material is placed inside the chamber under specified temperature, relative humidity, and airflow rate conditions. The concentration profile of the target compound in the chamber air is measured after sealing the chamber for a specified duration. For intra-laboratory and inter-laboratory comparisons, material samples of the same batch are used in the different chambers, so that the measured concentration profiles of the target compounds among the different chambers are comparable.

Drying or Curing Reference Material

Examples of drying or curing reference materials have used lacquer or adhesive as the carrier substrate of the target compounds. The reference material is comprised of a Petri dish and a layer of the cured mixture and target compounds (Fig. 2). The reference material can be designed for emission of the mixture of several target compounds if the compounds are compatible with the lacquer or adhesive solvent and form a uniform mixture.

Nohr et al. (2014a, b) prepared lacquer reference materials using the following steps:

1. The selected lacquer product is decanted into a screw-cap bottle to serve as the carrier substrate of the reference material.
2. Defined amounts of the target compounds in pure liquid form are added to the lacquer using gas-tight syringes. The lacquer is stirred magnetically to form the mixture. The compounds existing in the solid form under room temperatures, such as lindane, are dissolved in methanol before being added to the lacquer.
3. The bottle is then sealed. The mixture of the lacquer and the target compounds is agitated for 1 h to ensure a mixed solution.
4. Based on the expected emission rates of the target compounds, specified amounts of the lacquer mixture are spread on Petri dishes.
5. After the preparation of a batch, the Petri dishes are immediately placed into an environmental controlled chamber for 1 day to 3 days for the lacquer mixture to cure.
6. Then the Petri dishes are capped, moved out of the environmental chamber, sealed with aluminum-coated polyethylene composite foils, and shipped to users.

Since lacquer or adhesive is used as the carrier substrate of the reference material and also emits certain solvents, the selected lacquer should account for the following requirements.

Fig. 2 Photo of a batch of lacquer reference materials. Used with permission from Bundesanstalt für Materialforschung und -prüfung, Berlin (BAM)

1. The target compounds of the reference material should not be contained in the original lacquer or adhesive. This ensures that the emission rates of the target compounds are designable and controllable.
2. The signals of the solvents emitted from the lacquer or adhesive should not overlap with the signals of the target compounds for the analytical system. This ensures quantification of the target compounds.
3. The lacquer or adhesive should have low emission rates of solvents. This ensures that the analytical system is not overloaded, and the signals of the solvents do not mask the signals of the target compounds.

Nohr et al. (2014b) examined 12 lacquers for use as a reference materials (6 acrylic-based and 6 alkyd-based) made by the same manufacturer and purchased from the same local building supply store. The acrylic lacquers contained water, a dispersion of acrylate and polyurethane, glycols, additives, preservatives (methyl-, benzyl-, and chlor-isothiazolinone), and pigments (for colored lacquers). The alkyd lacquers contained alkyd resin, additives, white spirit, and pigments (for colored lacquers). The lacquers were mixed with the target compounds following the preparation protocols of the lacquer reference materials listed above. After being cured, the samples were placed in an environmental chamber. Solvents were detected in the air of the chambers loaded with the alkyd lacquers. The signals of the alkyd lacquers masked the signals of some target compounds, such as *n*-methyl- α -pyrrolidone and 2-ethyl-1-hexanol. The high solvent concentrations remained in the chambers for more than 3 days, and the high solvent signals resulted in significant carryover in the analytical system. Compared to the alkyd lacquers, the acrylic lacquers had lower emission rates of solvents, which allowed the emission rate profiles of the target compounds to be more accurately quantified.

For intra-laboratory and inter-laboratory measurements, the chamber air should be sampled at a specific time after loading the reference materials into the environment chambers to reduce the measurement errors associated with the emission rate decay of the reference materials. Moreover, to ensure homogeneity of the material samples, the sample preparation requires large chamber capacities for curing the liquid lacquer mixture of the same batch at the same time.

Film Reference Material

Film reference materials use a solid film as substrate, and the target compound is adsorbed into the film (Fig. 3). The reference material is designed for single-compound emission to avoid competitive diffusion and adsorption of multiple compounds in the diffusion film.

The reference material samples can be prepared by the following steps (Howard-Reed et al. 2011, 2014; Liu et al. 2013, 2014; Cox et al. 2010):

1. A single film sheet is cut into a batch of film samples with the same size.
2. The film samples are placed in loading vessels. Each film is exposed on both sides to the air in the vessel. The air outlet of the last vessel is connected to a

microbalance system. A film sample is hanging inside the microbalance system to monitor its mass during the loading process.

3. According to the mass of the target compound expected to be loaded in each film, the gas-phase target compound at a certain concentration is passed continuously through the vessels and the microbalance system.
4. The mass increase of the single film inside the microbalance is monitored continuously until it reaches steady state. It is assumed the films in vessels upstream of the microbalance are at the same steady-state value. The loading of the target compound is then complete.
5. The film samples are taken out of the vessels, sealed, packed, and are ready to be shipped to the users.

The emission rate of the reference material depends on the mass of the target compound adsorbed in the film and the material properties of the film. The important material properties include thickness, surface area, and the diffusion and partition coefficients of the film. After loading the reference material with the target compound and placing it in a clean environmental chamber, the concentration profile of the target compound in the chamber air should be similar to that generated by a typical homogeneous dry building material.

Significant variation in the emission rate among different material samples of the same batch has been observed after loading. This suggests that loading optimization is needed for the film reference material to improve the measurement reproducibility of its emission rate.

For emission of toluene, a polymethyl pentene (PMP) polymer film (Fig. 3) was selected as a substrate (Cox et al. 2010). The PMP film does not contain organic additives such as plasticizers or stabilizers that could complicate emission rates. For emission of formaldehyde, the PMP film and a polycarbonate (PC) film were both evaluated in terms of their adsorption and desorption properties. Since PC is polar

Fig. 3 Film reference material in loading vessel and last film attached to a microbalance

and PMP is non-polar, the PC film had a much greater formaldehyde solubility than the PMP film (Liu et al. 2013).

The emission rate of the target compound from the reference material and the concentration of the compound in the chamber air can be well-characterized by the mechanistic emission model (Cox et al. 2010). The model considers the reference material as a single-layer porous material with a uniform initial concentration of the target compound. This model is frequently used to characterize the emission of VOCs from dry surface materials. Therefore, the emission profile of the film reference material should be representative of that of dry surface materials.

TPU Reference Material

Thermoplastic polyurethane (TPU) reference materials use molded TPU plates as substrates. The target compounds are impregnated into the TPU plates using high-pressure liquid carbon dioxide (CO_2 , Fig. 4). The reference material can be designed for emission of the mixture of several target compounds. A uniform mixture of the target compounds and liquid CO_2 can be injected into the TPU plates.

The TPU reference material samples can be prepared by the following steps (Richter et al. 2017):

1. A batch of molded TPU plates with designed dimensions is produced. The TPU samples are then stored in a dehydrator for 24 h.
2. The TPU sample masses are measured and placed in a high-pressure view cell. After sealing the cell, certain amounts of the target compounds are injected into the cell using syringes.
3. Liquid CO_2 is added to the cell using a regulating valve until the liquid CO_2 and the target compounds combine into one phase. This typically occurs above a pressure of 60 bar and at a temperature of 20 °C.
4. The high pressure is maintained in the cell for a designated time to allow the target compounds to permeate the TPU plates. A magnetic stirrer is used inside the cell to increase the mass transport during the permeation process.
5. The chamber is then slowly depressurized to allow the CO_2 to leave the TPU samples.
6. The TPU samples are stored in a dehydrator for 4 h, then shrink-wrapped in aluminum-coated polyethylene foil.

Fig. 4 Schematic of the TPU reference material. Used with permission from Bundesanstalt für Materialforschung und -prüfung, Berlin (BAM)

The emission test of a TPU reference material impregnated with styrene measured in an environmental chamber for 25 days showed that the emission rate of the styrene reference material decreased with time (Richter et al. 2017). Significant variation in the emission rate among different material samples of the same batch was observed within 10 days after their fabrication. This suggests that sample storage and hominization may be needed for the TPU reference material to improve the measurement reproducibility of its emission rate. Moreover, studies of the emission mechanism of the TPU reference material are also needed. An emission mechanism study will allow a better understanding of the emission characteristics of the reference material and determining the theoretical emission rates for future development.

LiFE Reference Material

A liquid diffusion-film-emission (LiFE) reference material is comprised of a polytetrafluoroethylene (PTFE) or stainless-steel bottle containing pure liquid VOC as the emission source, a thin diffusion film to cover the opening of the bottle to control the emission rate and fastening pieces to hold the bottle and film in place (Fig. 5). The bottle and all the fastening pieces are made of PTFE or stainless steel. Due to low diffusivity of VOCs through PTFE and stainless steel, VOC diffusion through the bottle container can be neglected compared to that through the diffusion film at room temperatures (Wei et al. 2012a, b, 2013; Poppendieck et al. 2018).

The reference material is designed for single-compound emission to avoid competitive diffusion and adsorption of multiple compounds in the diffusion film. The film material is chosen based on the properties of the chemical. An aluminum oxide melamine-impregnated paper was selected to be the diffusion film for the toluene reference material (Wei et al. 2012a, b, 2013), and a polydimethylsiloxane film was selected to be the diffusion film for the formaldehyde reference material (Wei et al. 2013).

The reference material samples can be prepared by the following steps (Wei et al. 2012a, b, 2013).

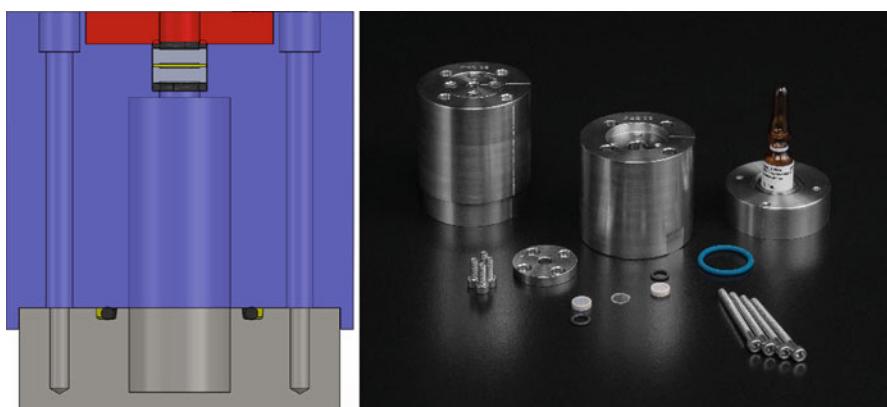

Fig. 5 LiFE reference material assembly and components. Photo Credit Dan Greb, 2021

1. Based on the expected emission rate of the target compound, and the diffusion and partition coefficients of the selected diffusion film, the diameter of the film is calculated, and the bottle and fastening pieces are chosen according to the size of the diffusion film.
2. The target compound in liquid form is placed into the bottle. Pure VOC liquid at room temperatures is used as the emission source of the reference material. Formaldehyde exists in the gas phase under room temperatures; thus, formalin solution (formaldehyde in water) is used as the emission source.
3. The diffusion film is then fixed on top of the bottle using fastening pieces. These can include screws, stainless steel frits, and o-rings.

During the use of the reference material, the concentration of the target compound at the lower surface of the diffusion film is its saturation concentration. Volatile compounds, such as formaldehyde, benzene and toluene, can diffuse through the film within a few hours (Wei et al. 2012a, b, 2013; Poppendieck et al. 2018). The reference material has a constant emission rate of the target compound under constant temperature and relative humidity. The emission rate of the reference material should be representative of the emission levels of building materials. To reach a desired emission rate, the diameter of the film increases with decreasing diffusion coefficient of the film. Therefore, the mass transfer and geometric parameters of the film need to be optimized. Reference materials with large diameters may be difficult to load in small environmental chambers. Reference materials with small diameters may have higher uncertainties in the emission rate.

The constant emission rate can be described as a function of the diffusion and partition coefficients as well as the diameter and thickness of the film. Figure 6 shows the geometry-diffusion relation of the film for different emission levels. The zone in the dashed line is optimized with regard to the mass transfer and geometric parameters.

The variability in LiFE reference materials is directly tied to the film. Film thickness, flatness, seals, and handling of films can all lead to varying emission rates from otherwise identical LiFE bottles. Films specifically produced for uniform thickness, placed between stainless steel frits, and held together with a constant pressure using o-rings have been employed to reduce variability between LiFE reference materials (Poppendieck et al. 2018).

Temperature-Controlled Diffusive Evaporator

The temperature-controlled diffusive evaporator reference material is comprised of a stainless steel bottle containing pure liquid VOC as the emission source, a thin diffusive capillary acting as an emission restrictor, and a temperature control system to heat the bottle to a set temperature (Fig. 7) (Uhde and Aksteiner 2018). The battery-powered, electronic control system is contained within the sealed bottle. The reference material allows for multiple-compound emission depending on the liquid reservoir. The bottle is sized so ampules of liquid source fluid can be directly placed within the bottle. The temperature of the bottle can be adjusted from 30 °C to 55 °C.

Fig. 6 Geometry-diffusion relation of the diffusion film (A : surface area, L : thickness, D_m : diffusion coefficient, K : partition coefficient)

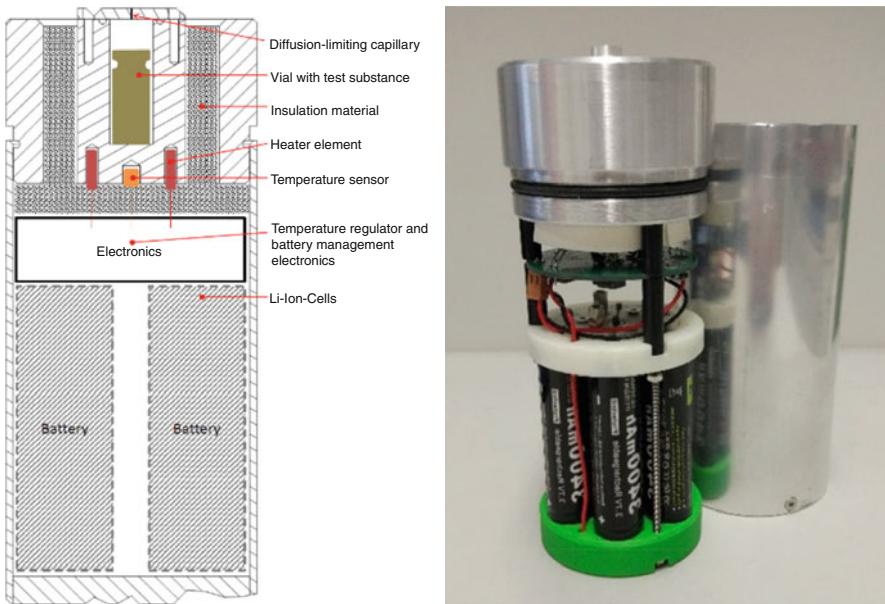

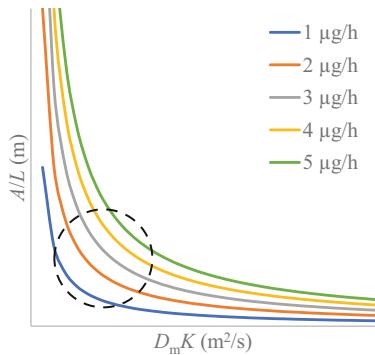

Fig. 7 Diagram of temperature-controlled diffusive evaporator (Illustration and Photo used with permission from creator Erik Uhde)

The reference material samples can be prepared by the following steps (Uhde and Aksteiner 2018).

1. The target compound in liquid form is placed into the bottle.
2. Based on the volatility of the target compound the bottle temperature is set.
3. The bottle is sealed and place in the chamber.

The elevated temperature of the system allows the quantification of less volatile chemicals like dodecane. Long-term performance and inter-laboratory tests have not been performed on temperature controlled diffusive evaporator reference materials.

Inter-laboratory Proficiency Testing Studies of Reference Materials

Between 2009 and 2018 a total of eight inter-laboratory studies using designed reference materials were reported in the literature (Table 3). These studies used films, lacquer, adhesives, and LiFE reference materials with 4 to 55 participating laboratories. A variety of chamber sizes, analyses, and chamber methods were used. Reported RSDs quantify the combined uncertainty from: (1) sample variation of the material being tested, (2) the emission testing system, (3) the analytical concentration measurement, and (4) procedure variability.

Reference Material Studies

Each of the eight reference materials studies had unique challenges and drew varying conclusions.

Film. There have been two inter-laboratory studies using film reference materials conducted by the same group. Howard-Reed et al. (2011) conducted a pilot inter-laboratory study with four laboratories using a film loaded with toluene as the reference material. Average RSDs of toluene emission rates determined by different laboratories were 9% to 15%. Generally, RSDs were lower for samples taken at later times. Analysis of between-batch and within-batch variance indicated that the film sample age (time between produced and tested) may be a more important variable than differences between the batches or among samples within a batch. This study highlights the challenge of storage for commercial reference materials prior to sale.

Howard-Reed et al. (2014) conducted a follow-up inter-laboratory study to evaluate a toluene film in chambers of various sizes in 14 laboratories in seven countries. Each laboratory was provided duplicate specimens, standard analytical solutions, and a test protocol. Based on chamber size used in the study, ten laboratories were grouped as small chambers and the remaining four were considered large chambers. RSDs range from 19% to 23% for laboratories using a small chamber and meeting all the test method criteria. RSDs for laboratories using a large chamber were higher (55–57%). Keeping the film at a subzero Celsius temperature until tested proved difficult for international shipping. This study highlights how challenging shipping and storage temperature can be for reference material distribution.

Lacquer. The Bundesanstalt für Materialforschung und -prüfung (BAM, Federal Institute for Materials Research and Testing) has conducted four international proficiency tests (2009, 2014, 2016, 2018) using lacquer reference materials (Wilke et al. 2021). A separate group (Oppl et al. 2020) also conducted an independent lacquer and adhesive study.

In 2009, Wilke et al. (2011) from BAM conducted a study that involved 37 international laboratories. A lacquer standard reference material containing nine chemicals was used as the testing material. Of the nine chemicals diethyl phthalate

Table 3 Summary of inter-laboratory studies of designed reference materials for chamber testing of chemical emissions.

Reference	Test Year	Test material	Chemicals	Chamber method	Chamber	Inter-laboratory RSDs
Howard-Reed et al. (2011)	2009	film	Toluene	ASTM 5116	0.05 m ³ to 0.086 m ³	9% to 15% (n = 4)
Howard-Reed et al. (2014)	2012	film	Toluene	ASTM 5116	0.024 m ³ to 0.12 m ³ 0.225 m ³ to 1.0 m ³	19% to 23% (n = 10) 55% to 57% (n = 4)
Wilke et al. (2011)	2009	lacquer	9 VOCs (styrene, diethyl glycol dimethyl ether, phenol, limonene, tridecane, benzene, hexanal, diethyl phthalate and D4-siloxane)	ISO 16000-9	N = 32 < 0.1 m ³ 0.1 m ³ < n = 34 < 1 m ³ N = 34 > 1 m ³	28% to 69% (n = 37)
Horn et al. (2018)	2014	lacquer	9 VOCs (hexanal, styrene, n-decane, limonene, 2-ethyl-1-hexanol, N-methyl- <i>o</i> -pyrrolidone, 2-ethylhexyl acrylate, dimethyl phthalate, and n-hexadecane)	ISO 16000-9	0.02 m ³ to 3 m ³	29% to 63% (n = 55)
Wilke et al. (2021)	2016	lacquer	8 VOCs (Butyl acetate, Styrene, Decane, 1,3,5-Trimethylbenzene, 3-Carene, Dodecane, Texanol, 2-Propoxyethanol)	ISO 16000-9	n = 13 < 0.1 m ³ 0.1 m ³ < n = 51 < 1 m ³ n = 36 > 1 m ³	22% to 48% (n = 49)
Oppl et al. (2020)	2017	adhesive and lacquer	7 VOCs (2-Ethyl-1-hexanol, Acetic acid, 1-Butanol, Propylene glycol, Triethylamine, Dipropylene glycol mono methyl ether, and Butylhydroxy- toloul)	GEV / EN 16516	—	30% to 41% (n = 33); 21% - 64% (n = 25)
Wilke et al. (2021)	2018	lacquer	12 VOCs (Styrene, Toluene, Decane, 2-Propoxyethanol, Triethylamin, Cyclohexanone, Camphene, Octanal, p-Cymene, Butylglycol acetate, Dimethyl adipate, Butyl hydroxy toluene)	EN 16516	n = 7 < 0.1 m ³ 0.1 m ³ < n = 66 < 1 m ³ n = 27 > 1 m ³	22% to 39% (n = 50)
Poppendieck et al. (2018)	2017	LiFE	Formaldehyde	ASTM 6007	0.02 m ³ to 0.086 m ³	14% (n = 4)

and D4-siloxane were not detected by most of the laboratories. Benzene, the most volatile compound, had the highest RSD of 69%. The authors hypothesized this may be due to varying air velocities over the lacquer surface during the drying process of the lacquer causing different evaporation rates among samples. The RSDs for the other six chemicals ranged from 28% to 50%. This study highlights the difficulties in manufacturing consistent reference materials.

In 2014, the BAM group (Horn et al. 2018) challenged 55 laboratories with a lacquer standard reference material. Nine VOCs were tested in chambers ranging in size from 0.02 m³ to 3 m³. Generally, both the inter-laboratory and intra-laboratory variations for *n*-methyl- α -pyrrolidone, 1,2-dimethyl phthalate, and *n*-hexadecane were higher than the other chemicals. The authors attribute this to analytical issues. The overall results show that the inter-laboratory RSDs ranged from 29% to 63% for all 55 participants, while the intra-laboratory RSDs ranged from 5% to 19%. This study highlights the need for precise reference materials to allow for determination of causes of inter-laboratory variations.

In 2016, the BAM group (Wilke et al. 2021) challenged 49 laboratories with a lacquer reference material spiked with eight VOCs. In 2018, they repeated the study with 50 laboratories with a lacquer reference material spiked with 12 VOCs. In these studies, VOCs with higher boiling points (dimethyl adipate, 227 °C; butyl hydroxy toluene, 265 °C; texanol, 244 °C) had similar magnitude RSDs as those with lower boiling points. All sampling was conducted within 7 days of drying of the lacquer. There may be a challenge to store commercial lacquer reference materials for longer periods prior to sale.

Oppel et al. (2020) conducted an inter-laboratory study with 33 laboratories from 12 countries. Two spiked flooring adhesives and one spiked parquet lacquer were tested using the GEV testing method for emission testing of products for flooring installation, adhesives, and building materials. The testing included the preparation of the test materials by the participants, rather than a central manufacturer. Participants were not informed of the VOCs to be analyzed. This resulted in variations in which chemicals were analyzed with substance specific calibration versus toluene equivalents. A total of 15 laboratories quantified the concentrations of 2-methyl-4-isothiazolin-3-one with substance-specific calibration (mean 27 mg m⁻³), while 19 laboratories reported 2-methyl-4-isothiazolin-3-one concentrations using toluene equivalents with a mean concentration of 10 mg m⁻³. Non-identified VOCs were reported by 15–20 of the laboratories for the three reference materials. RSDs for individual target VOCs ranged from 21% to 64%. This study highlights how analytical challenges can affect the reported concentrations for emission reference materials, especially when the chemicals are unknown to the user.

LiFE. Poppendieck et al. (2018) conducted an inter-laboratory study with four laboratories. Formalin was placed in stainless steel bottles, and formaldehyde diffused through a polydimethylsiloxane (PDMS) film at the top. Intra-laboratory RSD of six bottle systems was 5%. Inter-laboratory RSD between four laboratories was 14%. Testing laboratories had slightly different temperatures, relative humidities and chamber air change rates. The authors theorized that variability in commercially purchased film thickness effected the results. This study highlights the potential

difficulty in producing commercially viable reference materials due to material component challenges.

Inter-laboratory Summary

The RSDs for inter-laboratory tests have varied with year of the study, the type of reference material and the chemicals studied.

Wilke et al. (2021) notes a decrease in RSD over the last 20 years for European inter-laboratory testing. A review by Oppl (2008) in which six published and several unpublished inter-laboratory tests with 10–20 participants were summarized showed that the included studies using building materials had similar RSDs of $\pm 50\%$. The study by De Bortoli et al. (1999), which also used building product reference materials, had a mean RSD of 51%, while the most recent lacquer study by Wilke et al. (2021) in 2018 had a mean RSD of 28%.

This trend coincides with the transition away from building material reference materials to designed reference materials for use in inter-laboratory studies (Fig. 8). In addition, studies using multiple chemical lacquer reference materials (Table 3) have had higher RSD than those using single chemical film or LiFE reference materials. However, the studies using film or LiFE reference materials have had far fewer participants than the Lacquer studies.

Wilke et al. (2021) examined trends in four lacquer reference material studies from 2009 to 2018 (Table 3) in the context of chemical properties. There was a relationship between a chemical's RSD and Log K_{ow} (octanol-water partition coefficient) values. For chemicals with a Log K_{ow} less than 0, the RSD values were between 38% and 58%, while for chemicals with a Log K_{ow} greater than 4 the RSD

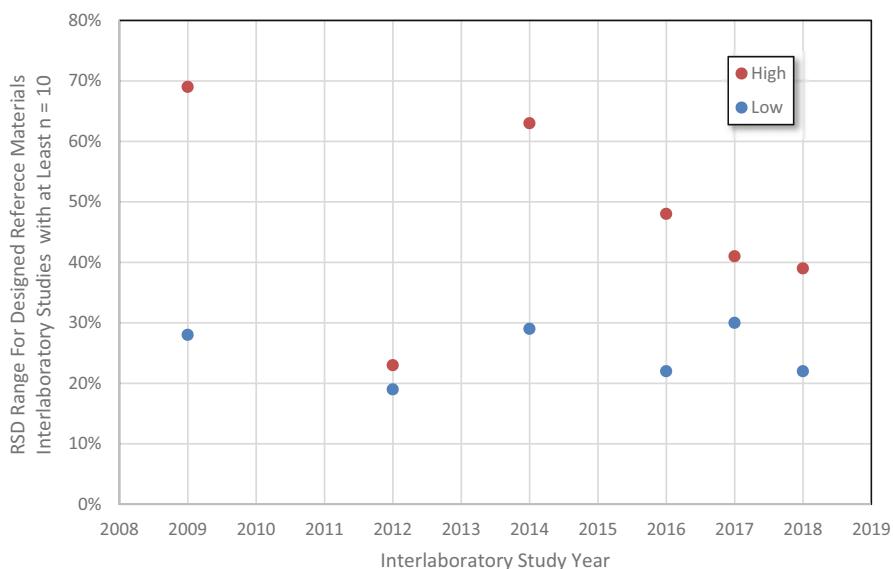

Fig. 8 RSD values for designed reference material inter-laboratory studies

values were between 20% and 32%. However, Wilke et al. (2021) showed that the boiling point was a poor predictor of the inter-laboratory RSD for chemicals with boiling points below 270 °C.

Generally, several factors have been controlled or examined to reduce variability in the inter-laboratory testing. These factors include preliminary testing to check the heterogeneity of testing materials, packaging and shipping. However, few studies discussed the influence of different factors on the variability in detail. Chemical analysis of the samples of the chamber air has been considered as the main factor for variation in the emission testing results Oppl (2008), but no quantitative analysis has been given for this conclusion. Identification of important influencing factors and quantification of the degree of influence of each factor on the observed discrepancies would be helpful for better control of the factors and thus reduction of the variability of inter-laboratory study results. In addition, as test materials and analytical techniques are evolving, it is important to evaluate testing procedures regularly.

Uncertainties in Emission Testing When Using Reference Materials

Uncertainty quantified in inter-laboratory studies using reference materials can be attributed to four major components:

1. Reference material variability
2. Emission testing system variability
3. Analytical measurement variability
4. Inter-laboratory study procedure variability

These issues are discussed in detail below.

Reference Material Variability

There are three major issues that are of concern and can affect reference material variability: producibility, homogeneity, and stability.

Producibility

Emission reference materials need to be able to be produced safely in a large enough batch to be useful for comparison purposes. To produce the emission reference materials, target compounds at high concentrations are often used. These concentrations potentially can be dangerous to the manufacturer or user of the reference material. For drying or curing reference materials, neat compounds are added to the lacquer or adhesive. For the LiFE reference material, pure liquid compounds and formalin solution are used to be the emission source. For the film and TPU reference materials, high concentrations of target compounds are adsorbed or impregnated into the substrate materials to be the emission source. The target compound, such as

formaldehyde and toluene, or the source solution like formalin, can have hazardous effects if improperly handled.

To produce a batch of reference materials for inter-laboratory comparisons, all the material samples should be produced at the same time for homogeneity. Designing a production method to make sufficient emission materials in one batch can be challenging. For the film and TPU reference materials, the number of reference materials produced in one batch is limited by the volume of the vessels for the target compounds to be adsorbed or impregnated into the substrate materials. Larger volumes may have mixing issues that can lead to homogeneity issues between samples. For lacquer reference materials, the lacquer mixture is poured into Petri dishes under a certain time limit to ensure the homogeneity among the samples, and the number of Petri dishes in one batch is limited by the volume of the environmental chamber for the lacquer mixture to cure.

User operation also needs to be considered to ensure that varying user techniques do not affect the emission rate. For instance, for the LiFE and temperature-controlled evaporator reference materials, the bottle filled with the liquid compound should always be moved in a slow, level manner to avoid contact of the liquid compound with the diffusion film.

Homogeneity

Homogeneous reference materials are needed for intra-laboratory test results to be reproducible and for the inter-laboratory test results to be comparable (Horn et al. 2018). Homogeneous reference materials ideally have an identical emission rate profile among different material samples for the target compound. The homogeneity of the reference materials is associated with the nature of the materials and their production methods. Historically, challenges associated with acquiring or producing homogenous reference materials (De Bortoli et al. 1999) have been one of the largest barriers to commercially viable certified reference materials.

For the lacquer and adhesive reference material, adequate stirring is essential to form a uniform mixture of the target compounds. For the TPU reference material, stirring also allows formation of a uniform mixture of the liquid CO₂ and target compounds, so that the target compounds can be impregnated homogeneously into the TPU substrate. Richter et al. (2017) noted that TPU emission variability between batches persisted for up to ten days after production. After ten days the emission profiles between batches homogenized.

For the LiFE and film reference materials, the emission rate of the reference material is controlled by the diffusion films. Varying film thickness was identified as one reason for variation in emission rates for LiFE systems (Poppendieck et al. 2018). The selected films should be as homogeneous as possible, with film thickness of each sample measured.

Stability

Time is required for shipment of the reference materials and storage at the laboratory prior to chamber testing. For inter-laboratory comparisons, the time needed for shipments ranges often from 2 days to 14 days, depending on if the shipment is

local or international (Horn et al. 2018; Howard-Reed et al. 2011, 2014). Reference materials containing hazardous materials can be delayed further, especially when transported through international borders. In addition, for commercially viable products the reference material may need to be stored prior to sale for months or years prior to use.

The environmental conditions, for example, temperature and relative humidity, during shipment and storage may influence the stability of the reference materials, and the target compounds may emit from the reference material and be lost through the packaging (Horn et al. 2018; Howard-Reed et al. 2014). To reduce loss of the target compounds, the film reference material has been shipped on dry ice to reduce the temperature in the package (Howard-Reed et al. 2011, 2014). However, the environmental conditions during shipment can be altered due to unexpected delays or other problems. Therefore, losses of target compounds may occur during shipment and storage, especially of high volatility compounds. To evaluate the stability of the lacquer reference materials, two material samples were wrapped in aluminum-coated polyethylene composite-foils and stored at 23 °C and 50% RH. A total of 14 days was the estimated maximum time for shipment and storage (Horn et al. 2018). Among the nine compounds emitted by the lacquer reference material, the emission rates of hexanal, styrene and *n*-decane decreased by 10% to 30% after 14 days, while the emission rates of limonene, 2-ethyl-1-hexanol, *n*-methyl- α -pyrrolidone, 2-ethylhexyl acrylate, dimethyl phthalate, and *n*-hexadecane were consistent with the freshly produced samples (Horn et al. 2018).

Storage test results suggest that (1) the environmental conditions for storage and shipment need to be verified prior to usage of the reference materials; (2) emission rate decay needs to be verified for certain compounds prior to chamber testing; and (3) to ensure the comparability of the inter-laboratory test results, reference materials with short storage lives should be from the same batch and loaded in the environmental chambers at the same time.

Emission Test System Variability

The emission rate of the reference material can be influenced by the experimental condition of the environmental chamber, for example, temperature, relative humidity, and air change rate (Howard-Reed et al. 2014; Nohr et al. 2014a, b; Wei et al. 2012a, 2013). Systematic bias in these parameters can result in bias in the measured emission rate of the reference material. This is one reason intra-laboratory variability is typically lower than inter-laboratory variability (Risholm-Sundman et al. 2007; Horn et al. 2018; Wilke et al. 2021; De Bortoli et al. 1999; ISO 2015; Richter et al. 2017).

Temperature

Emission rates often increase with increasing chamber temperature. Wei et al. (2013) noted that formaldehyde emitted from the LiFE bottle is controlled by the Henry's law constant, the film diffusion coefficient, and the air-membrane

partition coefficient, all of which are temperature dependent. Liu et al. (2014) highlighted for a film reference material that as temperature increases the diffusion coefficient for the target chemical in the film decreases and the partition coefficient between the air and film increases. The results by Liu et al. (2014) demonstrate these impacts as toluene concentrations more than tripled as temperatures increased from 10 °C to 30 °C in a chamber with a film reference material. Wei et al. (2012a) found an R² (square of correlation coefficient) value of 0.97 for the correlation between the emission rate and temperature for toluene emitted from a LiFE bottle between 10 °C and 30 °C.

Hence, chamber temperature control or measurement issues could be a significant contributor to elevated inter-laboratory RSD values. To address temperature uncertainty, temperature should be measured in each individual chamber, as temperature can vary in large temperature-controlled enclosures. In addition, temperature measurements should be checked to traceable standards on a regular basis.

Relative Humidity

The influence of relative humidity on the emission rate may depend on the target compound and reference material (Liu et al. 2014). Wei et al. (2013) note that mechanistically relative humidity affects a chemical's film diffusion coefficient and partition coefficient for a LiFE system, but to a lesser degree than the temperature. Wei et al. (2012a) found toluene emitted from a LiFE bottle decreased when relative humidity increased from 33% to 50%, but the impact was mixed at 70%. Overall, Wei et al. (2012a) found the impact of changes in relative humidity on toluene emissions was less than those of temperature. Liu et al. (2014) showed the changes in the relative humidity did not significantly influence the diffusion coefficient and partition coefficient for a film system at tested temperatures.

Air Change Rate

The air change rate, λ (1/time), will directly affect the concentration in the chamber. When steady state is achieved the chamber mass balance takes the form in Eq. 1:

$$C = \frac{E}{\lambda V} = \frac{E}{Q} \quad (1)$$

where E is the emission rate (mass/time), C is concentration in the chamber (mass/sample volume), and V is chamber volume (volume). The air change rate is defined as the chamber flow rate, Q (volume/time) divided by the chamber volume V. Hence, if the actual airflow rate is greater than intended, the measured concentration will be lower than intended for the same emission rate. This is important for regulations that rely on chamber concentrations rather than emission rates (e.g., USEPA Formaldehyde Emission Standards for Composite Wood Products Rule).

In addition, under certain conditions the emission rate can be dependent upon the air speed above the material. Wei et al. (2012a) noted that the influence of the airflow speed on the emission rate is less than 1% if

$$\frac{1}{h_m} < 0.01 \frac{L}{D} \quad (2)$$

where L is the material thickness (length), D is the material diffusion coefficient (length squared/time), and h_m is the convective mass transfer coefficient (length/time). Typically, the airflow speed over the material can be ignored for most VOCs if it is higher than 0.014 m/s, while it can be an important factor for SVOCs. To address uncertainties due to airflow, flow measurements should be validated to traceable standards on a regular basis.

Chamber Impacts

Less volatile chemicals can sorb to the chamber walls to various degrees depending on the chamber material and chamber loading rate (Horn et al. 2018; De Bortoli et al. 1999). This sorption can complicate the calculation of the emission rate for these chemicals.

Summary

To reduce the uncertainty in the emission rate of reference materials, mass-transfer parameters, for example, diffusion and partition coefficients of the target compounds in the reference material, should not vary significantly with the temperature, relative humidity, and airflow.

Analytical Measurement Variability

Analytical measurements to quantify chamber concentrations can also lead to uncertainty in quantified chamber emission rates. In most cases, over half of the combined standard uncertainty of inter-laboratory studies has been attributed to the calibration and precision of analytical equipment (Howard-Reed et al. 2014). Contributors to uncertainty can include analytical equipment type, sampling uncertainty, and standard bias.

Analytical Equipment

One issue in comparing chamber concentrations for inter-laboratory studies is that each lab could quantify the chemical using a different method. For instance, there now exist a wide range of commercial means to quantify formaldehyde concentrations in chambers, including chromotropic acid, 2,4-Dinitrophenylhydrazine (DNPH) derivatization, Hantzsch reaction derivatization, electrochemical cell, photoacoustic, cavity ringdown, FTIR spectrometry, chemical ionization mass spectrometer, and laser adsorption spectrometer. Sample times for the varying methods can be every second or last an hour, and the sensitivity can vary for each technique.

Sampling Uncertainty

Each sample pump or flow controller will also introduce uncertainty in the final emission rate measurement. Derivatization and sorbent methods will be affected by the stability of the derivatization or sorbent under the storage conditions used after sampling but prior to analysis. Wet chemistry methods introduce uncertainty related to acid strength, solvent volumes, and other reagents.

Gas chromatograph columns, co-eluting peaks, unresolved baselines, and method of peak integration can all impact quantification analysis of chemicals using gas chromatographic methods (De Bortoli et al. 1999; Oppl 2008).

Standards Bias

Use of toluene equivalence analysis for quantification will result in different values than when using specific calibrants (Oppl 2008). Oppl et al. (2020) reported that for a 33-participant inter-laboratory study the RSDs of total volatile organic compounds (TVOC) (the sum of VOC concentrations) quantified using toluene equivalence were between 30% and 38%. In the same study, the RSD for TVOC values determined from specific calibrants ranged from 36% to 41%. The same study showed that the TVOC values determined from specific calibrants were 1 to 2.5 times larger than those determined from toluene equivalents.

Inter-laboratory Study Procedure Variability

Inter-laboratory study participants are often given a set of procedures and parameters under which to run the experiment (e.g., ASTM E691 Standard Practice for Conducting an Inter-laboratory Study to Determine the Precision of a Test Method) (ATSM 2020). For instance, the inter-laboratory study may specify the chamber volume, airflow rate, temperature and relative humidity, air speed above the material, the sampling time(s) along with the sampling device, tubes, columns, internal standards, thermal desorption, and GC operation (Horn et al. 2018). Some inter-laboratory studies create data entry spreadsheets to ensure uniform data collection (Howard-Reed et al. 2014).

However, the instructions may not always be followed exactly. De Bortoli et al. (1999) and Howard-Reed et al. (2014) had issues with participants using the correct chamber airflow rates and storage temperature. Some inter-laboratory studies notify the participants of the target chemicals (Poppendieck et al. 2018) while others do not (Horn et al. 2018). A study by Oppl et al. (2020), which did not notify participants of the target chemicals, showed between 4 and 8 of the 33 participants were unable to quantify the target chemical depending on the matrix. Some inter-laboratory studies send a liquid calibration solution to separately assess the laboratory performance. However, not all laboratories used it in the Howard-Reed et al. (2014) study. Finally, studies need to have enough participants to evaluate statistical significance. Some preliminary studies (e.g., (Howard-Reed et al. 2011; Poppendieck et al. 2018) only involved four laboratories.

Conclusions

Regulators and emission certification programs are implementing emission test systems in an ever-increasing frequency to reduce or at least monitor the impacts of materials on indoor air quality. Validation of these testing platforms has relied on inter-laboratory testing for the last 30 years. Over that period, emission testing performance has improved (Fig. 8), as measured by reduced relative standard deviations of inter-laboratory studies. Over the last 15 years inter-laboratory studies have moved away from using existing building materials to specifically designed materials for emission testing. However, use of these designed materials still requires a time-consuming inter-laboratory effort, as currently there are no certified reference materials available on the market. This is due to the challenges associated with determining the uncertainty associated with the material (as opposed to the emission testing and analytical systems) and determining the metrological traceability of the measurements. However, it is hoped that in the future designed reference materials can be certified and manufactured that are fit-for-purpose, homogeneous, and stable.

Disclaimer Certain commercial equipment, instruments, or materials are identified in this chapter in order to specify the procedures adequately. Such identification is not intended to imply recommendation or endorsement by NIST, nor is it intended to imply that the materials or equipment identified are necessarily the best available for the purpose.

chambers, and the presence of occupants can greatly affect indoor air quality. First, this chapter addresses multiple VOC emission/sorption of building materials in different indoor settings. Then, VOC emissions from occupants due to the use of personal care products in university classroom are introduced. Following that, the indoor chemistry of VOCs related to ozone/squalene reactions in real residence is given. Aside from VOCs, it is also of concern to predict concentrations and fate of indoor SVOCs to further assess human exposure to these ubiquitous chemicals and their potential health effects. Based on the source emission characteristics of SVOCs, emission models are described as well as critical differences between modeling VOCs and SVOCs. Due to the substantial partitioning of SVOCs among the gas, particle, dust, and surface, partitioning models and correlations for estimating partition coefficients are reviewed. Lastly, the dynamics of SVOCs in different phases are described using fugacity-based and mass-transfer-based models.

Keywords

Volatile organic compounds (VOCs) · Semi-volatile organic compounds (SVOCs) · Personal care products · Indoor chemistry · Complex indoor environments

Introduction

Due to the ubiquitous use of a wide range of consumer products and articles such as building materials, decorative items, furniture, personal care products, and baby care products in real indoor environments, it is important to assess human exposure to volatile organic compounds (VOCs) and semi-volatile organic compounds (SVOCs) emitted from these products and articles. For this purpose, data on the concentration of VOCs and SVOCs in indoor environments is needed. Predicting VOC and SVOC concentrations with models can provide detailed information, for example, about concentration changes over time, chemical distribution among indoor compartments, and the influence of certain activities, which may help implement measures to improve indoor air quality. In this chapter, models that focus on VOC and SVOC emission, transport, and fate in real indoor environments are reviewed.

According to definition, VOCs are classified as a class of organic compounds with a boiling point ranging from 50 °C to 240 °C, while SVOCs with a boiling point ranging from 240 °C to 400 °C. Compared with VOCs, SVOCs have higher boiling points and lower saturated vapor pressures. Since the chemical properties of VOCs and SVOCs are different, it leads to that the described models and key parameters are also different. Therefore, the predictions on VOCs and SVOCs in real indoor environment are introduced separately, by different sections in this chapter.

As far as the VOCs are concerned, in contrast to controlled chamber studies, the mass transport of VOCs occurred in real indoor environments owns several characteristics: (1) Multiple sources, sinks, and surfaces coexist (Wang et al. 2020), and the

ventilation conditions vary with time and space (Liu et al. 2019), which complicates VOC emission and transport behaviors. The emissions from one material may interact with emissions from other materials, which means that a simple summation of emissions from individual materials may not represent reality. (2) In addition to the emissions from indoor materials and products, the presence of occupants contributes significantly to indoor air composition (Weschler and Carslaw 2018), especially in densely occupied indoor settings, e.g., classroom, meeting room. The impact of occupancy includes two aspects. On one hand, the use of personal care products and cleaning products will affect the concentration of chemicals indoors. On the other hand, there are many sources of reactive chemicals in real indoor air, including outdoor air. Pollutants such as ozone can enter with the ventilation air or air that infiltrates through window frames, doors, and other openings in the building envelope. The reactions between ozone and squalene, which is abundant in human skin oil, will generate a variety of oxidation products, which may further have an adverse effect on indoor air quality. Therefore, the introduction on the prediction of VOCs in real indoor settings will include three sections: section “[VOC Emission/Sorption from Multiple Sources/Sinks in Different Indoor Settings](#)”; section “[VOC Emission from Occupants Due to the Use of Personal Care Products](#)”; section “[Reactions of Ozone with Squalene in Realistic Indoor Environments](#).“ These sections represent the VOC transport in different indoor settings (including in-cabin environment, classroom and residence) on different levels (including physical transport, chemical reaction, and physical-chemical combined transport). Since much work has been done, we just introduce some typical work in these three aspects. It should be noted that, field observations in realistic indoor settings under normal occupancy are important complements to laboratory investigations. The application of highly accurate online equipment for time- and space-resolved measurements provides the dataset for modeling input (Liu et al. 2019).

Similar to VOCs, SVOCs also include various kinds of compounds such as phthalate esters (PAEs), polycyclic aromatic compounds (PAHs), polybrominated diphenyl ethers (PBDEs), and polychlorinated biphenyls (PCBs) (Weschler and Nazaroff 2008). Field measurements show that SVOCs are ubiquitous in various consumer products and articles used in real indoor environment (Xu and Zhang 2011; Lucattini et al. 2018).

Carpets, textiles, and clothing became important emission sources of polyester and polypropylene, since woven carpets made of cotton and wool have been widely replaced by tufted carpets made of synthetic fibers such as nylon, rayon, and acrylics in the 1950s (Weschler 2009). Some additives including flame retardants (FRs) and surfactants are added to these materials, so FRs (organophosphate and brominated flame retardants (OPFRs and BRFs)) and per- and polyfluoroalkyl substances (PFASs) are commonly found in fiber carpets and other textile products. The use of electronic equipment is resulting in increased emission of some SVOCs including OPFRs and BFRs into indoor environments (Weschler 2009). One study from China (Chen et al. 2010) showed that PBDEs derived from penta-, octa-, and deca-mixtures were detected in 83.3%, 58.3%, and 83.3% of the television casings, respectively. Concentrations of PBDEs in computer monitor casings were generally <50 ng/g,

except for one sample which contained 13,304 ng/g. The concentrations of PBDEs were higher in computer components (mean value 279,965 ng/g) than in television and computer casings. Besides FRs, plasticizers, TBBPA, PBDEs, 1,2-Bis(2,4,6-tribromophenoxy)ethane (BTBPE), tris(phenyl)phosphate (TPhP), tris (2-chloroisopropyl) phosphate (TCIPP), and tris(methylphenyl) phosphate (TMPP) were also found at relatively high concentrations (ranging from $\mu\text{g}/\text{g}$ to mg/g) (Ballesteros-Gómez et al. 2013; Brandsma et al. 2014). In furniture, soft foam in cushioning for bedding, sofas, and chairs may emit some kind of FRs (Lucattini et al. 2018). Building materials such as insulating foams, flooring, facades, paints, varnishes, sealants, and adhesives mainly comprise of FRs, perfluorocarboxylic acids (PFCAs), PAEs, and PCBs (Lucattini et al. 2018). Interestingly, also products intended to improve hygiene, such as personal care, health care, and cleaning products, may emit SVOCs that can negatively affect people's health. Investigations showed at least one polyfluorinated compound (PFC) existed in any given household cleaning product or spray (Danish Environmental Protection Agency 2006). Some phthalates including diethyl phthalate (DEP) and dibutyl phthalate (DBP) were found in moisturizers and nail polish samples (Chen et al. 2005). Thus, it can be concluded that indoor SVOC sources are ubiquitous and various, and that the emissions are complicated, which makes the prediction of SVOC concentrations in indoor environments difficult.

Predicting VOC Concentrations in Real Indoor Environments

VOC Emission/Sorption from Multiple Sources/Sinks in Different Indoor Settings

Sink-Diffusion Model in Multi-Sink Residential Rooms

Due to the complexity of real indoor settings, many mass transfer processes may happen concurrently, e.g., emission or sorption from or to different materials and products. Singer and some co-authors (Singer et al. 2007) have done much work on the sorption behaviors of VOCs in residence. They conducted a series of experiments to characterize VOC sorption in residential rooms with furnishings and material surfaces unaltered and in a furnished chamber designed to simulate a residential room (Singer et al. 2007). For the tested ten rooms, multiple sinks coexisted, which can be grouped into four categories: (1) fleecy/padded (e.g., carpet, upholstery, bedding, other fabrics); (2) painted wallboard/plaster; (3) hard/porous (e.g., wood, plastic, laminate, paper); (4) hard nonporous (e.g., glass, metal, tile, porcelain). During the test, a VOC mixture was rapidly volatized into the room, which generated a net movement of VOC mass from the gas phase to the room materials. The sorption processes lasted for 5 h until quasi steady state was reached. Singer et al. (2007) applied the following sink-diffusion model to simulate the VOC mass balance in the residential room:

$$\frac{dC}{dt} = -(\lambda + \lambda_a)C + \lambda_d M \quad (1)$$

$$\frac{dM}{dt} = \lambda_a C - (\lambda_d + k_1)M + k_2 E \quad (2)$$

$$\frac{dE}{dt} = -k_2 E + k_1 M \quad (3)$$

where, C is the VOC concentration in the room air; M is the VOC mass in the exposed surface sink; E is the potentially embedded sink in contact with the surface but not directly with room air; λ_a , λ_d , k_1 , k_2 are coefficients describing rates of mass transfer among compartments.

Figure 1 shows the predictions of the sink-diffusion model for some tested VOCs, and the comparison with experimental data. The good agreement demonstrates the effectiveness of the sink-diffusion model in predicting multi-sorption scenarios. The main drawback of this model lies in that, the parameters (λ_a , λ_d , k_1 , k_2) in the model are fitting coefficients, which lack of clear physical meanings. Therefore, physics-based model is required.

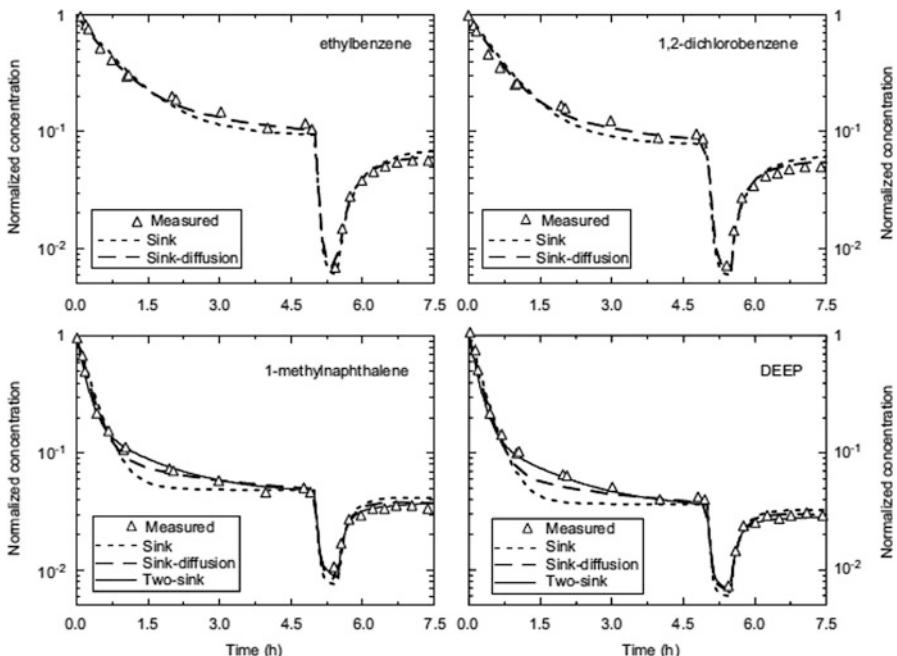

Fig. 1 Comparison of sink-diffusion model predictions with experimental data in multiple sink residential rooms (Singer et al. 2007)

Physics-Based Emission Model in Multi-Source In-Cabin Environments

In addition to the common built environment (residence, office, classroom, etc.), in-cabin environment is also regarded as a generalized indoor environment, in which people spend 6.5% of their time per day, with much longer times for taxi drivers, for example. The VOC concentrations in vehicle cabins are often very high, and the emission rate and concentrations of VOCs can increase dramatically when the vehicle is exposed to sun in the hot summer season, so more attention should be paid to this micro environment. In real in-cabin environments, multiple source materials (e.g., upholstery, carpet, seat, flooring materials) coexist. This generates a multi-source emission process, and these emissions may interact with each other, as shown in Fig. 2. By examining multiple VOC emissions in indoor environments, Deng et al. (2008) derived a physics-based analytical model to describe the multi-source emission behaviors by virtue of Laplace transformation. This model implicitly indicates the relationship between the gas-phase VOC concentrations and emission time. Since the derivation process and the analytical solutions are complicated, they are not given here.

By investigating the emissions of VOCs in in-cabin environments, Wang et al. (2020) applied a physics-based multi-source emission model to predict VOC emissions from multiple vehicle cabin materials. The emission rate from each material E_i can be calculated by Eq. (4):

$$E_i(t) = D_{m,i} \sum_{n=1}^{\infty} \frac{2(q_{n,i}^2 + Bi_{m,i}^2/K_i^2) \sin^2 q_{n,i}}{L_i(q_{n,i}^2 + Bi_{m,i}^2/K_i^2 + Bi_{m,i}/K_i)} \left[C_{0,i} e^{-D_{m,i}L_i^{-2}q_{n,i}^2 t} + \int_0^t e^{-D_{m,i}L_i^{-2}q_{n,i}^2(t-\tau)} K_i dC_a(\tau) \right] \quad (4)$$

where subscript i stands for the different vehicle cabin materials; C_0 is the initial emittable concentration, $\mu\text{g}/\text{m}^3$; D_m is the diffusion coefficient, m^2/s ; K is the partition coefficient; L is the thickness of the material; $q_{n,i}$ are the positive roots of

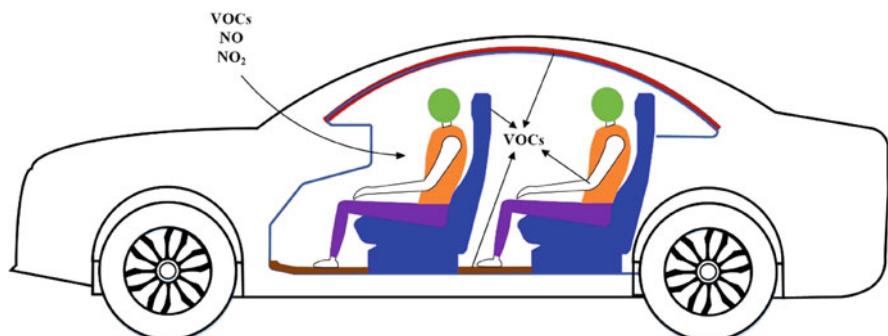

Fig. 2 Schematic of multi-source emissions in real in-cabin environment

$$q_{n,i} \tan q_{n,i} = \frac{Bi_{m,i}}{K_i} \quad (n = 1, 2, 3, \dots) \quad (5)$$

According to mass conservation, the gas-phase VOC concentration in the in-cabin environment conforms to the following equation:

$$V \frac{dC_a(t)}{dt} = QC_{in} - \sum_i A_i E_i(t) - QC_a(t) \quad (6)$$

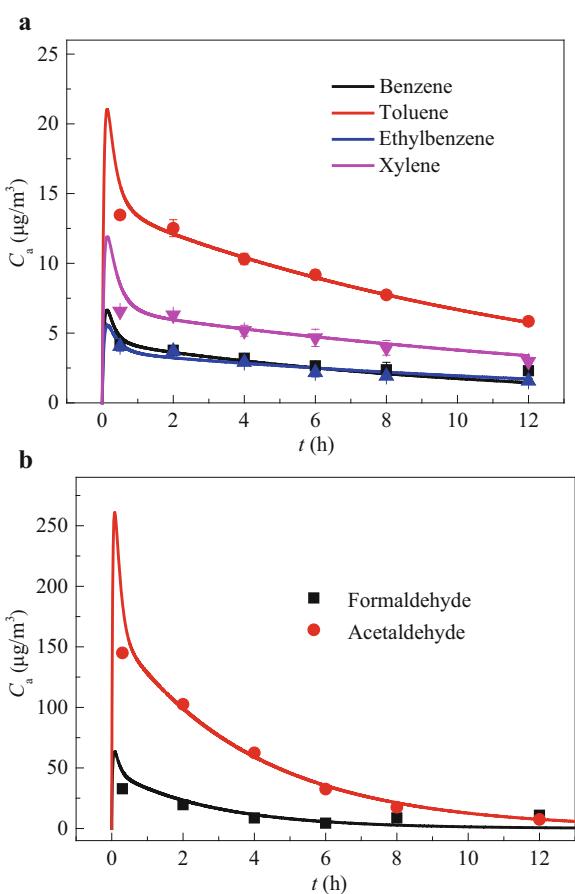

where A_i is the surface area of the vehicle cabin material i , m^2 ; Q is the ventilation rate, m^3/s ; V is the volume of the environment, m^3 ; and C_{in} is the inlet concentration, $\mu\text{g}/\text{m}^3$. The initial condition is:

$$C_a(t) = 0, \quad t = 0 \quad (7)$$

The gas-phase VOC concentration C_a in the in-cabin environment for multi-source emissions can be solved by combining the above Eqs. (4), (5), (6), and (7).

The above model can be regarded as a physics-based semi-analytical model. The key parameters for each vehicle cabin material in the multi-source model can be determined using a ventilated-chamber C-history method (Huang et al. 2013). To validate the multi-source emission model, Wang et al. (2020) built a simulated in-cabin environment with similar volume and materials as a realistic vehicle cabin. The testing system is comprised of a 3 m^3 environmental chamber with controlled temperature, relative humidity, and air exchange rate. Prior to the experiment, the gas-phase VOC concentrations in the environmental chamber were sampled to obtain the background concentration. The temperature was set at 25°C , and the humidity was maintained at 50%. One type of car roof upholstery, one carpet, and two seats were positioned in a typical vehicle cabin arrangement in the test chamber. During the experiment, a constant flow of 99.9% clean air (air exchange rate: 1 h^{-1}) was introduced into the 3 m^3 environmental chamber, and the VOCs were sampled at regular intervals using thermal desorption (TD) sampling tubes (Tenax-TA and DNPH were used as sorbents), which were then analyzed using GC-MS or HPLC to obtain the gas-phase VOC concentrations in the chamber. The key parameters determined by the ventilated-chamber C-history method in a small-scale chamber were used to predict the emission behaviors in the simulated vehicle cabin using the multi-source emission model. The comparison between model predictions and experimental data for the different VOCs is shown in Fig. 3. From this figure, we can see that most of experimental data are located on or near the curve predicted by the model. This good agreement ($R^2 = 0.82\text{--}0.99$) not only verifies the reliability of the multi-source model, but more importantly demonstrates the feasibility of applying key parameters determined in small-scale chamber tests to predict multiple emission scenarios in large-scale vehicle cabin environments. This means that the measured key parameters for different vehicle cabin materials are helpful for predicting pollution levels and for assessing exposure in realistic vehicle cabins, thus

Fig. 3 Comparison between the model prediction and experimental data for multi-source emissions in a simulated vehicle cabin (Wang et al. 2020)

providing a technical means to theoretically evaluate in-cabin air quality when designing a new vehicle.

VOC Emission from Occupants Due to the Use of Personal Care Products

Background

The emission of cyclic volatile methylsiloxanes (cVMS) due to the use of personal care products is regarded as an important contributor to indoor air pollution (Tang et al. 2015). cVMS are organic chemicals used in a wide range of personal care products due to their high thermal stability and smooth texture. Products containing cVMS include antiperspirants, skin and hair care formulations, sunscreen, and cosmetics (Montemayor et al. 2013). Octamethylcyclotetrasiloxane (D4), decamethylcyclopentasiloxane (D5), and dodecamethylcyclohexasiloxane

(D6) are three widely used cVMS. These cVMS are of particular concern, because they are potentially persistent, bioaccumulative and toxic, and have been shown to be associated with connective tissue disorders, adverse immunologic responses, and fatal liver and lung damage (Lieberman et al. 1999). cVMS can be emitted from the original sources and then partition into the indoor air due to their high Henry's law constants. The concentrations of cVMS in indoor air may differ based on regional regulations and regional preferences for different types of personal care products and compounds. The analysis of 91 samples from different sites in the United Kingdom (UK) and Italy indicated that the D4, D5, and D6 concentrations in indoor air were in the range of 19–270 $\mu\text{g m}^{-3}$, 2.4–440 $\mu\text{g m}^{-3}$, and 0.47–79 $\mu\text{g m}^{-3}$, respectively (Pieri et al. 2013). Based on 3857 samples of Canadian residential indoor air, Zhu et al. (2013) reported that the representative levels of indoor D4 and D5 concentrations were within the range of 5.45–7.94 $\mu\text{g m}^{-3}$ and 35.47–47.18 $\mu\text{g m}^{-3}$, respectively. In Chicago, the indoor air concentrations of D4, D5, and D6 were measured to be 0.03–0.5 $\mu\text{g m}^{-3}$, 0.97–56 $\mu\text{g m}^{-3}$, and 0–2.8 $\mu\text{g m}^{-3}$, respectively (Yucuis et al. 2013). Therefore, modeling and prediction of cVMS due to the frequent use of personal care products in indoor environment is very important.

Model for Predicting cVMS Emissions

Most experimental studies indicated that D5 is the dominant cVMS, both in personal care products and in indoor air, even comprising more than 90% of total cVMS (Tang et al. 2015; Yucuis et al. 2013). The modeling of D5 concentrations in the outdoor atmosphere is well developed. However, very little research has been done to model D5 emissions in indoor environments, especially from human skin after the use of personal care products. Up to now, three kinds of models have been proposed, including the multi-pathway exposure model (Ernstoff et al. 2016), the adsorption/desorption model (Xiong et al. 2016), and the physics-based model (Yang et al. 2018).

In the multi-pathway exposure model, the mass transfer of D5 through the skin lipids and the indoor air can be described by the following two equations (Ernstoff et al. 2016):

$$\frac{dm_c(t)}{dt} = -k_{p,a} \cdot m_c(t) - k_{p,s} \cdot m_c(t) \quad (8)$$

$$V \frac{dC_a}{dt} = Q \cdot C_{in} - Q \cdot C_a + k_{p,a} \cdot m_c(t) \quad (9)$$

where, $m_c(t)$ is the remaining mass of D5 in the skin lipids at time t (μg) and $k_{p,a}$ and $k_{p,s}$ are the product-to-air rate constant and the product-to-skin (dermal uptake) rate constant, respectively, (h^{-1}), which can be calculated by the following equations:

$$k_{p,s} = 1 / \left(L / K_p^{\text{aq}} + L / \varphi_w \right) \quad (10)$$

$$k_{p,a} = 1 / (L / \varphi_a + L / \varphi_w) \quad (11)$$

where, K_p^{aq} is the skin-permeation coefficient (m/h); φ_w is the mass-transfer coefficient through the aqueous film (m/h); $k_{p,a}$ is the mass-transfer coefficient from the aqueous film to the air (m/h); and L is the thickness of the skin lipids (m).

Detailed calculation indicates that the ratio of $k_{p,a}$ to $k_{p,s}$ for D5 is about 27, meaning that most of D5 is volatilized from the skin lipid surface. Therefore, dermal uptake can be neglected. Based on this analysis, the solution of Eqs. (8) and (9) can be derived as:

$$C_a(t) = C_{\text{in}} + \frac{M_0 \cdot k_{p,a}}{Q - k_{p,a} \cdot V} \left(\exp(-k_{p,a}t) - \exp\left(-\frac{Q}{V}t\right) \right) \quad (12)$$

where, $M_0 = C_0 \times A \times L$ is the initial mass of D5 inside the skin lipids, μg ; C_0 is the initial emittable concentration of D5, $\mu\text{g}/\text{m}^3$.

For the adsorption/desorption model, by neglecting the internal diffusion process, the indoor gas-phase D5 concentration emitted from skin lipids can be described as (Xiong et al. 2016):

$$C_a(t) = \frac{M_0 \cdot A \cdot h_m \cdot LF}{K_e \cdot (r_2 - r_1)} [\exp(-r_1 t) - \exp(-r_2 t)] \quad (13)$$

where r_1 and r_2 are the two roots of the following equation:

$$r^2 - (h_m/K_e + N + h_m L)r + N h_m / K_e = 0 \quad (14)$$

where $K_e = K \times L$ is the skin/air partition coefficient (m); $LF = A/V$ is the loading factor (m^2/m^3); and $N = Q/V$ is the air-exchange rate (h^{-1}).

A recent study found that the physics-based model agrees better with experimental data than the multi-pathway exposure model and the adsorption/desorption model (Yang et al. 2018). Therefore, the physics-based model will be introduced in more detail here, including model development, determination of key parameters in the model, and validation.

When personal care products are applied, the ingredients are initially present in a separate layer on top of the skin lipids, and some of the ingredients will partition into the skin lipids from this separate layer. The following assumptions are introduced to obtain the physics-based model: (1) The diffusion of D5 through the skin-lipid layer is represented as one-dimensional; (2) the skin forms an impermeable barrier with regard to D5 penetration, which is consistent with earlier dermal absorption studies (Montemayor et al. 2013); (3) adsorption/absorption of D5 to interior surfaces is negligible (this assumption needs further validation); and (4) the D5 level indoors is well mixed. With these assumptions, emission can be described as shown in Fig. 4.

The analytical solution of the indoor D5 concentration can be derived as (Xiong et al. 2012):

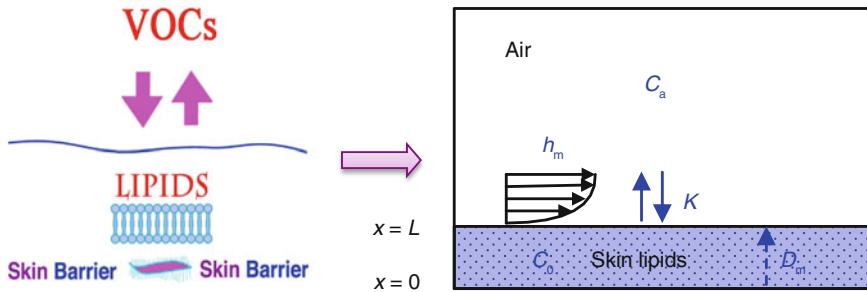

Fig. 4 Schematic of D5 emission from skin lipids

$$C_a(t) = A_1 + 2A_2 \cdot \sum_{n=1}^{\infty} \frac{A_3 \cdot q_n \sin q_n - A_4 \cdot \cos q_n}{G_n} e^{-D_m L^{-2} q_n^2 t} \quad (15)$$

where $G_n = [K\beta + (\alpha - q_n^2)KBi_m^{-1} + 2]q_n^2 \cos q_n + [K\beta + (\alpha - 3q_n^2)KBi_m^{-1} + \alpha - q_n^2]q_n \sin q_n$; $A_1 = C_{in}$; $A_2 = C_0$; $A_3 = \beta$; $A_4 = 0$; $\alpha = QL^2/D_m V$; $\beta = AL/V$; $Bi_m = h_m L/D_m$; and q_n are the positive roots of

$$q_n \tan q_n = \frac{\alpha - q_n^2}{K\beta + (\alpha - q_n^2)KBi_m^{-1}} \quad (n = 1, 2, \dots) \quad (16)$$

For real occupant emission tests, the volume of the environment is often very large (room or full-scale chamber) and the convective mass-transfer coefficient is very small (natural convection in many scenarios). Under this condition, the term $K\beta$ will be much smaller than $\alpha K/Bi_m$ (generally by two to four orders of magnitude smaller) in Eq. (16), and thus can be ignored. Equation (16) can then be simplified:

$$q_n \tan q_n = \frac{Bi_m}{K} \quad (n = 1, 2, \dots) \quad (17)$$

With Eq. (13) and the condition $K\beta \ll \alpha K/Bi_m$, the analytical solution (Eq. (15)) can be further reduced to:

$$C_a(t) = C_{in} + \sum_{n=1}^{\infty} \frac{2\beta C_0}{(\alpha - q_n^2)(1 + K/Bi_m + q_n^2 K^2/Bi_m^2)} e^{-D_m L^{-2} q_n^2 t} \quad (18)$$

Determination of Key Parameters in the Model

To calculate the indoor D5 concentration, the three key parameters (C_0 , D_m , K) for the model need to be known. The key parameters C_0 and D_m can be determined using a C-history method based on the analytical solution (Yang et al. 2017). During the mid-term emission period (i.e., when the mass-transfer Fourier number, Fo_m , is larger than 0.125), the following equation exists:

$$\ln [C_a(t) - C_{in}] = SL \cdot t + INT \quad (19)$$

with

$$SL = -D_m L^{-2} q_1^2 \quad (20)$$

$$INT = \frac{2\beta C_0}{(\alpha - q_1^2)(1 + K/Bi_m + q_1^2 K^2 / Bi_m^2)} \quad (21)$$

where q_1 is the first positive root of Eq. (17), which is in the range of $0-\pi/2$.

Equations (19), (20), and (21) indicate that the logarithm of $C_a(t)-C_{in}$ correlates linearly to the emission time t , and the slope (SL) and intercept (INT) are functions of the two key parameters C_0 and D_m . Therefore, if linear curve fitting is performed with the experimental data of $C_a(t)-C_{in}$ against t , SL and INT can be obtained, following which C_0 and D_m can be determined by solving two equations with these two key parameters. For D5 emission from skin lipids, the initial K can be approximately predicted by the following correlation:

$$\log K = \log K_{ow} + \log (HRT) \quad (22)$$

where K_{ow} is the octanol-water partition coefficient; H is the Henry constant; R is the gas constant; and T is the temperature.

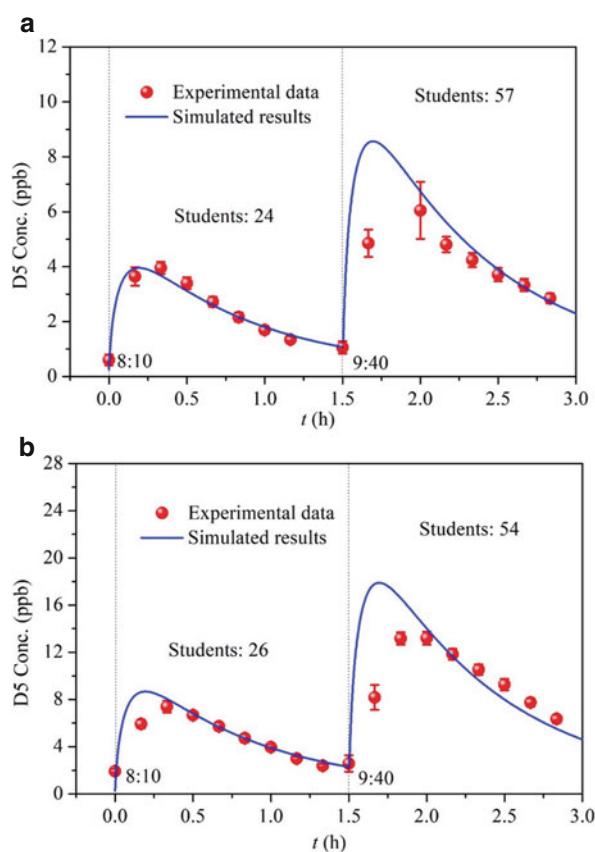

The thickness of the skin lipid layer is an important parameter for D5 emission models and varies for different persons and different regions of the body. It is generally in the range of 0.5–1.3 μm . To simplify the analysis, the thickness of skin lipid layer is assumed to be 1 μm throughout the entire body.

A field campaign was conducted in 2014 during several class sessions in a university classroom to examine the emission characteristics of D5 from skin lipids (Tang et al. 2015). Based on the SL and INT by using Eq. (19) with the experimental data, values determined for C_0 and D_m during class session 1 on Nov 6 (number of students: 24) are $C_0 = (8.80 \pm 0.62) \times 10^{10} \mu\text{g}/\text{m}^3$ and $D_m = (1.46 \pm 0.08) \times 10^{-16} \text{ m}^2/\text{s}$, while the values for class session 1 on Nov 13 (number of students: 26) are $C_0 = (1.93 \pm 0.16) \times 10^{11} \mu\text{g}/\text{m}^3$ and $D_m = (1.35 \pm 0.07) \times 10^{-16} \text{ m}^2/\text{s}$. These results indicate that the relative standard deviation for C_0 and D_m is less than 10%, which is relatively small. By comparing the determined key parameters from different test days, it can be concluded that the range of values for D_m is very narrow, while C_0 differs by about one order of magnitude. The reason needs further investigation.

Validation of the Physics-Based Model

With the above key parameters, the D5 concentration for other class sessions can be predicted. Figure 5a shows the comparison between model prediction and experimental data for class session 1 and class session 2 (number of students: 57) on Nov 6, while Fig. 5b shows the comparison for class session 1 and class session 2 (number of students: 54) on Nov 13. The agreement for the mid- and long-term emissions in Fig. 5 is good, demonstrating the effectiveness of the emission model as well as of the parameter estimation method. In the field test, class session 1 and 2 have different

Fig. 5 Comparison between model predictions and experimental data for D5 concentrations for different class sessions on (a) Nov 6 and (b) Nov 13 (Yang et al. 2018)

numbers of students (both on Nov 6 and Nov 13), and thus can be regarded as independent experiments. The good agreement between model predictions and experimental data for class session 2 can be taken as independent validation, which speaks for the accuracy of the physics-based model.

Reactions of Ozone with Squalene in Realistic Indoor Environments

Background

In addition to VOC sorption and emission, ozone-initiated chemistry is also important for indoor air quality (Weschler and Carslaw 2018). Most previous studies were performed in unoccupied indoor settings, and only a few studies refer to the influence of occupants on indoor chemistry. In densely occupied settings, people can be the dominant sink for indoor ozone. Studies in a simulated aircraft cabin confirmed that the reactions between ozone and occupants were responsible for more than 50% of the total ozone removal (Weschler et al. 2007). Measurements of the

ozone concentration in a real classroom indicated that the ozone removal caused by 25 occupants was approximately 2.6 times larger than that caused by the available surfaces in the classroom including its furniture (Fischer et al. 2013). The presence of human occupants can substantially reduce indoor ozone concentrations and increase the levels of byproducts (Weschler 2016). This is because ozone can react with the constituents of skin lipids on the exposed body parts, worn clothing fabrics, and human hair to generate a series of oxidation products (Wisthaler and Weschler 2010). Squalene has been reported to be the single-most abundant ozone-reactive constituent of skin lipids (Fu et al. 2013). Ozone reacts with squalene to generate a range of VOCs, such as acetone, geranyl acetone (GA), 6-methyl-5-hepten-2-one (6-MHO), and 4-oxopentanal (4-OPA) (Wisthaler and Weschler 2010). Some of these volatile products have been characterized as sensitizers and asthma triggers (Anderson et al. 2012). Additional low volatility products that accumulate in the lipids may be skin irritants and could also diffuse into the bloodstream over time to cause more adverse health effects. Hence, understanding the heterogeneous reaction between squalene and ozone and transport characteristics of the products is very important.

Models for Predicting Ozone/Squalene Reactions

The kinetic characteristics of heterogeneous reactions between ozone and squalene including the reaction rate constants as well as products have been investigated in various studies (Fu et al. 2013; Zhou et al. 2016). At present, the most common and effective way to explore dermal exposure to gas-phase chemicals is through mathematical models (Gong et al. 2014; Morrison et al. 2016). Gong et al. (2014) proposed a transient-state mass transfer model to predict air-to-skin-to-blood absorption of six phthalate esters for varying exposure conditions. Morrison et al. (2016) improved Gong et al.'s model by including a layer of skin surface lipids and the effect of clothing. However, these models describe only the physical transport of a chemical from the air into the blood stream without taking chemical reactions into account.

Incorporating both mass transport and chemical reactions, Lakey et al. (2017) developed a kinetic multilayer (KM-SUB-Skin) model to estimate the concentrations of squalene ozonolysis products in the gas phase and in the skin. This model includes different layers: a gas phase, a near-surface gas phase, a sorption layer, a skin oil layer, a number of bulk layers in the stratum corneum and the viable epidermis. The concentration of the various reactants and products in the gas phase ($[Z]_g$), the sorption layer ($[Z]_s$), the skin oil layer ($[Z]_{oil}$), the stratum corneum layers ($[Z]_{sc}$), the viable epidermis layers ($[Z]_{ve}$) in the KM-SUB-Skin model were determined over time through a set of differential equations describing the mass balance of each molecule for gas, surface, and skin bulk layers, which have been adapted from Shiraiwa et al. (2010). For the $[Z]_g$, $[Z]_s$, $[Z]_{oil}$, the differential equations are given below:

$$\frac{d[Z]_g}{dt} = (J_{\text{des},Z} - J_{\text{ads},Z}) \frac{S}{V_{\text{room}}} + P_{g,Z} \quad (23)$$

$$\frac{d[Z]_s}{dt} = J_{\text{ads},Z} - J_{\text{des},Z} + J_{s_oil,Z} - J_{oil_s,Z} \quad (24)$$

$$\frac{d[Z]_{\text{oil}}}{dt} = (J_{s_oil,Z} - J_{oil_s,Z}) \frac{A}{V_{\text{oil}}} + (J_{sc1_oil,Z} - J_{oil_sc1,Z}) \frac{A}{V_{\text{oil}}} + P_{oil,Z} \quad (25)$$

where J represents various different types of mass transport fluxes such as adsorption and desorption (shown by the subscripts ads and des, respectively) and mass transport between different layers; P is a production or loss term in a given layer due to reactions; S is the total surface area of the people in the room; A is the surface area of a layer; and V_{room} is the volume of the room.

This model neglects the convective mass-transfer resistance from air to skin and the partitioning (adsorption/desorption) processes on indoor surfaces, which will cause some deviations for realistic indoor setting simulations. Later, Lakey et al. (2019) improved the KM-SUB-Skin model by taking into account the convective effect from the gas phase to the human surface and clothes (called KM-SUB-Skin-Clothing model), while the effect of indoor-surface partitioning was still not included. Xiong et al. (2019) developed a kinetic model by considering the adsorption/desorption of products on indoor surfaces to predict the concentration of squalene/ozone reaction products in a classroom. However, this model does not consider the transport of products inside the skin, and thus cannot further evaluate the exposure via dermal uptake. Recently, Zhang et al. (2021) developed a physical-chemical coupling model to more accurately predict the characteristics of squalene/ozone reaction products in the gas phase and in the skin, by considering the external convection along the skin lipid surface, internal diffusion inside the skin, indoor surface uptake (including surface partitioning, and diffusion inside the wall). Considering that the concept of KM-SUB-Skin-Clothing model is very similar to the model described by Eqs. (23), (24), and (25), we just briefly introduce the physical-chemical coupling model here.

The physical-chemical coupling model is based on the transient-state mass-transfer models described by Gong et al. (2014) and Morrison et al. (2016). As shown in Fig. 6, during the uptake of chemicals from the gas phase to the dermal capillaries, the chemical will pass through three layers: skin surface lipids (SSL), stratum corneum (SC), and viable epidermis (VE). SSL, a thin layer consisting of sebum secreted by sebaceous glands and a small amount of lipids from SC, is assumed to be $\sim 0.5 \mu\text{m}$ in this model (Lakey et al. 2017). SC, which consists of about 15–20 layers of dead cells, is the outermost part of the epidermis and its thickness is $\sim 25 \mu\text{m}$. VE, consisting of some living cells, is between the SC and dermis, with a thickness of $\sim 100 \mu\text{m}$. Squalene in the SSL can be oxidized by ozone to produce some primary and secondary products. Among them, 6-MHO and 4-OPA are the most abundant, thus are selected as the analysis targets. The absorption process of 6-MHO and 4-OPA from air to dermal capillaries mainly includes

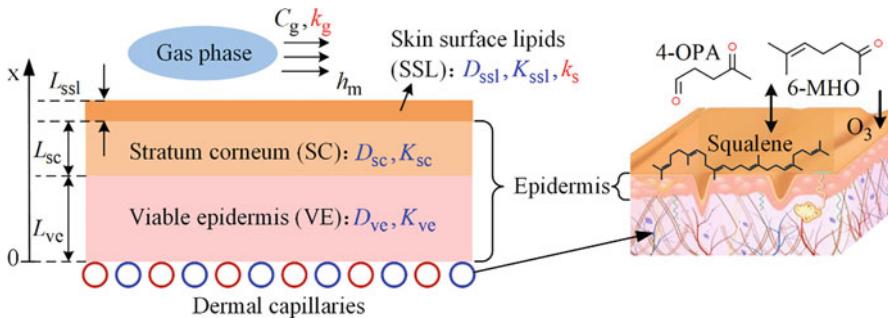

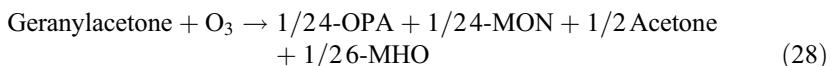

Fig. 6 Schematic illustrating layers and parameters involved in dermal exposure processes. The blue parameters describe the physical diffusion and partitioning; the red parameters indicate chemical reactions; the remaining parameters are defined in the context (Zhang et al. 2021)

chemical reactions in the gas phase and in the SSL; convective mass transfer at the air-SSL boundary layer; diffusion inside the SSL, SC, and VE; and indoor surface uptake (i.e., surface partitioning and internal diffusion of permeable material). Relevant chemical reactions are given by Eqs. (26), (27), and (28):

Here, Eqs. (26), (27), and (28) are simplified to focus only on the dominant stable products, while the moderately lived intermediate products (e.g., secondary ozonides) and other products such as organic acids, hydroxyl acetone, 4-MON, 4-MOD, and various organic hydroperoxides are not included.

Several assumptions are made to derive the physical-chemical coupling model: (1) The three layers (SSL, SC, VE) of the skin are homogeneous, and the mass transfer through each layer is assumed to follow one-dimensional diffusion; (2) the concentration of all products in the blood at the VE-dermis interface is assumed to be zero because of the abundant capillaries at VE-dermis interface and fast blood flow; (3) equilibrium exists at the interfaces between two contiguous layers and the flux is conserved; and (4) the squalene concentration in SSL is regarded as constant since it can be produced by the human body naturally and continually. With these assumptions, the governing equations of the oxidation products Y (6-MHO, 4-OPA, and GA) can be described as follows (Zhang et al. 2021):

$$\frac{\partial C_{ve_Y}}{\partial t} = D_{ve_Y} \frac{\partial^2 C_{ve_Y}}{\partial x^2} \quad \text{for } 0 < x < L_{ve} \quad (29)$$

$$\frac{\partial C_{sc_Y}}{\partial t} = D_{sc_Y} \frac{\partial^2 C_{sc_Y}}{\partial x^2} \quad \text{for } L_{ve} < x < L_{ve} + L_{sc} \quad (30)$$

$$\frac{\partial C_{ssl_Y}}{\partial t} = D_{ssl_Y} \frac{\partial^2 C_{ssl_Y}}{\partial x^2} + P_{ssl_Y} \quad \text{for } L_{ve} + L_{sc} < x < L_{ve} + L_{sc} + L_{ssl} \quad (31)$$

$$\begin{aligned} \frac{\partial C_{g_Y}}{\partial t} = & N(C_{out_Y} - C_{g_Y}) - \frac{A_h}{V_r} D_{ssl_Y} \frac{\partial C_{ssl_Y}}{\partial x} \Big|_{x=L_{sc}+L_{ve}+L_{ssl}} + P_{g_Y} \\ & + q_{ob_Y} C_{in_O_3} - \frac{A_r}{V_r} E_Y \quad \text{for } x \\ & > L_{ve} + L_{sc} + L_{ssl} \end{aligned} \quad (32)$$

where the subscripts ve, sc, ssl, and g represent the layers of VE, SC, SSL, and the gas phase, respectively; C_{ve_Y} , C_{sc_Y} , C_{ssl_Y} , and C_{g_Y} are the concentrations of Y in the corresponding layers (ppb); D_{ve_Y} , D_{sc_Y} , and D_{ssl_Y} are the diffusion coefficients of Y in the corresponding layers ($\text{cm}^2 \text{ s}^{-1}$); L_{ve} , L_{sc} , L_{ssl} are the thicknesses of the corresponding layers (cm); t is time (s); x is the distance vertical to the VE-dermis interface (cm); N is the air exchange rate (h^{-1}); C_{out_Y} is the concentration of Y in the supply air from outdoors (ppb); A_h and A_r are the surface areas of human skin and room, respectively (cm^2); V_r is the volume of indoor space (cm^3); P_{ssl_Y} and P_{g_Y} are the production or loss term in the SSL and gas phase due to chemical reactions (ppb s^{-1}); q_{ob_Y} is the production rate of Y from off-body squalene in indoor environment (e.g., furnishings, worn clothing), which is determined by curve fitting (s^{-1}); $C_{in_O_3}$ is the concentrations of ozone in indoor air (ppb); and E_Y represents the convective mass-transfer flux on the indoor surface, which can be written as

$$E_Y = h_{ms}(C_{g_Y} - C_{gi_Y}) \quad (33)$$

where h_{ms} is the convective mass-transfer coefficient across the indoor surface (cm s^{-1}); C_{g_Y} is the concentration of Y in indoor air (ppb); and C_{gi_Y} is the gas-phase concentration of Y at the surface (ppb).

Since indoor surfaces are generally permeable, the internal diffusion of products in the materials should be considered. A sink model proposed by Jorgensen et al. (2000) is applied to reflect this effect. The time-dependent concentrations of ozone in the SSL and gas phase can be represented by the following equations:

$$\begin{aligned} \frac{\partial C_{ssl_O_3}}{\partial t} = & D_{ssl_O_3} \frac{\partial^2 C_{ssl_O_3}}{\partial x^2} - k_{1s} C_{ssl_O_3} C_{sq} - k_{2s} C_{ssl_O_3} C_{ssl_6MHO} \\ & - k_{3s} C_{ssl_O_3} C_{ssl_GA} - k_{4s} C_{ssl_O_3} C_{others} \quad \text{for } L_{ve} + L_{sc} \\ & < x < L_{ve} + L_{sc} + L_{ssl} \end{aligned} \quad (34)$$

$$\frac{\partial C_{\text{in_O}_3}}{\partial t} = N(C_{\text{out_O}_3} - C_{\text{in_O}_3}) - \frac{A_h}{V_r} D_{\text{ssl_O}_3} \frac{\partial C_{\text{ssl_O}_3}}{\partial x} \Big|_{x=L_{\text{sc}}+L_{\text{ve}}+L_{\text{ssl}}} \\ - k_{2g} C_{\text{in_O}_3} C_{\text{g_6MHO}} - k_{3g} C_{\text{in_O}_3} C_{\text{g_GA}} - k_r C_{\text{in_O}_3} \quad \text{for } x \\ > L_{\text{ve}} + L_{\text{sc}} + L_{\text{ssl}} \quad (35)$$

where $C_{\text{ssl_O}_3}$ is the concentrations of ozone in the SSL (ppb); $D_{\text{ssl_O}_3}$ is the diffusion coefficient of ozone in the SSL ($\text{cm}^2 \text{s}^{-1}$); k_{1s} , k_{2s} , and k_{3s} are the second-order rate constants occurring in the SSL ($\text{ppb}^{-1} \text{s}^{-1}$); k_{4s} is the second-order rate constants for reactions of ozone with other double bonds in the SSL ($\text{ppb}^{-1} \text{s}^{-1}$); C_{others} is the concentration of other unsaturated reactants in the SSL (ppb); C_{sq} is the concentration of squalene in the SSL (ppb); k_{2g} and k_{3g} are the second-order rate constants occurring in the gas phase ($\text{ppb}^{-1} \text{s}^{-1}$); $C_{\text{out_O}_3}$ is the ozone concentration in the supply air from outdoors (ppb); and k_r is the removal rate of ozone caused by other indoor reactions (s^{-1}).

Validation of the Chemical-Physical Model with Test Data in a House

Experiments were conducted in a single-family house to validate the accuracy of the model (Liu et al. 2019), by using PTR-TOF-MS. To find a common parameter set that could explain both occupied and unoccupied scenarios, a global optimization based on the Multi-objective optimization using Genetic Algorithm and Monte Carlo search is applied for parameters determination. With the determined parameters, the concentrations of ozone, 6-MHO, and 4-OPA in the house on other test days can be predicted using the physical-chemical coupling model. Figure 7 provides the scatter plots at 30 min time resolution of all the model predictions and measurements for ozone, 6-MHO, and 4-OPA, including 9 days (13–19 August, and 22–26 August) in the single-family house (about 350 data points). The data points are evenly distributed around the 1:1 line ($y = x$). For 6-MHO and 4-OPA, more than 90% of the points are within $\pm 15\%$ fluctuation (uncertainty). For ozone, more than 80% of the points are within $\pm 20\%$ fluctuation. The R^2 for the three modeled compounds are above 0.82, indicating good accuracy of the developed model. To examine the applicability of the model to different indoor settings, the model was used to predict the concentrations of ozone, 6-MHO, and 4-OPA in a simulated occupied office in the study of Wisthaler and Weschler (2010). The comparison of model prediction with experimental data, as shown in Fig. 8, indicates that predictions based on the physical-chemical coupling model agree well with the experimental data, with R^2 above 0.9, demonstrating the generalizability of the model for different indoor settings.

Predicting SVOC Concentrations in Complex Indoor Environments

Due to low vapor pressure, SVOCs tend to adhere to indoor surfaces including walls, floors, ceilings, airborne particles, dust, and so forth. Therefore, the fate of indoor SVOCs is much more complex than VOCs due to dynamic interaction between

Fig. 7 Scatter plots of model prediction with measured data for (a) 6-MHO and 4-OPA, (b) ozone (Zhang et al. 2021)

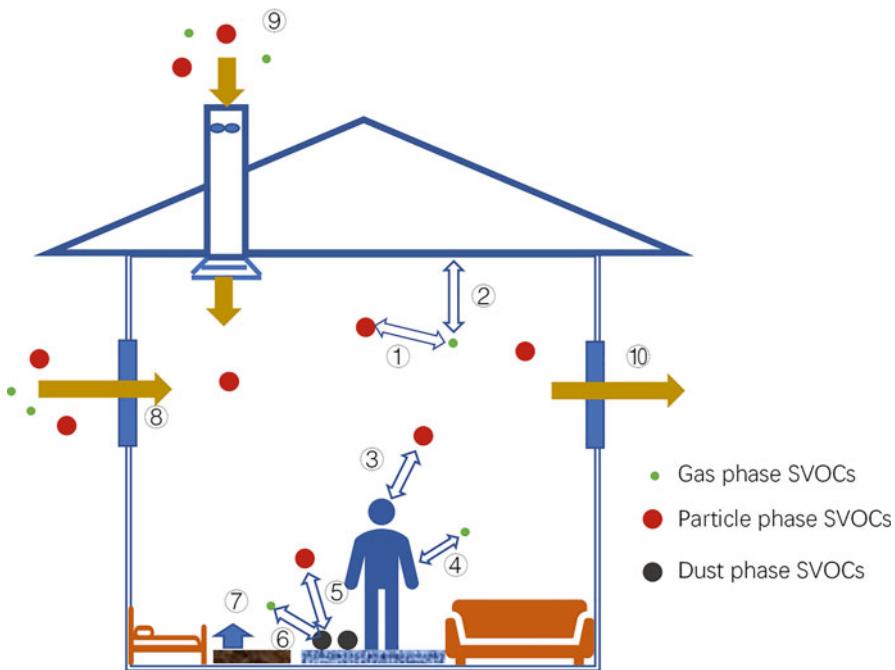

Fig. 9 Schematic shows for indoor SVOC fate. ① Interaction between gas and particle phase SVOCs; ② Interaction between gas and surface phase SVOCs; ③ and ④ Interaction between particle phase SVOCs and human body; ⑤ Interaction between particle and dust phase SVOCs; ⑥ Interaction between gas and dust phase SVOCs; ⑦ Emission from the source; ⑧ Natural ventilation; ⑨ Mechanic ventilation; ⑩ Exhaust out of the buildings

SVOCs and various indoor sinks, as shown in Fig. 9. Indoor concentrations of SVOCs in different phases are affected by many factors including source and sink characteristics, dynamic partitioning between different phases, natural and mechanical ventilation, behavior of residents such as house cleaning, cooking activities, and so forth as shown in Fig. 10. The fate and transport of indoor SVOCs is a very complex process and it is a great challenge to accurately simulate indoor SVOCs dynamics. To predict SVOC concentrations in real indoor environments accurately, reasonable physical models to reveal how these factors affect indoor SVOC fate are the foundation together with the determination methods for the parameters in the models as shown in Fig. 11. The mechanism methods for predicting the fate and transport of SVOCs fall into three categories: mass transfer-based methods, fugacity theory methods, and data-driven models. Due to scarce measured data, especially instantaneous data with time for indoor SVOC concentrations, there is no data-driven model for predicting indoor SVOC concentrations (Wei et al. 2019a). For the other two kinds of methods, the framework as illustrated in Fig. 12 should be followed. Knowledge of the mechanisms and characteristics of SVOC emission and partitioning in indoor environments is essential for predicting SVOC

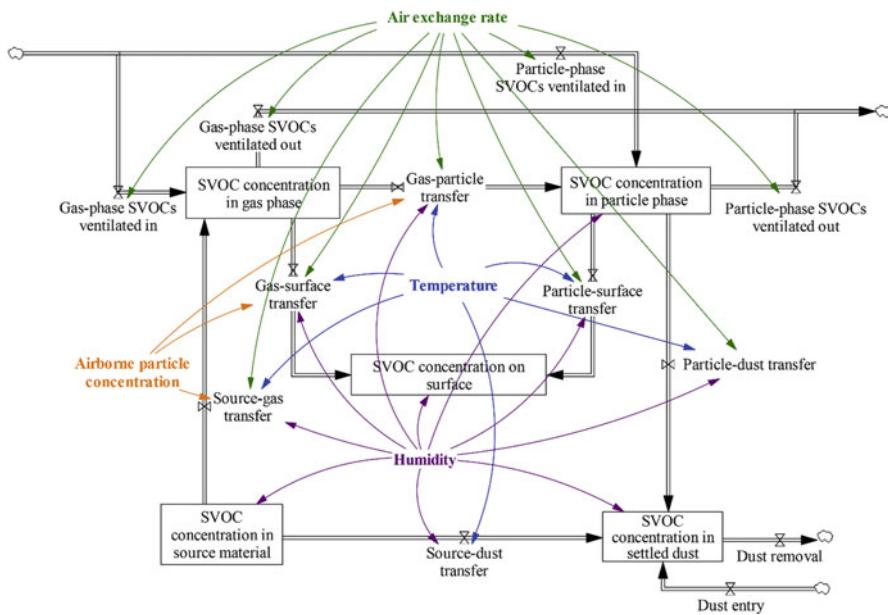

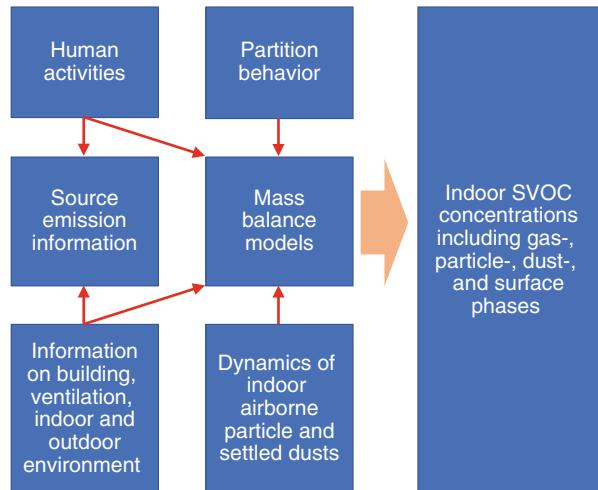

Fig. 10 Influence of environmental factors on indoor SVOCs. (Reprinted from Wei et al. (2019a), Copyright 2021, with permission from Elsevier)

Fig. 11 A modular framework for predicting indoor SVOC concentrations in complex indoor environments

concentrations. These models are described in detail in ▶ Chap. 23, “Source/Sink Characteristics of SVOCs.” As the focus, the mass transfer models will be introduced in section “Two Types of Models for Predicting the Fate and Transport of SVOCs in Real Indoor Environments.” Besides, the estimation methods on the

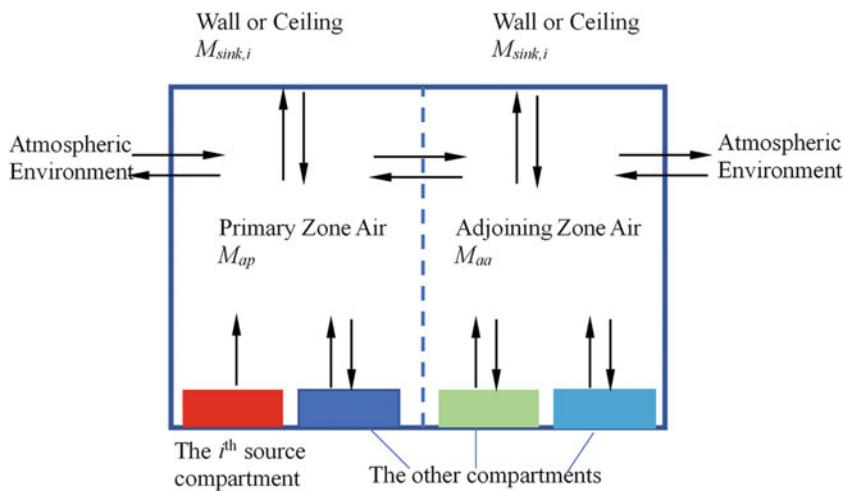

Fig. 12 Model framework for the indoor fugacity models. (Reprinted from Bennett and Furtaw (2004), Copyright 2021, with permission from American Chemical Society)

partition coefficients of SVOCs between different compartments in the models will also be described as key factors in section “[Estimating Partition Coefficients of SVOCs Between the Gas Phase, Airborne Particles, Settled Dust, and Surfaces](#).” Finally, the challenge to prediction accuracy will be discussed in section “[Challenge to Accurate Prediction of Indoor SVOC Concentration in Complex Indoor Environment](#).”

Two Types of Models for Predicting the Fate and Transport of SVOCs in Real Indoor Environments

Both mass transfer models and fugacity models are based on mass balance. Fugacity models are a kind of models early and widely used for indoor fate modeling (Bennett and Furtaw 2004) to describe the dynamic mass balance of indoor chemicals with different compartments based on the concept of fugacity (Shin et al. 2012). The models are applied for predicting indoor fate of pesticides (Bennett and Furtaw 2004) and PBDEs (Zhang et al. 2009). In the models, some typical compartments including floorings, walls, furniture, and other media are considered as shown in Fig. 12 (Zhang et al. 2009; Shin et al. 2012).

In the fugacity models, the mass of the compound in the compartment (g) can be expressed in terms of fugacity (Bennett and Furtaw 2004). The governing equation for the change of mass in the *i*th compartment over time can be written as Eq. (36-1) (Bennett and Furtaw 2004):

$$\frac{dM_i}{dt} = -L_i M_i + \sum_{j=1}^N T_j M_j \quad (36-1)$$

Table 1 The expression of fugacity capacities of SVOCs with different phases in different compartments

Compartments	Phase	Equations	Remarks
Air	Gas	$Z_a = \frac{1}{RT}$	R is the ideal gas constant, T is the absolute temperature of air
	Particle	$Z_p = K_{pg} TSP Z_p$	K_{pg} is the particle-gas partition coefficient; TSP is the particle concentration
Source	Source	$Z_{source} = KZ_a$	K is the source-air partition coefficient
Sink(walls)	Surface	$Z_{sink} = K_{sg} Z_a$	All non-source surface can be regarded as sink
Dust	Dust	$Z_{dust} = K_{dg} Z_a$	

where L_i is the loss rate constant for the i^{th} compartment (g/d) and M_j is mass of the j^{th} compartment connected with compartment i and T_j is the transfer factor (1/d). For different compartments, T_j and L_i have different meanings. For example, if i represents surface compartment, L_i is the desorption coefficient and T_i is the adsorption coefficient. Hence, the governing equation for the surface can be expressed as shown in Eq. (36-2):

$$\frac{dM_{surface}}{dt} = -k_d M_{surface} + k_s \frac{M_{air}}{V} \quad (36-2)$$

M_i can be expressed in terms of fugacity through Eq. (37):

$$M_i = f_i Z_i V_i \quad (37)$$

where f_i is the fugacity of the chemical in the i^{th} compartment, Z_i is the fugacity capacity to characterize the holding capacity of the i^{th} compartment for a chemical substance based on the properties of both the material and the chemical. Obviously, Z_i is a key parameter to determine fugacity of SVOCs in media and the values of Z_i in different media are listed in Table 1 (Zhang et al. 2009).

Recently, Liang et al. (2019) developed a general mass transfer-based model for predicting the fate and transport of phthalates in indoor environments. In this model, the indoor fate of phthalates including emission from indoor sources, indoor transport in the air, interaction with particle and dusts, uptake by impermeable surfaces (e.g., wood floors, furniture, ceilings, tiles, glass, or windows), and accumulation of phthalates within porous materials (e.g., carpet) with consideration of particle penetration is shown in Fig. 13. Based on the mass balance, the variation of phthalates in well-mixed environments obeys the following equation:

$$\begin{aligned} V \frac{dC_g}{dt} + V \frac{dC_{part}}{dt} &= Q(C_{g,in} + C_{part,in}) - Q(C_g + C_{part}) + h_{m,s} A_s (y_0 - C_g) \\ &\quad - h_{m,ns} A_{ns} (C_g - C_{ns}) - v_d (A_s + A_{ns}) C_{part} \\ &\quad + R M_s A_s P_{dust,s} + R M_{ns} A_{ns} P_{dust,ns} \end{aligned} \quad (38)$$

where V is the volume of the room, m³; t is time (h); C_g and C_{part} are the phthalate concentrations in the gas and particle phases in indoor air, respectively ($\mu\text{g}/\text{m}^3$); Q is

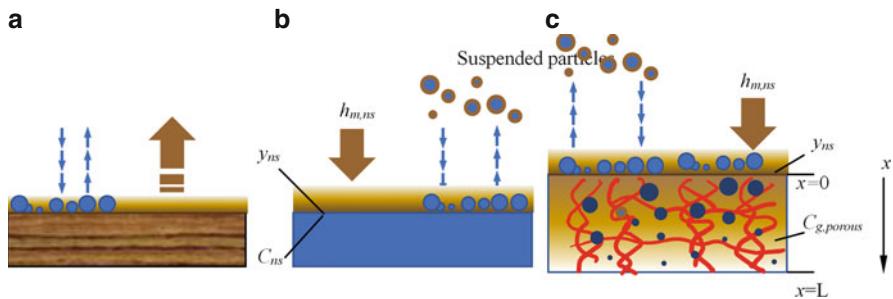

Fig. 13 SVOCs dynamics on the surface. (a) The source surface; (b) the non-source impermeable surface; (c) the non-source porous surface

flow rate of outdoor air (m^3/h); $C_{g,in}$ and $C_{part,in}$ are the phthalate concentrations in gas and particle phases in the outdoor air ($\mu\text{g}/\text{m}^3$); $h_{m,s}$ and $h_{m,ns}$ are the convective mass-transfer coefficients on the source and non-source surfaces, respectively, (m/h); A_s and A_{ns} are the areas of indoor source and non-source surfaces, respectively, (m^2); y_0 is the gas-phase concentration in the air adjacent to the source ($\mu\text{g}/\text{m}^3$); v_d is the deposition rate of particles onto indoor surfaces (m/h); R is the resuspension rate (h^{-1}); M_s and M_{ns} are the mass loadings of settled dust on source and non-source surfaces, respectively ($\mu\text{g}/\text{m}^2$); and $P_{dust,s}$ and $P_{dust,ns}$ are the concentrations of phthalates in the dust settled on source and non-source surfaces, respectively ($\mu\text{g}/\text{g}$).

Diffusion of SVOCs inside particles can be ignored (Liu et al. 2013), that is, the phase concentration can be regarded as a uniformly lumped concentration in particle. Thus, the adsorption rate of SVOCs by particles can be described by Eq. (39):

$$\dot{m}_{p,s} = h_{m,p} A_p N_p \left(C_g - \frac{C_{part}}{K_p TSP} \right) \quad (39)$$

where $h_{m,p}$ is the convective mass transfer coefficient (m/s); A_p is the area of a single particle (m^2), and N_p is the particle number per m^3 air ($1/\text{m}^3$).

Considering the dynamics of particle-phase phthalates, its concentration can be determined by Eq. (40):

$$V \frac{dC_{part}}{dt} = Q(C_{part,in} - C_{part}) + \dot{m}_{p,s} - v_d(A_s + A_{ns})C_{part} + RM_s A_s P_{dust,s} + RM_{ns} A_{ns} P_{dust,ns} \quad (40)$$

If fine particles with diameters smaller than $2.5 \mu\text{m}$ dominate in indoor air, the other terms except $\dot{m}_{p,s}$ on the right side of Eq. (40) can be ignored. For SVOCs with vapor pressures in the range between pyrene and DEHP (not including DEHP), equilibrium can be reached within a short time. Thus, Eq. (40) can be further simplified by replacing $C_{part} = K_p TSP C_g$.

The dynamics of indoor particles can be described as:

$$V \frac{dTSP}{dt} = QP_p TSP_{in} - QP_p TSP - v_d(A_s + A_{ns})TSP + RM_s A_s + RM_{ns} A_{ns} + S \quad (41)$$

where P_p is the penetration coefficient of particles from outdoors to indoors and S is the source density of indoor particles (mg/h).

Equation (42) describes that the dust loading of the settled dust on the source or non-source surfaces changes with time due to the particle deposition and the dust resuspension as shown in Fig. 13.

$$\frac{dM_s}{dt} = -v_d TSP + RM_s A_s \text{ and } \frac{dM_{ns}}{dt} = -v_d TSP + RM_{ns} A_{ns} \quad (42)$$

In Liang et al. (2019), a simple equilibrium between $P_{dust,s}$ and y_0 on the source surface is assumed, that is, $P_{dust,s} = K_{dust,s} y_0$ as shown in Fig. 13a. Similarly, a simple equilibrium between $P_{dust,ns}$ and C_{ns} on the non-source surface as $P_{dust,ns} = K_{dust,ns} C_{ns}$ is assumed. Different from the source surface, the accumulation of phthalates on the non-source surface should be considered. For those impermeable surfaces such as wood floors, glass mirrors, and windows, Eq. (43) can be used to describe the variation of phthalate concentrations on the surface as shown in Fig. 13b.

$$\frac{d(C_{ns} + M_{ns} P_{dust,ns})}{dt} = h_{m,ns} (C_g - C_{ns}) + v_d C_{part} - RM_{ns} P_{dust,ns} \quad (43)$$

For the porous surfaces such as carpet, diffusion into the inside of the surfaces cannot be ignored, as shown in Fig. 13c. In the model, multi-phase mass-diffusion theory in porous media is employed to describe the process with the governing equation and initial and boundary conditions as follows:

$$(\varepsilon + (1 - \varepsilon)K_{ns} + K_{dust,ns} m_x) \frac{\partial C_{g,porous}}{\partial t} = \varepsilon D_g \frac{\partial^2 C_{g,porous}}{\partial x^2} \quad (44-1)$$

$$C_{g,porous} = 0, \text{ for } t = 0, 0 \leq x \leq L \quad (44-2)$$

$$\frac{\partial C_{g,porous}}{\partial x} = 0, \text{ for } t > 0, x = L \quad (44-3)$$

$$C_g = y_{ns}, \text{ for } t > 0, x = 0 \quad (44-4)$$

where ε is the porosity of the material; x is the coordinate along the depth (m); m_x is the dust mass concentration at the depth x ($\mu\text{g}/\text{m}^3$), and m_x distributes with x as $m_x = \frac{m_{x=0}}{e^x}$, m_x can be obtained by solving $\int_0^L m_x dx = M_{ns}$; $C_{g,porous}$ is the gas concentration of SVOCs in the pore of the material ($\mu\text{g}/\text{m}^3$); and L is the thickness of the material (m).

Thus, the fate and concentrations of SVOCs in the different phases in indoor environments can be described by Eqs. (38), (39), (40), (41), (42), (43), and (44). To predict the fate and transport of SVOCs in real indoor environments using the model, the parameters for describing building characteristics, ventilation, atmospheric environmental conditions (particle concentration, particle- and gas-phase SVOC concentration in ambient air), indoor temperature, source characteristics parameters, surface characteristics parameters have to be provided at first, then the partition coefficients between different phases can be estimated by the method described in section “[Estimating Partition Coefficients of SVOCs Between the Gas Phase, Airborne Particles, Settled Dust, and Surfaces](#).” Based on the determined or estimated parameters, by numerically solving Eqs. (38), (39), (40), (41), (42), (43), and (44) in coupled mode, the instantaneous concentration of SVOCs in the different phases in the media will be obtained. The details on the methods of numerical solution can refer to Patankar’s classic book (Partankar 1980). Besides this model, some similar models (Wei et al. 2019a; Shi and Zhao 2015) with some special considerations were proposed to predict indoor concentrations of SVOCs and the solution method is similar.
